The contracted muscles, unlike muscles in other involuntary spasms, no longer use energy and they are more or less electrically silent (i.e., no electrical activity is recorded from maximally contracted muscle during the cramps). Moreover, the muscle does not produce lactic acid. The shortened state is spoken of as *physiologic contracture* as discussed in the introductory sections of this chapter. Ischemia contributes to this condition by denying glucose to the muscle, which then cannot function adequately on fatty acids and nonglucose substrates. These features are the basis of the *forearm ischemic exercise test*, which, although controversial in its use and sensitivity, may be helpful if performed carefully. An indwelling catheter is placed in the antecubital vein and a basal blood sample is obtained. Above the elbow, a sphygmomanometer cuff is inflated to exceed arterial pressure. After 1 min of vigorous hand exercise (30 hand closures against an ergometer), blood samples are obtained at 1 and 3 min. Normal individuals show a 3- to 5-fold increase in blood lactate. In patients with either McArdle or Tarui disease, the lactate fails to rise. This procedure has reportedly caused a localized rhabdomyolysis (Meinck et al), for which reason Griggs and associates recommend that the test be carried out *without* a blood pressure cuff. Problems with consistency in conducting the test and in processing blood samples for lactate limit its validity unless it is performed by experienced individuals and laboratories. Definitive diagnosis depends more on the histochemical stains of biopsied muscle, which reveal an absence of phosphorylase activity (in McArdle disease) or of phosphofructokinase activity (in Tarui disease). Genetic analysis, can be used to corroborate the diagnosis, but it is unnecessary if the histochemical tests are definitive.

Treatment The main treatment is a planned reduction and intermittency in physical activity. Sucrose, taken as 75 g in a beverage, has been shown to cause a short-lived improvement in exercise tolerance, and it has been proposed that exercise-induced rhabdomyolysis can be avoided by a well-timed drink (Vissing and Haller). Fructose and creatine taken orally are also said to be helpful in some cases, but the reported results are not as impressive as they are for sucrose. Improvement has also been described after the administration of glucagon (Kono et al) and with a high-protein diet (Slonim and Goans), but these effects are not consistent.

Other Forms of Glycogenosis (See Table 45-5)

Of the remaining glycogen storage diseases, type III (*debranching enzyme deficiency; Cori-Forbes disease, AGL* Mutation) affects muscle but only inconsistently. The childhood form is characterized mainly by a benign hepatopathy, sometimes accompanied by diminished muscle strength and tone. An adult form beginning in the third and fourth decades presents with proximal and distal myopathy. The course is slowly progressive and may

[a]All types: elevated creatine kinase (CK); myopathic electromyogram, with increased irritability and myotonia.

[b]A, adult; Ad, adolescence; C, childhood; I, infancy.

Additional features (not charted above): feeding difficulties, II Pompe; retarded growth, III; neurologic abnormalities, II Pompe, IX; seizures, VIII, IX; hypoglycemic seizures, III; jaundice, VII, IX; cirrhosis, IV; generalized scaling erythema, XI; firm consistency of muscle, II Pompe; elevated serum aspartate aminotransferase and lactic dehydrogenase, II; elevated serum bilirubin, VII, IX; failure of lactate dehydrogenase to rise proportionally to elevation of CK, XI; fasting hypoglycemia, III; hemolytic anemia and reticulocytosis, VII, IX; hemoglobinuria, IX; excessive rise in serum pyruvates during ischemic exercise test, XI.

be associated with wasting of the leg and hand muscles. Several patients have developed weakness during adult life complained of rapid fatigue and aching of muscles, occurring with exertion and first noticed at an early age. Serum CK values were elevated and the EMG showed a myopathic picture as well as increased insertional activity, pseudomyotonic discharges, and fibrillation potentials. Rarely in the adult form, glycogen also accumulates in the peripheral nerves, giving rise to mild symptoms of polyneuropathy. The enzymatic defect is one of amylo-1, 6-glucosidase deficiency.

Disturbance of skeletal muscle is even less prominent in type IV glycogenosis (*branching enzyme deficiency*, or *Andersen disease*, which is also implicated in the polyglucosan disease that causes a special neuropathy discussed in Chap. 43, a motor system disease with flaccid bladder, or a leukoencephalopathy with dementia). This is a progressive disease of infancy and early childhood, characterized by cirrhosis and chronic hepatic failure, usually with death in the second or third year. Hepatomegaly as a result of accumulation of an abnormal polysaccharide is a universal finding. Muscle weakness and atrophy, hypotonia, and contractures occur less regularly and are overshadowed by the liver disease. The diagnostic hallmark of the myopathy is the presence of basophilic, intensely PAS-positive polysaccharide granules in skin and muscle.

The remaining nonlysosomal glycogenoses (types VIII through XI) need only be mentioned briefly. They are all rare and clinically heterogeneous, and a myopathy—characterized by intolerance to exercise, cramps, myoglobinuria, elevated CK, and, sometimes, renal failure—has been observed in a small proportion of them. Phosphoglycerate kinase deficiency (type IX glycogenosis, *PGK1* mutation) differs in that it is inherited as a sex-linked recessive trait localized to chromosome Xq13. Hemolytic anemia—becoming evident soon after birth—mental retardation, seizures, and tremor are other features that set this glycogenosis apart from the others. The myopathic features of the lysosomal and nonlysosomal glycogenoses are listed in Table 45-5 (Griggs and associates; Engel and Franzini-Armstrong).

Disorders of Lipid Metabolism Affecting Muscle (Lipid Myopathies)

Although it has long been known that lipids are an important source of energy in muscle metabolism (along with glucose), it was only in 1970 that W.K. Engel and associates reported the abnormal storage of lipid in muscle fibers attributable to a defect in the oxidation of long-chain fatty acids. The subjects of their report were twin sisters who had experienced intermittent cramping of muscles associated with myoglobinuria after vigorous exercise. In 1973, A.G. Engel and Angelini described a young woman with progressive myopathy, lipid storage predominantly in type 1 muscle fibers, and a deficiency of muscle carnitine, a cofactor required for the oxidation of fatty acids. Since that time, highly sophisticated biochemical techniques have greatly expanded the study of fatty acid metabolism and the identification of many of the primary defects.

Carnitine (β-hydroxy-gamma-*N*-trimethylaminobutyrate), derived from lysine and methionine, plays a central role in the metabolism of fatty acids. Approximately 75 percent of carnitine comes from dietary sources (red meat and dairy products); the remainder is synthesized in the liver and kidneys. Practically all of the body carnitine is stored in muscle, where it has two main functions: (1) transporting long-chain fatty acylcoenzyme As (CoAs) from the cytosol compartment of the muscle fiber into the mitochondria, where they undergo beta-oxidation, and (2) preventing the intramitochondrial accumulation of acyl-CoAs, thus protecting the muscle cell from the membrane-destabilizing effects of these substances.

To be oxidized, the long-chain fatty acids undergo a series of biochemical transformations. First they are activated to corresponding acyl-CoA esters by acyl-CoA synthetase, which is located on the outer mitochondrial membrane. Because the inner mitochondrial membrane is impermeable to acyl-CoA esters, they are transferred into the mitochondria as acylcarnitine esters. This is accomplished by carnitine palmitoyltransferase I (CPT I), also located on the outer mitochondrial membrane. A second carnitine palmitoyltransferase (CPT II), bound to the inner face of the inner mitochondrial membrane, reconverts the acylcarnitines to fatty acyl-CoAs, which undergo beta-oxidation within the mitochondrial matrix (DiMauro and colleagues; DiDonato and Taroni). Isoforms of CPT are critically involved in this process at the inner and outer membranes of the mitochondria.

Despite the many biochemical abnormalities that have been identified in the fatty acid metabolic pathways, there are essentially three clinical patterns by which these defects are expressed:

1. One constellation of symptoms referred to as the *encephalopathic* syndrome has its onset in infancy or early childhood. Its very first manifestation may be sudden death (sudden infant death syndrome [SIDS]), or there may be vomiting, lethargy and coma, hepatomegaly, cardiomegaly, muscular weakness, and hypoketotic hypoglycemia, with prominent hyperammonemia, that is, a Reye-like syndrome. Undoubtedly, instances of this syndrome have not been recognized as abnormalities of fatty acid metabolism but have been designated incorrectly as the Reye syndrome or as SIDS. They are discussed in Chap. 36 with other inherited metabolic disorders.
2. A second (*myopathic*) syndrome appears in late infancy, childhood, or adult life and takes the form of a progressive myopathy, with or without cardiomyopathy. The myopathy may follow episodes of hypoketotic hypoglycemia or may develop de novo.
3. The third syndrome is one that usually begins in the second decade of life and is induced by a sustained period of physical activity or fasting. It is characterized by repeated episodes of *rhabdomyolysis* with or without myoglobinuria.
4. Summarized in the following text are the main disorders of fatty acid metabolism that affect skeletal muscle; these are rare but interesting diseases.

Primary Systemic Carnitine Deficiency (*SLC22A5* Mutation)

To date, this is the only form of carnitine deficiency that can be considered primary (see further on for discussion of the secondary types). Its main clinical features are progressive lipid storage myopathy and cardiomyopathy, sometimes associated with the signs of hypoketotic hypoglycemia. There is no dicarboxylic aciduria, in distinction to the secondary beta-oxidation defects, in all of which dicarboxylic aciduria is present. The cardiomyopathy, which is fatal if untreated, responds to oral administration of L-carnitine, 2 to 6 g/d. This disorder is inherited as an autosomal recessive trait. In these families there is frequently a history of sudden unexplained death in siblings, so that early identification of affected children is essential.

Carnitine Palmitoyltransferase Deficiency (*CPT1A* Mutation)

This disease is also inherited as an autosomal recessive trait and the gene encoding carnitine palmitoyltransferase (CPT) has been identified. There are three types: types I, IIA, and IIB. Type I is the most common. It affects males predominantly, beginning in the second decade of life. Attacks of myalgia, cramps, and muscle weakness, "tightness," and stiffness are precipitated by sustained (although not necessarily intense) exercise and less often by a prolonged period of fasting. Fever, anesthesia, drugs, emotional stress, and cold have been additional but rare precipitating events. The attacks vary greatly in frequency. They are usually accompanied by myoglobinuria, with resultant renal failure in about one-fourth of cases (DiMauro et al, 1973). Rest does not abort the attacks and, once initiated, there is no second-wind phenomenon. There are no warning signs of an impending attack. Any muscle group may be affected. Persistence of weakness after an attack is uncommon. Serum CK rises to high levels not only during attacks but also after vigorous exercise without myoglobinuria. A mild form is more likely to occur in females.

In type I deficiency, necrosis of muscle fibers, particularly type I fibers, occurs during attacks, followed by regeneration. Between attacks, the muscle appears normal. In type IIA, lipid bodies accumulate in the liver, and in type IIB, excess lipid is detected in heart, liver, kidneys, and skeletal muscle.

CPT is either undetectable or greatly reduced in muscle, and assays are now available for the measurement of CPT I and II in circulating lymphocytes and cultured fibroblasts. Testing for the mutation is available.

Treatment A high-carbohydrate, low-fat diet, ingestion of frequent meals, and additional carbohydrate before and during exercise appear to reduce the number of attacks. Patients need to be instructed about the risks of prolonged exercise and skipped meals. Recently, the use of bezafibrate, a drug used for dyslipidemia, has been helpful in patients with mild CPT II.

Secondary Systemic Carnitine Deficiency

This is occasionally the result of severe dietary deprivation or impaired hepatic and renal function. Such instances have been observed in patients with alcoholic–nutritional diseases and kwashiorkor, in premature infants receiving parenteral nutrition, in patients with chronic renal failure undergoing dialysis, and rarely, as a complication of valproate therapy. However, most cases of systemic carnitine deficiency are a result of defects of beta-oxidation, described as follows.

Other Lipid Myopathies

Carnitine acylcarnitine translocase deficiency This condition causes muscular weakness, cardiomyopathy, hypoketotic hypoglycemia, and hyperammonemia, which develop in early infancy and usually lead to death in the first month of life.

Long-chain acyl-CoA dehydrogenase deficiency (ACLDVL mutation) The presentation is in infancy, with recurrent episodes of fasting hypoglycemic coma, muscle weakness, and myoglobinuria, and sometimes sudden death. Survivors may develop a progressive myopathy. Administration of carnitine improves the cardiac disorder and prevents metabolic attacks.

Medium-chain acyl-CoA dehydrogenase deficiency (ACADM mutation) This is a cause of SIDS and a Reye-like syndrome. About half of survivors develop a lipid-storage myopathy in childhood or adult life. The abnormal gene has been mapped to chromosome 1p31. Oral L-carnitine may be of therapeutic value.

Short-chain acyl-CoA dehydrogenase deficiency This myopathy in a limb-girdle distribution may appear initially in older children and adults, or it may follow episodic metabolic disorders in infancy.

Long-chain hydroxyacyl-CoA dehydrogenase deficiency This is a disease of infancy marked by episodes of Reye-like syndrome, hypoketotic hypoglycemia, lipid storage myopathy, cardiomyopathy, and sometimes sudden death.

Short-chain hydroxyacyl-CoA dehydrogenase deficiency This presents as an episodic disorder such as the one described previously, long-chain hydroxyacyl-CoA dehydrogenase deficiency (HAD), but its onset is in adolescence. Recurrent attacks may be associated with myoglobinuria.

Multiple acyl-CoA dehydrogenase deficiency; glutaric aciduria type II Some cases are caused by a deficiency of electron transfer flavoprotein (ETF) and others by a deficiency of electron transfer flavoprotein-ubiquinone oxidoreductase (ETF-QO). In the severest form of multiple acyl-CoA dehydrogenase deficiency (MADD), infants are born prematurely and many die within the first week of life; added to the common metabolic abnormalities are multiple congenital defects and a characteristic "sweaty feet" odor. In less severe cases, the congenital anomalies are absent. In the least severe form, the onset may be in late infancy (with episodic metabolic disturbances) or in childhood or adult life (with a lipid storage myopathy and a deficiency of serum and muscle carnitine). The prenatal diagnosis of glutaric aciduria type II (GA II) is suggested by the finding of large amounts of glutaric acid in the amniotic fluid. In the milder forms of the disease, oral riboflavin (100 to 300 mg/d) may be helpful.

Muscle coenzyme Q10 deficiency This condition presents as a slowly progressive lipid storage myopathy from early childhood. The basic defect is in coenzyme Q10 in the respiratory chain of muscle mitochondria.

The administration of coenzyme Q10 has improved the myopathic weakness.

Neutral lipid storage diseases (*Chanarin-Dorfman disease, PNPLA2 mutation*) These abnormalities of lipid metabolism are distinct from the beta-oxidation defects; they occur in two forms, Chanarin disease, which is characterized by ichthyosis, and a form without skin changes. A progressive myopathy is combined with neurologic manifestations, such as developmental delay, ataxia, neurosensory hearing loss, and microcephaly. The lipid material is stored in muscle as triglyceride droplets that are nonlysosomal and non–membrane-bound.

ENDOCRINE MYOPATHIES

Thyroid Myopathies

Several myopathic diseases are related to alterations in thyroid function: (1) chronic thyrotoxic myopathy; (2) exophthalmic ophthalmoplegia (Graves disease); (3) myasthenia gravis associated with thyrotoxicosis; (4) periodic paralysis associated with thyrotoxicosis; and (5) muscle hypertrophy and slow muscle contraction and relaxation associated with myxedema and cretinism.

Chronic Thyrotoxic Myopathy

This disorder, first noted by Graves and Basedow in the early nineteenth century, is characterized by progressive weakness and wasting of the skeletal musculature, occurring in conjunction with overt or covert ("masked") hyperthyroidism. The thyroid disease is usually chronic and the goiter is usually of the nodular rather than the diffuse type. Exophthalmos and other classic signs of hyperthyroidism are often present but need not be. This complication of hyperthyroidism is most frequent in middle age, and men are more susceptible than women. Some degree of myopathy has been found when sought in more than 50 percent of thyrotoxic patients, although the manifestations may be subtle. The onset is insidious, and the weakness progresses over weeks and months. The muscular disorder as noted is most often mild in degree, but it may be so severe as to suggest progressive spinal muscular atrophy (motor system disease). Muscles of the pelvic girdle and thighs are weakened more than others (Basedow paraplegia), although all are affected to some extent, even the bulbar muscles and, albeit rarely, the ocular ones. However, the shoulder and hand muscles show the most conspicuous atrophy (not an obligatory feature). Tremor and twitching during contraction may occur, but we have not seen fasciculations. The tendon reflexes are of average briskness, possibly more lively than normal. Both the contraction and relaxation phases of the tendon reflexes are shortened, but usually this cannot be detected by the clinician.

Serum concentrations of muscle enzymes are not increased and may be reduced. The EMG is typically normal, although the action potentials may be abnormally brief or polyphasic. Biopsies of muscle, except for slight atrophy of both types 1 and 2 fibers and an occasional degenerating fiber, have been normal. Muscle power and bulk are gradually restored when thyroid hormone levels are reduced to normal levels.

Exophthalmic Ophthalmoplegia (Graves Ophthalmopathy) (See discussion in Chap. 13)

This refers to the cooccurrence of weakness of the ocular muscles and exophthalmos in patients with Graves disease (pupillary and ciliary muscles are always spared). The exophthalmos varies in degree, sometimes being absent at an early stage of the disease, and it is not in itself responsible for the muscle weakness. Often there is some degree of orbital pain. Both the exophthalmos and the weakness of the extraocular muscles may precede the signs of hyperthyroidism, be associated with the other classic features of hyperthyroidism (tachycardia, weight loss, tremor), or may follow effective treatment of the disorder.

The eye signs, both ocular paresis and exophthalmos, become apparent over days or weeks and may occasionally be unilateral, especially at the onset. Any of the external eye muscles may be infiltrated, usually one more than others, accounting for strabismus and diplopia; the inferior and medial recti are the most frequently affected, but upward movements are usually limited as well. The typical but not invariable sign of lid retraction imparts a staring appearance. Subtle exophthalmos can be appreciated by standing above and behind the seated patient and observing the relative positions of the lids and the eyelashes. Conjunctival edema and vascular engorgement over the insertions of the medial and lateral rectus muscles can be appreciated by inspecting and palpating the globe in its extreme lateral positions. These swollen muscles are easily visible on orbital ultrasonography, CT, and MRI. The differential diagnosis of this imaging appearance is from orbital pseudotumor, a usually painful condition, which is discussed in Chap. 13.

Examination of the eye muscles in biopsy and autopsy material has shown prominent fibroblasts, many degenerated fibers, and infiltrations of lymphocytes, mononuclear leukocytes, and lipocytes; hence the term *infiltrative ophthalmopathy*. These histopathologic findings are suggestive of an autoimmune disease—a hypothesis supported by the finding of serum antibodies that react (inconsistently) with extracts of eye muscles (Kodama et al). Possibly the antibodies target glycosaminoglycans of the orbital fibroblasts. A sensitivity of muscle fibers to beta-adrenergic activity caused by excessive thyroid hormone has also been postulated. Other factors are almost certainly involved, such as the small size of oculomotor motor units, the absence of dystrophin, and the rich mitochondrial content.

Treatment Because the ophthalmoparesis often runs a self-limited course, as does the exophthalmos, therapy is difficult to evaluate. Certainly the maintenance of a euthyroid state seems desirable (Dresner and Kennerdell). If the exophthalmos is slight, topical applications of adrenergic blocking agents (guanethidine eye drops, 5 percent) and ophthalmic ointment to prevent corneal drying are adequate. Severe exophthalmos, marked by periorbital and conjunctival edema, and the extraocular muscle weakness may be partially controlled by high doses of corticosteroids (about 80 mg/d prednisone). Because of the hazards of protracted corticosteroid therapy, this approach should be

reserved for patients who would otherwise require surgical intervention to decompress the contents of the orbit. In a number of such cases, it has been possible for the patient treated with corticosteroids to weather the crisis for several weeks or more and avoid the damaging effects of extreme exophthalmos and risks of surgery. Exophthalmos of a degree that threatens to injure the cornea or cause blindness requires tarsorrhaphy or decompression by removal of the roof of the orbit. Teprotumumab is a monoclonal insulin growth factor-receptor antagonist that substantially improves outcomes in patients with more severe disease (Douglas).

Thyrotoxic Hypokalemic Periodic Paralysis

This disorder closely resembles familial hypokalemic periodic paralysis (as described in Chap. 46). It consists of attacks of mild to severe weakness of the muscles of the trunk and limbs; usually the cranial muscles are spared. The weakness develops over a period of a few minutes or hours and lasts for part of a day or longer. In some series of patients with periodic paralysis, as many as half have had hyperthyroidism and most of them have been Asian males. Unlike the typical hypokalemic form, thyrotoxic periodic paralysis is not a familial disorder and its onset is usually in early adult life. Nevertheless, in most of the thyrotoxic cases, the serum potassium levels have been low during the attacks of weakness and the administration of 100 to 200 mg of potassium chloride has terminated the episodes. Propranolol in doses of 160 mg daily in divided doses is also helpful in preventing the episodes. More importantly, effective treatment of the hyperthyroidism abolishes the periodic attacks of weakness in more than 90 percent of cases. A mutation in the potassium channel, Kir2.6, has been found to confer susceptibility to the disease. Other aspects of periodic paralysis are discussed in Chap. 46.

Myasthenia Gravis With Hyperthyroidism

Myasthenia is discussed fully in Chap. 46. Here only a few remarks are made on its special relationship to thyrotoxicosis. Myasthenia gravis in its typical autoimmune, anticholinesterase-responsive form may accompany hyperthyroidism or rarely, hypothyroidism, which are also autoimmune in nature. Approximately 5 percent of patients with myasthenia have hyperthyroidism and the frequency of myasthenia gravis in patients, while low, is 20 to 30 times higher in hyperthyroidism than in the general population. Either condition may appear first, or they may coincide. The weakness and atrophy of chronic thyrotoxic myopathy may be added to that of the myasthenia without appearing to affect the requirement for or response to anticholinesterase medications. By contrast, hypothyroidism, even of mild degree, seems to aggravate the weakness of myasthenia gravis, greatly increasing the need for pyridostigmine and at times inducing a myasthenic crisis. In these cases, thyroxine is beneficial and, with respect to myasthenia, restores the patient to the status that existed before the onset of thyroid insufficiency. The myasthenia should probably be regarded as an autoimmune disease independent of the thyroid disease and each must be treated separately.

Hypothyroid Myopathy

Abnormalities of skeletal muscle consisting of diffuse myalgia and increased volume, stiffness, and slowness of contraction and of relaxation are common manifestations of hypothyroidism, whether in the form of myxedema or cretinism. These changes probably account for the relatively large tongue and dysarthria that one observes in myxedema. Weakness, however, is not a prominent feature. The presence of action myospasm and myokymia (both of which are rare) and of percussion myoedema and slowness of both the contraction and relaxation phases of tendon reflexes assists the examiner in making a bedside diagnosis. The administration of thyroxine corrects the muscle disturbance.

Cretinism in association with these muscle abnormalities is known as the *Kocher-Debré-Semelaigne syndrome*, and myxedema in childhood or adult life with muscle hypertrophy is the *Hoffmann syndrome*; the latter simulates hypertrophia musculorum vera and myotonia congenita. In neither cretinism nor myxedema, however, is there evidence of true myotonia, either by clinical testing or by EMG, although muscle action potentials are myopathic and often show bizarre high-frequency discharges. Serum transaminase values are normal but CK levels are usually elevated, often markedly so. Muscle biopsies have disclosed only the presence of large fibers or an increase in the proportion of small fibers (either type 1 or 2) and slight distention of the sarcoplasmic reticulum and subsarcolemmal glycogen (probably all a result of disuse atrophy).

Pathogenesis of the Thyroid Myopathies

How thyroid hormone affects the muscle fiber is still a matter of conjecture. Clinical data indicate that thyroxine influences the contractile process in some manner but does not interfere with the transmission of impulses in the peripheral nerve across the myoneural junction or along the sarcolemma. In hyperthyroidism an undefined functional disorder enhances the speed of the contractile process and reduces its duration, the net effect being fatigability, weakness, and loss of endurance of muscle action. In hypothyroidism, muscle contraction is slowed, as is relaxation, and its duration is prolonged.

The speed of the contractile process is related to the quantity of myosin adenosine triphosphatase (ATPase), which is increased in hyperthyroid muscle and decreased in hypothyroid muscle. The speed of relaxation depends on the rate of release and reaccumulation of calcium in the endoplasmic reticulum. This is slowed in hypothyroidism and increased in hyperthyroidism (Ianuzzo et al). The myopathic effects of hypothyroidism need to be distinguished from those of a neuropathy, which may rarely complicate hypothyroidism (see Chap. 43).

Corticosteroid Myopathies

The widespread use of adrenal corticosteroids has created a class of muscle diseases similar to the one that occurs in the Cushing disease as described many decades ago by Müller and Kugelberg. A deficiency of corticosteroids, as occurs in Addison disease, also causes generalized weakness and asthenia, but without an identifiable muscle disease.

Corticosteroid and Cushing Disease Myopathy

The prolonged use of corticosteroids causes the proximal limb and girdle musculature to become weak to the point of causing difficulty in elevating the arms and arising from a sitting, squatting, or kneeling position; walking upstairs may also be hampered. Some individuals seem to be more susceptible than others. The problem often arises of distinguishing an iatrogenic steroid-induced myopathy from the weakness produced by a primary neuromuscular disorder that is being treated with these medications such as one of the myositides or myasthenia. In some of our myasthenic patients, the use of high-dose corticosteroids has resulted in a selective, rapid, and severe weakness of the hip flexors.

The EMG is normal or mildly myopathic, with small and abundant action potentials but no fibrillations. Biopsies disclose only a slight variation in fiber size with atrophic fibers, mainly of type 2b, but little or no fiber necrosis and no inflammatory cells. Under electron microscopic examination there are aggregates of mitochondria, accumulations of glycogen and lipid, and slight myofibrillar loss that suggest more disuse atrophy than they do a primary muscle disorder. The serum CK and aldolase are usually normal. These changes are the same in Cushing disease and an otherwise unexplained proximal myopathy with these features suggests that diagnosis (Cushing disease and Cushing syndrome).

There is an imprecise correlation between the total dose of corticosteroid administered and the severity of muscle weakness. Nevertheless, in patients who develop this type of myopathy, the corticosteroid dosage has usually been high and sustained over a period of months or years. All corticosteroids may produce the disorder, although fluorinated ones, on uncertain evidence, are said to be more culpable than others. Discontinuation or reduction of corticosteroid administration leads to gradual improvement and recovery; alternate-day regimens may also allow recovery, albeit gradually.

As the foregoing discussion implies, the mechanism by which corticosteroids cause muscle weakness is not known. In corticosteroid-treated animals, there is a measurable decrease in the uptake of amino acids and protein synthesis by muscle, but the underlying pathways have not been elucidated. This has even greater bearing on the next discussed subject.

Critical Illness Myopathy (Acute Steroid Myopathy; Acute Quadriplegic Myopathy)

In addition to the proximal myopathy induced by the long-term use of steroids, an acute and far more severe myopathy has been recognized in critically ill patients. It was described initially with cases of severe asthma in patients who were exposed to high doses of steroids for treatment. Subsequently, this acute myopathy has been recognized with all types of critical systemic diseases and organ failure, again, usually in the context of the administration of high doses of corticosteroids but in a few cases, with sepsis and shock without exposure to this class of medication. Moreover, the use of neuromuscular blocking agents appears to play an important complementary role in the genesis of the myopathy, being reported as a factor in more than 80 percent of cases; it is uncertain whether these agents alone, without sepsis or organ failure, can produce a similar process (see reviews by Gorson and Ropper, Lacomis et al, and Barohn et al).

Patients who acquire this problem may have been exposed to high doses of corticosteroids for only brief periods. Exceptional instances have been reported in which the myopathy was induced by doses as low as 60 mg prednisone administered for 5 days, but we have not encountered such a case. The degree and type of simultaneous exposure to neuromuscular blocking agents have varied, but the doses have generally also been quite high, falling in the range of a total dose of 500 to 4,000 mg of pancuronium or an equivalent, over several days.

The severe generalized muscle weakness usually becomes evident when the systemic illness subsides, often as attempts are made to wean the patient from the ventilator. The tendon reflexes are normal or diminished, and there may be confounding features of a "critical illness polyneuropathy," which is discussed in Chap. 43. Most of our patients with acute myopathy have recovered over a period of 6 to 12 weeks after the corticosteroid agent has been greatly reduced in dose or withdrawn, but a few have remained weak for as long as a year.

Serum CK is elevated, at least early in the process. The EMG discloses the characteristic features of a myopathy; often there are fibrillations as well, theorized to be a result of separation of the motor endplate region from intact segments of muscle fibers. A concurrent polyneuropathy and any residual effects of neuromuscular blockade can be excluded by appropriate electrophysiologic studies. Muscle biopsy shows varying degrees of necrosis and vacuolation affecting mainly type 2 fibers. The identifying histologic feature is a striking loss of thick (myosin) filaments. Severe degrees of muscle necrosis occur and have been accompanied by massively elevated CK levels and by myoglobinuria with renal failure.

Several experimental observations may explain the apparent additive effect on muscle of corticosteroids and neuromuscular blocking agents. Animals exposed to high doses of steroids soon after experimental denervation of a muscle display a selective loss of myosin, the characteristic finding of acute steroid myopathy. Myosin depletion is reversed by reinnervation but not by withdrawal of the corticosteroids. Furthermore, denervation of muscle has been found to induce an increase in glucocorticoid receptors on the surface of the muscle. On this basis, it has been postulated that exposure to neuromuscular blocking agents creates a functional denervation, rendering the muscle fiber vulnerable to the damaging effects of steroids (Dubois and Almon). It is curious that this myopathy has not been seen after high-dose corticosteroid administration for neurologic diseases such as multiple sclerosis, but the observation of Panegyres and colleagues of a patient with myasthenia who developed a severe, myosin-depleted myopathy following high doses of methylprednisolone supports such a dual action of denervation (at the postsynaptic membrane) and glucocorticoids. Whether it also explains the more common circumstance of clinical worsening of myasthenia gravis that sometimes accompanies the initial administration of corticosteroid treatment is also not clear.

Adrenocortical Insufficiency

Generalized weakness and fatigability are characteristic of adrenocortical insufficiency, whether *primary* in type, that is, because of *Addison disease* (infectious, neoplastic, or autoimmune destruction of the adrenal glands or adrenal hemorrhage), or secondary to a pituitary deficiency of adrenocorticotropic hormone (ACTH). The weakness and fatigability, however, are probably related to mostly water and electrolyte disturbances and hypotension, not to a primary disorder of muscle. Perhaps there is also an element of reduced central drive of motor activity. Biopsy has not disclosed any abnormalities of muscle and postmortem examination in one case showed no changes. Likewise, the EMG is normal, and the tendon reflexes are retained. Addisonian weakness responds (as does hyperkalemic paralysis) to glucocorticoid and mineralocorticoid replacement.

Primary Aldosteronism

Production of excess aldosterone by adrenal adenomas has been the subject of many articles, one of the earliest and most notable being that of Conn muscular weakness has been observed in 75 percent of the reported cases of hyperaldosteronism. In nearly half of those with muscle weakness there was either hypokalemic periodic paralysis or tetany. Chronic potassium deficiency may express itself either by periodic weakness or by a chronic myopathic weakness. An associated severe alkalosis causes the tetany. As in the weakness of Addison disease, there is no structural disorder of muscle, except perhaps for vacuolation, which is the result of severe hypokalemia.

Diseases of Parathyroid Glands and Vitamin D Deficiency

A proportion of patients with *parathyroid adenomas* complain of weakness and fatigability. Vicale described the first example of this disorder and remarked on the muscular atrophy and weakness and the pain on passive or active movement. The tendon reflexes were retained. A few scattered muscle fibers had undergone degeneration, but claims for a denervative muscle process are disputed. We have not been impressed with either a myopathy or neuropathy in this disease.

In *hypoparathyroidism*, muscle cramping is prominent, but there are no other neuromuscular manifestations. In both hypoparathyroidism and pseudohypoparathyroidism—the latter with characteristic skeletal abnormalities and, in some instances, mental slowness—the most important muscle abnormality is *tetany*. This is a result of low ionized serum calcium, which depolarizes axons more than muscle fibers.

Osteomalacia, as a result of vitamin D deficiency and disorders of renal tubular absorption, often includes muscle weakness and pain as common complaints, similar to those in patients with primary hyperparathyroidism and with uremia (see Layzer for further comment).

A chronic proximal myopathy can occur in conjunction with hypophosphatemia associated with solitary bone cysts. In two of our patients, removal of the cyst restored serum phosphorus levels and cured the generalized muscle weakness. Also known is an uncommon syndrome of severe hypophosphatemia and generalized bone pain in association with usually benign mesenchymal tumors of soft tissue and bone (*oncogenic hypophosphatemia*). These tumors express a fibroblast growth factor that induces renal wasting of phosphorous. *Hypophosphatemic myopathic weakness* has been noted in critical care units, precipitated by hyperalimentation solutions; the onset of weakness can be so abrupt in this circumstance, as to simulate the Guillain-Barré syndrome. The oral administration of phosphates to raise serum phosphorus cures the nonneoplastic cases. Presumably phosphorus depletion limits the phosphorylation reactions and the synthesis of ATP in muscle.

Weakness in Acromegaly

Proximal muscle weakness and atrophy have been recorded as late developments in many *acromegalic* patients. Formerly thought to be caused by neuropathy, these symptoms in acromegaly have been convincingly shown to be the result of a generalized myopathy (Mastaglia and colleagues). The serum CK is slightly elevated in some cases, and myopathic potentials are observed in the EMG. Biopsy specimens have shown atrophy and reduced numbers of type 2 fibers, but necrosis of only a few fibers. Treatment of the pituitary adenoma and correction of the hormonal changes restores strength. A mild peripheral neuropathy of sensorimotor type has also been reported in a few patients with acromegaly but is far less frequent than carpal tunnel syndrome and other focal entrapments in this disease.

MITOCHONDRIAL MYOPATHIES (SEE CHAP. 36)

The genetic aspects of mitochondrial diseases and the diverse and overlapping clinical syndromes that constitute this category—including the myopathic ones—are discussed in Chap. 36. The histologic change termed *ragged red fibers* reflects the mitochondrial changes of this class of diseases and is common to many of them, even without manifest symptoms of muscle disease.

MYOPATHIES CAUSED BY DRUGS AND TOXINS; RHABDOMYOLYSIS (SEE CHAP. 41)

A vast number of drugs and other chemical agents have been identified as myotoxic (See Table 45-6). In 1989, Curry and colleagues found reports (in the English literature alone) of approximately 100 drugs that had caused rhabdomyolysis and myoglobinuria, mostly acting in an idiosyncratic manner, and the list continues to grow. Additional myotoxic agents that can be expected to appear as new drugs are introduced. Because it is impractical to describe all the implicated drugs and toxins individually, they are broadly categorized and their main features listed in Chap. 41.

Exogenous agents may produce myopathic changes in several ways. They may act directly on muscle cells, either diffusely or locally, as occurs with intramuscular injections, or the muscle damage can be a result of diverse secondary

Table 45-6

FEATURES OF TOXIN-INDUCED MYOPATHIES

MYOPATHIC SYNDROME	AGENT	CLINICAL FEATURES	PATHOLOGY	LABORATORY FINDINGS[a]
Necrotizing myopathy (rhabdomyolysis)	1. Statin drugs-immune mechanism 2. Alcohol excess 3. Clofibrate, gemfibrozil 4. Amphetamine derivatives	Acute/subacute painful proximal myopathy; tendon reflexes usually preserved	Necrosis, regeneration	CK ↑↑, myoglobinuria +/–
	5. Hypervitaminosis E	5. Painless	5. Paracrystalline inclusion bodies	
	6. Organophosphates			
	7. Snake venoms	7. Severe, acute intoxication		
	8. High-dose corticosteroids in critical illness	8. Neuromuscular blockers implicated		
	9. Mushroom poisoning (*Amanita phalloides*)		9. Loss of myosin	
	10. Cocaine			
Steroid myopathy	1. Acute (high IV steroid doses, ventilated patients on pancuronium) 2. Myasthenics	Severe proximal and distal weakness	1. Necrosis of mainly type 2 fibers; loss of myosin; vacuolar changes	CK ↑↑, myoglobinuria +
	3. Chronic	2 and 3. Proximal atrophy, weakness	2. Type 2 fiber atrophy	Blood lymphocytosis
Hypokalemic myopathy	1. Diuretics 2. Laxatives 3. Licorice, carbenoxolone 4. Amphotericin B, toluene 5. Alcohol abuse	Weakness may be periodic, reflexes may be depressed or absent, rarely severe myoglobinuria	Necrosis, regeneration, vacuolization	CK ↑↑, myoglobinuria +/–, hypokalemia
Amphiphilic cationic drug myopathy (lysosomal storage, "lipidosis")	1. Chloroquine (>500 mg), hydroxychloroquine, quinacrine, plasmocid 2. Amiodarone 3. Perhexiline	Proximal muscle pain and weakness, sensorimotor neuropathy, cardiomyopathy	Chloroquine: vacuole formation, optically dense structures	CK ↑
Impaired protein synthesis	Ipecac syrup, emetine	Myalgia, proximal weakness, cardiomyopathy	Focal mitochondrial loss, vacuoles	CK ↑
Antimicrotubular myopathy	1. Colchicine 2. Vincristine	Proximal weakness, peripheral neuropathy; CK may be normal	Vacuolar myopathy (rimmed vacuoles)	CK ↑
Inflammatory myopathy	1. D-Penicillamine 2. Procainamide 3. Cimetidine? Ciguatera toxin?	Proximal muscle pain, weakness, skin changes possible	Inflammation, necrosis, regeneration	CK ↑, myoglobinuria +/–
Fasciitis, perimyositis, microangiopathy	1. Toxic oil syndrome 2. Eosinophilia-myalgia syndrome	Myalgia, skin changes, peripheral neuropathy, other systems also affected	Vasculitis, connective tissue infiltration	Eosinophilia
Mitochondrial myopathy	1. Zidovudine 2. Germanium	Proximal myalgia and weakness	Ragged red fibers, necrosis, regeneration	CK normal or ↑
Various	1. Cyclosporine 2. Labetalol			
	3. Anthracycline antibiotics	3. Humans: only cardiomyopathy		
	4. Rifampin, amiodarone			
Local myopathy due to IM injections	1. Acute: IM injection of various drugs—e.g., cephalothin, lidocaine, diazepam	Local pain, swelling, sometimes abscess formation	Focal necrosis	CK ↑
	2. Chronic: Repeated IM injections—e.g., pethidine, pentazocine, intravenous drug abuse, antibiotics (in children)	Induration and contracture of injected muscles	Marked fibrosis and myopathic changes	Normal

[a]CK (serum creatinine kinase): ↑ (mild), ↑↑ (moderate), ↑↑↑ (marked) elevations; myoglobinuria: +/– (may be present).

factors—electrolyte disturbances (hypokalemia), renal failure, excessive energy requirements of muscle (as occur with drug-induced seizures and malignant hyperthermia), or inadequate delivery of oxygen and nutrients. Of course, there is a derivative category of drug-induced coma with compressive-ischemic injury to muscle. However, the most important group is that of direct toxic effects on the muscle membrane on the internal apparatus of the cell.

Several clinical features mark a myopathy as toxic in nature: lack of preexisting muscular symptoms; a predictable delay in onset of symptoms after exposure to a putative toxin; the lack of any other cause for the myopathy; and often, complete or partial resolution of symptoms after withdrawal of the toxic agent. Pathologically, this group of disorders is characterized by nonspecific myopathic changes, which in most severe degrees take the form of myonecrosis (rhabdomyolysis) and resultant myoglobinuria. This necrotizing muscle syndrome is the most frequent and serious myotoxic syndrome.

In any disease that results in rapid destruction of striated muscle fibers (rhabdomyolysis), myoglobin and other muscle proteins enter the bloodstream and appear in the urine. The latter is "cola"-colored (burgundy red or brown), much like the urine in hemoglobinuria. In hemoglobinuria, however, the serum is pink, because hemoglobin (but not myoglobin) is bound to haptoglobin, and this complex is not excreted in the urine as readily as myoglobin; also in addition, the hemoglobin molecule is three times as large as the myoglobin molecule. (The hemoglobin–haptoglobin complex is removed from the blood plasma over a period of hours and haptoglobin may be depleted, so that hemoglobinuria is present without grossly evident hemoglobinemia.) Differentiation of the two pigments in urine is difficult; both are guaiac-positive and may be detected by the "dipstick" test that can be used to advantage at the bedside in appropriate circumstances. Only small differences are seen on spectroscopic examination. The most sensitive means of detecting myoglobin is by radioimmunoassay. It should be mentioned that porphyrins are another cause of discoloration of the urine. The clinical picture in porphyria is one of a polyneuropathy and not a myopathy.

Many of the causes of myonecrosis have already been mentioned in this chapter, including acute inflammatory myopathy, several types of glycogenoses, CPT deficiency, and as a result of poisoning or therapeutic use of a vast array of drugs (including the combination of steroids and pancuronium in critically ill patients, discussed earlier), environmental toxins, and venoms. Myoglobinuria is an important feature of many other medical conditions: crush injury; extensive infarction of muscle that occurs in cases of vascular disease and of diabetes; in cases of severe acute alcohol intoxication, excessive use or repeated injury to muscles in status epilepticus, generalized tetanus, malignant hyperthermia, malignant neuroleptic syndrome, prolonged marching, electrical and lightning injuries; or simply excessive exercise—although muscle necrosis after exercise suggests an underlying metabolic disease of muscle.

Regardless of the cause of the rhabdomyolysis, the affected muscles become painful and tender within a few hours and their power of contraction is diminished. Sometimes, the skin and subcutaneous tissues overlying the affected muscles (nearly always of the limbs and sometimes of the trunk) are swollen and congested. There is a marked elevation of CK in the serum and there may be a low-grade fever and a reactive leukocytosis. If myoglobinuria is mild, recovery occurs within a few days and there is only a residual albuminuria. When severe, renal damage may ensue and lead to anuric renal failure requiring dialysis. The mechanism of the renal damage is not entirely clear; it is not simply a mechanical obstruction of tubules by precipitated myoglobin (although this does occur).

Treatment of myoglobinuria Alkalinization of the urine by ingestion or infusion of sodium bicarbonate is said to protect the kidneys by preventing myoglobin casts, but in severe cases it is of doubtful value and the sodium may actually be harmful if anuria has already developed. Diuresis induced by mannitol or by loop diuretics such as furosemide and by the administration of intravenous fluids reduces the chances of anuric renal failure if given in time. Therapy is much the same as for the anuria that follows shock (see *Harrison's Principles of Internal Medicine*). In cases of focal muscle injury, for example, as occurs in diabetics or from vascular occlusion, surgical decompression of the overlying fascia and skin may be necessary to prevent ongoing ischemia, the "compartment syndrome."

Statin-Induced Myopathy

With the widespread use of these lipid-lowering medications, myotoxicity has become a well-described but possibly overrated problem. Symptoms range in severity from mild muscular aches with slightly elevated CK concentrations in the serum to a rare but potentially fatal rhabdomyolytic syndrome. (Myalgias alone are as common in patients taking placebo as in those taking statins). The incidence of true myopathy with statins has been estimated to be approximately 1 in 10,000 people treated per year. There appear to be two types of myopathy—one idiosyncratic and associated with direct toxicity and another, now thought to be more common, due to an antibody reaction. The first generation of these drugs were fungal metabolites (lovastatin, pravastatin, simvastatin) and were infrequently implicated in muscle damage, but the newer synthetic ones (atorvastatin, fluvastatin, cerivastatin) are more frequently toxic, especially when given with gemfibrozil (which has reportedly led to a small number of deaths from myoglobinuric renal failure and has been removed from the market). Few cases are this dramatic. The subject has been reviewed by Thompson and associates and by Mammen. Drugs in the statin class with higher lipid solubility appear to have a greater potential for toxicity as a result of their increased muscle penetration.

In addition to the direct toxicity, there is an autoantibody syndrome directed against HMGCo-A reductase, which may be induced by statins (of any type) or occur spontaneously and may cause necrotizing myopathy as discussed in an earlier section (Mammen).

The mechanism of directly toxic muscle damage is not well understood, but it is likely that inherent enzymatic defects are present in a proportion of the severe cases and that others are due to the aforementioned autoimmune

process (Farmer). A novel insight derived from genome-wide screening has been that variants in a gene (*SLCO1B1*) that codes for an organic anion-transporting polypeptide confers a risk of statin myopathy (4.5-fold for a heterozygous state and 17 times for the homozygous state; see the study by The SEARCH Collaborative Group). In addition, the chronic use of statin drugs reduces levels of both ubiquinone and small guanosine triphosphate (GTP)–binding proteins, also plausible factors in statin-induced muscle toxicity.

A clinical problem arises when the CK level is elevated, but the patient taking one of these medications has no muscular symptoms. It has been our general practice to continue the medication if the elevation of CK is in the low range and does not rise over time, and if the medication is considered necessary. If alternative and safe means of lowering the lipid level are available, they should be tried in lieu of a statin, but each patient's circumstances differ. A similarly vexing and not uncommon problem is myopathic symptoms such as muscle stiffness, tenderness, and weakness with normal CK concentrations in patients taking a drug in this class; a trial of discontinuing the medication might be appropriate (Phillips and colleagues). Finally, we have encountered a number of patients whose CK levels have remained high for months or longer after the medications have been stopped. In a few, CK elevations have remained over years, but we have had no way to ensure that the test was not abnormal before taking the statin.

As a rule, statins should be discontinued if the muscle disorder is serious. Treatment of the immune type of myopathy is complex as the syndrome may persist after discontinuation of the drug. In some instances, discontinuation is followed by spontaneous improvement but others may require glucocorticoids administration or an immunosuppressive agent such as mycophenylate or azathioprine. If there is no response, intravenous immunoglobulin or rituximab may be tried, although there have not been adequate trials to determine the best course of action (Mammen).

Colchicine Myoneuropathy

This condition is included here as much for its curious histopathologic features as for its clinical interest. The drug, used widely in the treatment of gout, often gives rise to a mild subacute proximal muscular weakness but has also produced an acute necrotizing myopathy. Most instances of the latter have occurred in patients with a degree of renal failure, which allows accumulation of the drug (even though the drug is metabolized predominantly by the liver). In rare instances the myopathy has affected the cranial musculature and the diaphragm. Many cases also show clinical or electrophysiologic evidence of a polyneuropathy, leading to the term *colchicine myoneuropathy* (Kuncl and colleagues). The reflexes are diminished and there is mild distal sensory loss. Rare cases of colchicine-induced hypokalemic periodic paralysis and also of myotonia have been reported.

The serum CK concentration may be elevated or normal. The muscle biopsy shows elements of both myopathic and neuropathic disease, with the special feature in muscle of rimmed vacuoles on the Gomori trichrome stain that are more central in the muscle fibers than those seen with inclusion body myositis. The mechanism of the muscle damage is unknown but is probably attributable to the drug's interference with tubulin, a protein required for the polymerization of microtubules in muscle and nerve. Weakness resolves in a matter of days or weeks when the drug is discontinued, but the neuropathic features may remain.

Other drugs that cannot be compactly summarized but may produce a toxic myopathy or neuromyopathy include *amiodarone*, *chloroquine*, and *hydroxychloroquine* as mentioned in Chap. 41.

Alcohol Myopathy (See Also Chap. 41)

Several forms of muscle weakness have been ascribed to alcoholism. In one type, a painless and predominantly proximal weakness develops over a period of several days or weeks in the course of a prolonged drinking bout and is associated with severe degrees of *hypokalemia* (serum levels < 2 mEq/L). The urinary excretion of potassium is not significantly increased, and depletion is probably the result of vomiting and diarrhea. In addition, serum levels of liver and muscle enzymes are markedly elevated. Biopsies from severely weakened muscles show single-fiber necrosis and vacuolation. Treatment consists of the administration of potassium chloride intravenously (about 120 mEq daily for several days), after which oral administration suffices. Strength returns gradually in 7 to 14 days, and enzyme levels return to normal concomitantly.

A more dramatic myopathic syndrome, occurring acutely at the height of a prolonged drinking bout and appropriately termed *acute alcoholic myopathy*, is manifest by severe pain, tenderness, and edema of the muscles of the limbs and trunk, accompanied in severe cases by renal damage (Hed et al). Hypokalemia is not implicated. The myonecrosis is generalized in some patients, and remarkably focal in others. A swollen, painful, tender limb or part of a limb may give the appearance of a deep venous thrombosis or lymphatic obstruction. Myonecrosis is reflected by high serum levels of CK and aldolase and the appearance of myoglobin in the urine, leading in the most severe cases to fatal myoglobinuric renal failure. Indeed, in a general hospital, alcoholism is one of the most common causes of rhabdomyolysis and myoglobinuria, rivaled only by status epilepticus and trauma. Some patients recover within a few weeks, but others require several months, and relapse during another drinking spree occurs frequently. Restoration of motor power occurs with muscle regeneration but may be hindered by polyneuropathy and other syndromes of neuromuscular disability associated with alcoholism. Rhabdomyolysis has been produced experimentally in rats by subjecting the animals to a brief fast following a 2- to 4-week exposure to alcohol, suggesting that a similar mechanism may be operative in alcoholic individuals (Haller and Drachman).

A third form of acute muscular disorder in alcoholics consists of severe muscular cramps and diffuse weakness in the course of a sustained drinking bout (Perkoff and his associates). They noted a number of biochemical abnormalities in these patients, as well as in asymptomatic alcoholics who had been drinking heavily for a sustained period

before admission to the hospital: elevated serum levels of CK, myoglobinuria, and a diminished rise in blood lactic acid in response to ischemic exercise.

From time to time in alcoholics one observes the subacute or chronic evolution of painless weakness and atrophy of the proximal muscles of the limbs, especially of the legs, with only minimal signs in the distal segments of the legs and feet. Cases such as these have been referred to as *chronic alcoholic myopathy*, implying a direct toxic effect of alcohol on muscle, but the data are insufficient to warrant such an assumption. Some of these cases have shown necrosis of individual muscle fibers and other signs of polymyositis; most cases prove to be neuropathic in nature (Faris and Reyes). Treatment follows along the lines indicated for nutritional-alcoholic neuropathy, and complete recovery can be expected if the patient abstains from alcohol and maintains adequate nutrition.

THE CONGENITAL MYOPATHIES

Included under this section are two sizable groups of muscle diseases: one is an assemblage of congenital deformities that involve muscle and the other is a unique class of congenital myopathies. Insofar as all of the disorders comprising these categories are congenital, it may be helpful by way of introduction to refer briefly the main facts about the natural development and aging of muscle in the introductory section of this chapter. These diseases are of particular importance in pediatric neurology, for most of them usually present at an early age.

Congenital Deformities of Muscle

Arthrogryposis (Table 45-7)

This disorder of multiple congenital contractures, now referred to as *arthrogryposis* (literally, curved joints), has been estimated to occur once in 3,000 births. The deformities result from a lack of movement during fetal development and are therefore produced by any disorder that immobilizes the developing embryo, whether from a lack of anterior horn cells, peripheral nerves, the motor end plate (as in an infant born to a myasthenic mother), or diseases of muscle. Often, there are associated developmental defects of the nervous system and somatic structures, low-set ears, wide and flat nose, micrognathia, and high-arched palate; less often, there are short neck, congenital heart disease, hypoplasia of the lungs, and cryptorchidism.

Table 45-7

THE MAIN CAUSES OF ARTHROGRYPOSIS

Werdnig-Hoffmann motor neuron disease
Myotonic dystrophy
Congenital myasthenia (see Chap. 46)
Congenital myopathy
Congenital muscular dystrophy
Neonatal neuropathy
Prader-Willi syndrome
Amyoplasia (focal arthrogryposis)

Of the many conditions that underlie arthrogryposis, developmental abnormalities of the anterior horn cells, mainly *Werdnig-Hoffmann disease* as discussed in Chap. 38, is by far the most common. A failure in development of anterior horn cells results in an uneven smallness and paresis of limb muscles. The unopposed contraction of relatively normally innervated muscles sets the fixed deformities. In a less common group of myopathic causes of arthrogryposis, the nervous system is usually intact and the disease is that of a congenital myopathy or congenital dystrophy. It has been observed that in the myopathic variety the limbs are fixed in a position of flexion at the hips and knees and adduction of the legs, in contrast to the variable postures of the myelopathic (anterior horn cell) form. In addition to these two well-recognized causes of arthrogryposis, occasional cases are attributable to a neonatal neuropathy, neonatal myasthenia gravis, or to the Prader-Willi syndrome (causing intrauterine hypotonia).

An infant with arthrogryposis should be evaluated with an EMG that is interpreted by an experienced electromyographer, and by a biopsy of muscle for the detection of group atrophy and of the congenital myopathies described further on in this chapter. Both these tests are difficult to interpret in the incompletely formed nervous system of the premature infant. In many circumstances, it is valuable to delay the tests until several weeks of postterm development when the results are usually clearer. Sometimes, the electrophysiologic and biopsy tests may have to be repeated after several weeks or more to give a definitive diagnosis. If the initial evaluations are unrevealing, an imaging study of the brain to detect cerebral malformations (and sequencing of the *PWCR* locus chromosome 5 for Prader-Willi syndrome) may prove useful.

Congenital Focal Fibrous Contractures

This term refers to a fixation of limb posture as a result of a developmental lack or destruction of muscles, with shortening and fibrosis of supporting tissue and ligaments. A surprising number of deformities in infants and children are traceable to this type of defect. The most common are congenital clubfoot (talipes), congenital torticollis (*wryneck*), congenital elevation of the scapula (Sprengel deformity), and congenital dislocation of the hips. In all these conditions, the postural distortion is produced and maintained either by a weakened, fibrotic muscle or by a normal one that is contracted and shortened because of the absence of a countervailing antagonist. Trauma to a muscle during intrauterine life or at birth may lead to fibrosis and to fibrous contracture in some cases.

Congenital clubfoot Here the deformity may be one of plantar flexion of the foot and ankle (talipes equinus), inversion (talipes varus or clubfoot), eversion (talipes valgus or splayfoot), or dorsiflexion of foot at the ankle (talipes calcaneus). Approximately 75 percent of cases are of the equinovarus clubfoot variety (i.e., the foot turns downward and inward). Usually both feet are affected. Multiple incidences may occur in one family. Several explanations of cause and pathogenesis have been offered: fetal malposition, an embryonic abnormality of tarsal and metatarsal bones, a primary defect in nerves or anterior horn cells of the spinal cord, or a congenital dystrophy of muscle.

No one theory explains all cases, and available pathologic data exclude a single cause and pathogenesis. In some instances, clubfoot is the only recognizable congenital abnormality, but as often it occurs as a manifestation of generalized arthrogryposis and is an indicator of a more widespread intrauterine involvement of the CNS. (See Kakulas and Adams and also Banker for pertinent literature on the subject.)

Congenital torticollis (*Wryneck*) This disorder begins during the first months of life and, unlike the torticollis of adults discussed in Chap. 4, it is not the result of a dystonia but instead is caused by congenital shortening of the sternocleidomastoid muscle, which is firm and taut. The head is inclined to one side and the occiput slightly rotated to the side of the affected muscle. This disorder is nonfamilial and is ascribed to injury to the sternocleidomastoid at birth. Whether the injury is a purely mechanical one to the muscle itself or is caused by ischemia stemming from arterial or venous occlusion (or an entirely different cause) is not clear. Congenital torticollis often gives rise to a sternocleidomastoid enlargement (a pseudotumor) that appears, on exploration, as a pale, spindle-shaped swelling of the muscle belly. The histologic findings are similar to those of Volkmann contracture, that is, replacement of the muscle fibers by relatively acellular connective tissue, suggesting that an ischemic mechanism underlies the defect in at least some cases.

Congenital Absence of Muscles (Amyoplasia)

It is well known that some individuals are born without certain individual muscles. This pertains not only to certain inconstant and functionally unimportant muscles, such as the palmaris longus, but also to more substantial ones. The muscles found to be absent most frequently are the pectoralis, trapezius, serratus anterior, and quadriceps femoris, but many single muscles may be missing in isolated cases.

Congenital absence of muscle is usually associated with congenital anomalies of neighboring nonmuscular tissues. For example, congenital absence of the pectoral muscle is accompanied by aplasia or hypoplasia of the mammary structures or of syndactyly and microdactyly. Agenesis of the pectoral muscle may also be associated with scoliosis, webbed fingers, and underdevelopment of the ipsilateral arm and hand (Poland syndrome). Another unusual constellation consists of congenital absence of portions of the abdominal muscles ("prune belly"), often in association with arthrogryposis and a defect of ureters, bladder, and genital organs. Amyoplasia also occurs in a few cases of facioscapulohumeral dystrophy.

Restricted Nuclear Amyotrophies

In another group of restricted palsies, the essential abnormality is in the CNS (nuclear amyotrophies). One of the most frequent is congenital ptosis as a result of an inborn defect of the innervation of the levator palpebrae muscles. Complete paralysis of all muscles supplied by the oculomotor nerve, apparently a result of hypoplasia of the third nerve nuclei, may be observed in several members of a family and occasionally in only one member. Bilateral abducens palsy is often associated with bifacial palsy in the newborn and is known as the *Möbius syndrome*; this usually nonfamilial anomaly, the cause of which is thought to be a nuclear hypoplasia or aplasia, is discussed with the developmental disorders in Chap. 37. In these familial nuclear amyotrophies, the muscles develop independently of the nervous system but have no prospect of surviving because of failure of innervation. It is, therefore, a kind of congenital denervation hypotrophy. Of course, a primary dystrophy may also give rise to bifacial weakness, as in FSHD.

Congenital Structural Myopathies (Table 45-8)

Beginning in 1956, with the account by Shy and Magee of a patient whose muscle fibers showed a peculiar central densification of sarcoplasm ("cores"), a new class of

Table 45-8

THE MAIN CONGENITAL MYOPATHIES

TYPE	GENETICS	GENE	ONSET DECADE	CK ELEVATION	REGIONS AFFECTED
Central core disease	AD, AR	Ryanodine receptor (*RYR1*)	1st–2nd	1–10 ×	Diffuse myopathy presenting in infancy Proximal myopathy beginning in adolescence Risk of malignant hyperthermia May include mental retardation
Nemaline rod myopathy	AD, AR	α-Tropomyosin Nebulin Coflin-2 β-Tropomyosin Ryanodine receptor Troponin T1 α-Actin	1st–2nd	1–2 ×	Diverse phenotypes May present as severe congenital myopathy or as childhood-onset myopathy May include facial weakness, high-arched palate, and high pedal arches
Myotubular myopathy	X-linked AD, AR,	Myotubularin Dynamin-2 *MYF6*	1st	1–4 ×	Proximal and distal weakness May include facial weakness, ophthalmoparesis, ptosis

AD, autosomal dominant; AR, autosomal recessive; CK, creatine kinase.

hereditary diseases of muscle was delineated. The more common and better-defined members of this group are the *central core*, *nemaline* (rod-body), myotubular, and *centronuclear myopathies.* A variety of other types of congenital myopathy have been described, but they are relatively uncommon and some are of dubious specificity; they are mentioned only briefly. As the names imply, in each of these diseases there is no loss of muscle fibers, but within each fiber there is a distinctive morphologic abnormality. These processes usually express themselves early in life by a lack of muscle bulk, hypotonia, weakness of the limbs, and often, with additional but subtle dysmorphic features of other parts of the body.

Further study has revealed that the diseases of this group are not confined to infancy and early childhood and some of them, especially those present at birth, are not as benign as their early descriptions implied. Each of the entities mentioned earlier has been observed at a later age, even in middle adult life. Indeed, if the disease is mild, there is often no way of deciding whether it has been present since birth.

The characteristic feature of most of these myopathies, in addition to usual early onset, is *lack of progression* or *extremely slow progression*, in contrast to the more rapid pace of many muscular dystrophies, Werdnig-Hoffmann disease, and of other forms of hereditary motor system disease of childhood and adolescence. Exceptionally, an example of more rapid progression of a congenital myopathy has been reported, and prior to the use of histochemical and electron microscopic techniques such patients were usually considered to have a "benign muscular dystrophy." Familial occurrence has also been established in some types, so the clinical line of separation between this group of diseases and some of the more slowly progressive muscular dystrophies may in certain cases remain ambiguous. There is no specific treatment for any of the congenital myopathies.

The characteristic lesions in the congenital myopathies are revealed most clearly by the systematic application of histochemical stains to frozen sections of muscle biopsy tissue and by phase and electron microscopy. Some of the abnormalities are also disclosed by the conventional stains used in light microscopy, but as a group their identification has been the product of newer histologic techniques.

A word of caution is in order about the specificity of some of the morphologic changes and the classifications of the congenital myopathies based on these changes. It is inadvisable to assume that a change in a single organelle or a subtle change in the sarcoplasm of a muscle fiber can be relied on to characterize a pathologic process. Indeed, as more careful studies have been made of this class of disease, the specificity of some of the changes has come to be questioned. For example, central cores are sometimes found in the same muscle as nemaline bodies, and so on, and each of the denotative lesions has been reported in association with other systemic diseases and even as a result of certain medications. Nevertheless, the prominence of the morphologic change in any individual case, along with certain characteristic clinical features, permits an accurate diagnosis to be made.

Central Core Myopathy (*RYR1* Mutation)

In the original family described by Shy and Magee, five members (four males) in three successive generations were affected, suggesting an autosomal dominant pattern of inheritance. The youngest was 2 years old; the oldest, 65 years. In each there was weakness and hypotonia soon after birth (again, "floppy infant") and a general delay in motor development, particularly in walking, which was not achieved until the age of 4 to 5 years. These patients had difficulty in rising from a chair, climbing stairs, and running. The weakness was greater in proximal than in distal muscles, although the latter did not escape, and shoulder-girdle muscles were affected less than those of the pelvic girdle. Facial, bulbar, and ocular muscles were spared. The tendon reflexes were hypoactive and symmetrical. Muscle atrophy was not a prominent feature, although poor muscular development was present in one patient and has since been reported in others. There were no fasciculations, cramps, or myotonia, but cramps following exercise have been described in other families. The ECGs were normal.

Almost all cases studied in the modern era have been due to variants in the ryanodine receptor 1 (*RYR1*), which is also implicated in the causation of a small number of cases of malignant hyperthermia (see Chap. 41) and of the rare recessively inherited condition of *minicore disease* (multiple, or multi-minicore), a congenital myopathy that may include ophthalmoplegia. The disease, therefore, has remarkable attribute in that every patient is a potential candidate for the development of *malignant hyperthermia* and should wear a medical alert bracelet or be otherwise identified to indicate vulnerability to this anesthetic-induced complication.

The disease is rare, but as additional cases have been discovered, milder forms have come to be recognized, and in some of them the symptoms first appeared in adult life. Originally these patients were thought to have limb-girdle dystrophy because of the disproportionate involvement of proximal muscles. In other families, such as the one reported by Patterson and colleagues, the disease was first recognized in middle adult life with the rapid evolution of a proximal myopathy. Dislocation of the hips, pes cavus or pes planus, and kyphoscoliosis has been found in a few children, but arthrogryposis is rare. In the majority of cases, the progress of the disease is extremely slow, with slight worsening over many years. These represent the two extremes of the process.

The EMG reveals brief, small-amplitude motor unit potentials with a normal interference pattern. Serum concentration of CK is normal or only slightly elevated, as it is in all the congenital myopathies.

Pathologically, the majority of the muscle fibers appears normal in size or enlarged, and no focal destruction or loss of fibers can be found. The unique feature of the disease is the presence in the central portion of each muscle fiber of a dense, amorphous condensation of myofibrils or myofibrillar material. This altered zone characteristically lacks mitochondria and other organelles and gives a reduced positive PAS reaction and a dark blue coloration with the Gomori trichrome stain, contrasting with the normal blue-green color of the peripheral myofibrils.

Within the core, there is a lack of phosphorylase and oxidative enzymes. Most of the cores are in type 1 fibers, which predominate in muscle biopsies. These cores run the length of the muscle fiber, thus differing from the multiple cores or minicores that are seen in oculopharyngeal and multiminicore myopathy.

Nemaline (Rod-Body) Myopathy (Various Mutations)

This disorder also expresses itself by hypotonia and impaired motility in infancy and early childhood, but unlike the case in central core disease, the muscles of the trunk and limbs (proximal greater than distal), as well as the facial, lingual, and pharyngeal muscles, are strikingly thin and hypoplastic. Several forms have been observed. One is congenital, with generalized weakness in the neonatal period, making breathing and feeding difficult. The limbs are flaccid and flexic (again "floppy" infant). Pneumonia and death occur within weeks to months. In forms that permit longer survival, the weakness is less severe, involving mainly the proximal muscles. Tendon reflexes are diminished or absent. The young child with this disease usually suffers from inanition and frequent respiratory infections, which may shorten life. Strength slowly improves with growth, the latter process evidently counteracting the advance of the disease.

A slender appearance, narrow face, open mouth, narrow, arched palate, and kyphoscoliosis are regular but not invariable accompaniments of nemaline myopathy. These dysmorphic features are not typical of the other congenital polymyopathies. Pes cavus or clubfoot may be added. Some of the milder cases reach adulthood, at which time a cardiomyopathy may threaten life. A.G. Engel, as well as W.K. Engel and Reznick, observed individuals who first showed signs of the disease in middle age; the weakness was mainly in proximal muscles and the dysmorphic and skeletal abnormalities of the childhood form were lacking. The EMG is "myopathic," and serum enzymes are normal or only slightly elevated.

Cases of nemaline myopathy have come to attention during adulthood because of disproportionate involvement of the *respiratory muscles*, a feature shared with the adult appearance of acid maltase deficiency. Usually, these patients have had a history of poor physical performance throughout their earlier life.

An unexplained accompanying monoclonal gammopathy has appeared in case reports of late-onset nemaline myopathy and probably represents a separate process that is more than chance occurrence. In the series of late-onset cases described by Chahin and colleagues, 7 of 14 cases had an abnormal blood protein and these authors suggested that the prognosis may be less favorable than in those lacking the protein. The patients who have been shown with this combination of adult proximal weakness and monoclonal protein had no dysmorphic features, suggesting that these cases are different from the typical genetically determined nemaline myopathy described as follows.

Nemaline myopathy appears to be genetically heterogeneous but about 20 percent are due to mutations in *ACTA1*. The pattern of inheritance is most often autosomal dominant with variable penetrance. In some families there has been an autosomal recessive or an X-linked pattern of inheritance. Studies of the various gene defects have begun to clarify the uncertainties about inheritance and explain the relationships between the different forms of the disease. The genes implicated in nemaline myopathy include those for alpha-tropomyosin, beta-tropomyosin, alpha-actin, nebulin, troponin, coflin-1, and the ryanodine receptor (the last of these is more commonly implicated in central core disease, as mentioned above).

The disease is so named for the rods or coils of thread-like structures in pathology material. Frozen muscle tissue stained with Gomori trichrome discloses the characteristic lesion, which can be seen under the light microscope. Myriads of bacillus-like rods, singly and in small packets, are seen beneath the plasma membrane of the muscle fiber. They are composed of material that resembles that of Z bands under the electron microscope, and often actin filaments are attached, just as they are to Z bands. The type 1 fibers, which usually predominate, are smaller than normal, as in central core disease. The size of the motor neurons has been reported to be reduced. Weakness is probably related to smallness and reduction in the number of muscle fibers and possibly to focal interruption of their cross-striations, particularly of the Z bands.

Centronuclear (Myotubular) Myopathy

In this familial disease, hypotonia and weakness become manifest soon after birth or in infancy or early childhood. In the mildest form, the diagnosis does not become evident until adult years. All the striated skeletal muscles are involved to some degree, but distinctive features are ptosis and ocular palsies combined with weakness of facial, masticatory, lingual, pharyngeal, laryngeal, and cervical muscles in most of the infants with this disease, but not in adults. In the limbs, distal weakness keeps pace with proximal weakness. The limbs remain thin and are flexic throughout life. Motor development is secondarily slowed, though some improvement with maturation can occur. Later, however, motor functions that had been acquired may be lost as the disease slowly advances. Several patients have shown signs of cerebral abnormality with seizures and an abnormal electroencephalogram (EEG), but it is not clear whether this is truly part of the disease. Needle EMG examination shows the usual myopathic pattern as well as both positive sharp waves and fibrillation potentials in some cases. Abundant spontaneous activity should suggest the diagnosis of centronuclear myopathy (Griggs et al).

This disorder can be classified into three types, based on severity, mode of presentation, and genetic pattern: (1) a severe neonatal X-linked recessive type, now known to be associated mainly with mutations in myotubularin, MTM1; (2) a less severe early infantile, late-infantile, or childhood autosomal recessive type associated with BIN1, RYR1, or titin; and (3) a still milder late childhood–adult autosomal dominant type associated in some cases with mutations in DYN2 (dynamin) or MYF6, a helix-loop-helix protein that appears to function as a myogenic transcription factor (Heckmatt and colleagues).

The outstanding pathologic features of the disease are the smallness of muscles and their constituent fibers and central nucleation. In one group of centronuclear myopathies, there is hypotrophy of type 1 fibers (Bethlem et al; Karpati et al). Surrounding most of the centrally placed nuclei is a clear zone, in which there is a lack of organization of contractile elements. Because of central nucleation, the disease has incorrectly been referred to as *myotubular myopathy*, implying an arrest in development of muscle at the myotubular stage. Actually, the nature of the pathologic process is obscure. The small, centrally nucleated fibers do not really resemble typical myotubes. There is evidence from electron microscopic studies of changes in the central parts of the fibers (lack of enzymatic activity in the clear zones surrounding the nuclei), leading in all probability to fiber loss. Such changes argue against a purely developmental abnormality.

Myopathy With Tubular Aggregates

The accumulation of tubular aggregates in the subsarcolemmal or more interior regions of muscle fibers was first observed in patients with hypokalemic periodic paralysis and myotonia congenita, and later with a number of diverse conditions, such as chronic drug intoxication, hypoxia, and congenital myasthenic syndromes. However, tubular aggregates are also the defining feature of several rare and purely myopathic syndromes: (1) a slowly progressive muscular weakness, in a limb-girdle distribution, with onset in childhood or early adult life; inheritance is either autosomal dominant or recessive in type; (2) a childhood onset of proximal weakness, easy fatigability, and myasthenic features; heredity is autosomal recessive. This syndrome may respond to pyridostigmine; and (3) muscle pain, cramps, and stiffness induced by exercise; the cases to date have been sporadic.

The histologic changes are readily overlooked in paraffin sections. Frozen sections show masses of material that is basophilic with hematoxylin and eosin and bright red with Gomori trichrome and shows an intense reaction with reduced form of nicotinamide adenine dinucleotide (NADH) dehydrogenase. By electron microscopy, the bundles of tubular aggregates are sharply demarcated from myofibrils.

Other Congenital Myopathies

The foregoing congenital myopathies—central core, nemaline, centronuclear, and tubular aggregate types—are fairly well-defined clinicopathologic entities. Other less common types have been described, each named according to a distinctive morphologic alteration of organelles in muscle fibers in histochemical and electron microscopic preparations. In none of these additional types has the pattern of inheritance or the gene locus been identified. Some of these myopathies (*multicore* [*minicore*], *fingerprint body*, *sarcotubular*) have been reported in only a few cases, quite insufficient to allow their categorization as disease entities. Two other types, *congenital fiber type disproportion* and *congenital fiber type predominance*, originally designated as congenital myopathies, have proved to be nonspecific histochemical alterations observed in many infants and children with congenital developmental abnormalities, delays in motor development, and other conditions. Other putative congenital myopathies include so-called *reducing body*, *trilaminar*, and *cap disease; zebra body*; and *familial myopathy with lysis in type 1 fibers*, among others. They most likely also represent nonspecific reactions in muscle or fixation artifacts; as yet there is no evidence that any one of them represents a clinicopathologic entity.

Myofibrillar Myopathy

This entity, more a group of myopathies, was formerly included among the congenital myopathies but now clearly belongs in the category of dystrophies and is discussed in an earlier section on that class of diseases.

As stated in the introductory section, there is currently no treatment for any of the congenital myopathies.

THE SPINAL MUSCULAR ATROPHIES OF INFANCY AND CHILDHOOD (SEE CHAP. 38)

Obviously this important group of diseases, appearing as they do in the same periods of life as the congenital myopathies and of certain of the congenital muscular dystrophies, must figure in the differential diagnosis of early onset muscle weakness, hypotonia, and of arthrogryposis. Indeed, they represent the main problems faced by the clinician studying neuromuscular diseases of the infant. Their hereditary nature, their progression to fatal outcome or delayed motor attainments, and their tendency in certain instances to produce disabling contractures are shared with the primary muscle diseases. The proper application of current laboratory techniques sets them apart in most instances. In deference to their neuronal origin, we have placed them with the other degenerative diseases in Chap. 38.

DISORDERS OF MUSCLE CHARACTERIZED BY CRAMP, SPASM, PAIN, AND LOCALIZED MASSES (SEE ALSO CHAP. 46)

Quite apart from spasticity and rigidity, which are caused by a disinhibition of spinal motor mechanisms, there are forms of muscular stiffness and spasm that can be traced to abnormalities of the lower motor neuron and its spinal inhibitory mechanisms or to the sarcolemma of the muscle fiber. Muscles may go into spasm because of an unstable depolarization of motor axons, sending volleys of impulses across neuromuscular junctions—as occurs in myokymia, hypocalcemic tetany, and pseudohypoparathyroidism. In other states, the innervation of muscle is normal, but contraction persists despite attempts at relaxation (myotonia). Or, after one or a series of contractions, the muscle may be slow in decontracting, as occurs in paradoxical myotonia and hypothyroidism. In the contracture of McArdle phosphorylase deficiency

and phosphofructokinase deficiency, muscle, once contracted, lacks the energy to relax. In yet another type of muscle stiffness, the muscle may ripple or respond to percussion by mounding and rapidly contracting and relaxing. Cramping should also be differentiated from restless leg syndrome (see Chap. 18), which is primarily a nocturnal disorder but may carry over into the daytime hours.

Each of these conditions evokes the complaint of cramp or spasm, which is variably painful and interferes with free and effective voluntary activity. Each condition has its own identifying clinical and EMG characteristics and most of them respond favorably to therapy.

Muscle Cramp (See Also Chap. 46)

This subject was introduced at the beginning of this chapter, where it is pointed out that everyone at some time or other experiences muscle cramps. Cramps often occur during the night, after a day of unusually strenuous activity; less frequently they occur during the day, either during a period of relaxation or occasionally after a strong voluntary contraction or postural adjustment. A random restless or stretching movement may induce a hard contraction of a single muscle (most frequently of the foot or leg) that cannot be voluntarily relaxed. The muscle is visibly and palpably taut and painful, and the condition is readily distinguished from an illusory cramp, in which the sensation of cramp is experienced with little or no contraction of muscle. The latter phenomenon may occur in normal persons as well as in those with peripheral nerve diseases. Massage and vigorous stretch of the cramped muscle will cause the spasm to yield, although for a time the muscle remains excitable and subject to recurrent cramps. Visible fasciculations may precede and follow the cramp, indicating excessive excitability of the terminal branches of motor neurons supplying the muscle. Sometimes the cramp is so intense that the muscle is injured; it remains sore to touch and painful on use for a day or longer. Cramps of precordial chest muscles or diaphragm may arouse fear of heart or lung disease. In the EMG, the cramp is marked by bursts of high-frequency, high-voltage action potentials, and the precramp phase shows runs of activity in motor units. Why cramps should be painful is not known; probably the demands of the overactive muscle exceed metabolic supply, causing a relative ischemia and accumulation of metabolites. Overwork of muscle with or without impairment of circulation is also painful. Between cramps, the muscles are normal clinically and electromyographically.

Cramps are known to increase in frequency under certain conditions and with certain diseases. They are common during pregnancy for reasons not fully understood. Dehydration and excessive sweating predispose to cramping and are a constant threat to athletes. Exertional cramps are elicited more easily than usual in motor system disease, hypothyroidism, and in chronic polyneuropathies. Focal cramping occurs after partial nerve or root injury. For example, the calf muscle on one side is subject to severe recurrent cramps after decompression of the S1 root for lumbar disc disease; in extreme cases, the muscle hypertrophies after long periods of intermittent cramping. Patients undergoing hemodialysis are subject to cramps, which can be suppressed by intravenous hypertonic saline or hypertonic glucose.

The mechanism of muscle cramping is obscure. Several enzymes have been implicated, controversially but often included among these is myoadenylate. This enzyme, which is present in high concentration in muscle, is thought to function primarily during aerobic exercise and facilitate the regeneration of ATP from ADP through the action of adenylate kinase. However, low levels of this enzyme are not specific, occurring in such unrelated disorders as hypokalemic periodic paralysis and spinal muscular atrophy (see Layzer for details).

Quinine sulfate (300 mg at bedtime and repeated in 4 h if necessary, or 300 mg tid for idiopathic diurnal cramping) had been an effective medication but is no longer widely used because of a low risk of ventricular arrhythmia. Some patients, nonetheless, seek relief from the use of quinine water, some brands of which still contain the chemical. Diphenhydramine hydrochloride (Benadryl) 50 mg or procainamide 0.5 to 1.0 g are alternatives. Phenytoin, carbamazepine, and other antiepileptic drugs, and clonazepam may be useful in alleviating repeated daytime cramping.

Tetany, Pseudotetany, and Related Cramp Syndromes

As pointed out earlier, a reduction in ionizable calcium and magnesium is associated with involuntary cramp-like spasms; in their mildest form they appear as distal carpopedal spasms, but they may involve any of the muscles except the extraocular ones. Under these circumstances, stimulation of a muscle through its nerve at high frequencies (15 to 20 times per second) reproduces spasms, and hyperventilation and ischemia increase the tendency. Indeed, the Trousseau sign—carpal spasms with occlusion of the blood supply to the arm—takes advantage of the latter phenomenon. Hypocalcemic tetany is attributable to an unstable depolarization of the axonal membrane of the nerve fiber. This mechanism is affirmed by (1) the sensitivity of nerve to percussion (e.g., tapping over the facial nerve near its foramen of exit induces a facial twitch, or Chvostek sign), (2) fast-frequency doublets and triplets of motor unit potentials in the EMG indicating excessive neural excitability, (3) evocation of spasm by application of a tourniquet to proximal parts of a limb (causing ischemia of segments of nerve beneath the tourniquet), and (4) the associated tingling, prickling paresthesias from excitation of sensory nerve fibers. Hypocalcemia also causes a lesser change in the muscle fibers themselves; hence nerve block does not completely eradicate tetany. Of note, however, the Chvostek sign is found in some normal individuals, without obvious explanation.

The previously described idiopathic benign cramps resemble tetany but without measurable hypocalcemia (*pseudotetany*). Just as in tetany, in about half of cases of benign cramp, stimulation of nerve at 15 or more times per second produces repetitive discharges. Biopsies have disclosed no abnormalities of the muscle fibers except for a few ringbinden (circumferential bands of myofibrils encircling a normal core of longitudinally oriented myofibrils). Calcium and diazepam are of no therapeutic value, but

some patients respond to phenytoin, quinine (no longer widely used because of the risk of arrhythmia), procainamide, or chlorpromazine.

A familial (autosomal dominant) form of the benign cramp syndrome has been reported; the cramps affected the distal limb muscles, began in childhood and adolescence, and persisted throughout life. Another such family with cramps beginning somewhat later in life and affecting the anterior neck, arm, and abdominal muscles as well as those of the thigh and calf has been described. Also, a familial myalgic-cramp syndrome alluded to early in this chapter has been associated with deletion of part of the dystrophin gene (but with little or no dystrophic weakness). A tendency to cramp and pain has also been noted in a number of the congenital myopathies and in some families with Duchenne and Becker dystrophies.

Satoyoshi Syndrome

Satoyoshi described a group of patients who, in addition to widespread and severe cramping of muscle, developed universal alopecia, amenorrhea, intestinal malabsorption with frequent diarrhea, and some developed epiphyseal destruction and retarded growth. Most Japanese patients he described were younger than 20 years, but the two cases we have observed in whites were middle-aged. The serum calcium in these patients is normal, and the EMG shows only high-frequency discharges that are characteristic of cramps. A patient of ours with this condition had decades of chronic diarrhea, alopecia, and continuous, extremely painful calf cramps that had the gross appearance of fasciculations. This triad virtually identifies the disease. The cause of the disorder is obscure but is tentatively presumed to be autoimmune. Glucocorticoids, particularly in high doses over short periods, have been tried with some success; dantrolene has also been used and we had the impression that plasma exchange may have been helpful in one case.

Continuous Muscle Fiber Activity Due to Disorders of Nerve and Distal Axons (See Chap. 46)

While the main manifestations of this group of disorders, muscular cramps, would seem to belong in this chapter on muscle diseases, they are, in fact, related to disorders of motor nerves, axons, and their terminal arborizations. For this reason, they appear in Chap. 46 on channelopathies and in Chap. 43, with disorders of the peripheral nerves.

MYALGIC STATES

Many of the muscle diseases described previously are associated with aching and discomfort. These are particularly prominent in conditions that are accompanied by cramp and biochemical contracture (phosphorylase and phosphofructokinase deficiency). Ischemia of muscle—that is, intermittent claudication—is also painful, as is dystonia in some cases. Muscle weakness that imposes persistent abnormal postures on the limbs may cause stretch injury to muscles and tendons. This is observed in a number of the congenital myopathies and dystrophies. In all these conditions, clinical study will usually disclose the source or sources of the pain.

Diffuse muscle pain, which merges with malaise, is a frequent expression of a large variety of systemic infections—for example, influenza, brucellosis, dengue, Colorado tick fever, measles, malaria, relapsing fever, rheumatic fever (in which it was called "growing pains"), salmonellosis, toxoplasmosis, trichinosis, tularemia, and Weil disease. When the pain is intense, especially if it is localized to one side of the lower chest and abdomen, the most likely diagnostic possibility is epidemic myalgia (also designated as *pleurodynia*, "devil's grip," and *Bornholm disease* caused by Coxsackievirus infection). Poliomyelitis may be accompanied by intense pain at the onset of neurologic involvement, and later the paralyzed muscles may ache. This is true also of the Guillain-Barré syndrome, in which the pain may precede weakness by several days. Little is known about the pathologic basis of the muscular pain in these diseases; it is not a result of muscle inflammation and is probably produced by circulating cytokines that are common to most systemic infections. Mild muscle pain is a frequent but not a necessary accompaniment of polymyositis and dermatomyositis.

Polymyalgia Rheumatica (See Chap. 10)

The major consideration in elderly and middle-aged patients with pain in proximal muscles of the limbs is polymyalgia rheumatica. This subject is mentioned briefly in other sections of this book in relation to back and extremity pain (see Chap. 10) and to temporal arteritis, to which it is closely connected (see Chap. 9). The muscular soreness may be diffuse or asymmetrical, particularly in the proximal arms and shoulders. Every movement is reported as stiff and painful. The periarticular tissues and their muscular attachments are affected primarily and may be tender, but this is difficult to interpret, because tenderness in these regions may be found in healthy individuals. The sedimentation rate is elevated in the majority of patients, and a 48-h trial of prednisone, by completely alleviating muscle pain, confirms the diagnosis. In the context of muscle pain, systemic symptoms such as weight loss, headache, and fatigue, as well as mild anemia, are particularly suggestive of polymyalgia rheumatica.

Fibromyalgia

This would appear, by definition, to represent an inflammation or other affection of the fibrous tissues of the muscles, fascia, and aponeuroses. Unfortunately, the pathologic basis of this state remains obscure. Only some clinical facts can be stated. During the first movements after a period of inactivity, a muscle or group of muscles may become painful and tender, particularly after exposure to cold, dampness, or minor trauma, but often for no reason that can be discerned. One looks in vain for signs of tendinous, muscular, or arthritic disease. The neck and shoulders are the most common sites. Tender areas, up to several centimeters in diameter, can be palpated within the muscles ("fibrositic nodules" by experts), and active

contraction or passive stretching of the involved muscles increases the pain—points said to be of diagnostic value, but disputed. Often, symptoms such as mental and physical fatigue, insomnia, and headache are associated and raise the suspicion of an anxiety state or depression. In a few instances the condition clears up in a few weeks; local heat and massage and local injections of anesthetics or steroids are found to give comfort while symptoms are present, but most often it becomes a chronic condition.

The chronic form of fibromyalgia presents far greater problems, usually disabling the patient and causing a change in accustomed habits and employment as discussed in Chap. 10. It has become one of the prime diagnoses made by rheumatologists and physiatrists, but the patient may first come to the attention of a neurologist. Most definitions of the syndrome have been circular or somewhat arbitrary. Those now in general use are similar to the one proposed by a committee of the American College of Rheumatology. The basis for diagnosis is the presence of widespread pain, including focal areas of pain (trigger points) that can be produced by 4 kg of digital pressure in 11 of 18 typical locations over muscles, tendons, or bone—these are concentrated around the shoulders and paraspinal regions—and there is no requirement for the presence of the several common systemic complaints that accompany the illness in most patients (fatigue, difficulty concentrating, sleeping difficulty, or anxiety). In the past, similar pains were associated with cases of irritable bowel or irritable bladder syndromes, dysmenorrhea, chronic headache, and cold intolerance. Depending on how broad a definition one allows for the widespread pain and painful trigger points, most or all patients in our experience manifest many of the same complaints as those with the chronic fatigue syndrome, which is discussed in Chap. 24. Writers on the subject, however, have pointed out that in the majority of patients, formal assessment by modern criteria fails to confirm the presence of depression, and that when depression coexists with the muscular complaints, the two are discordant temporally and in severity. While we acknowledge that antidepressants often give disappointing results and that in our practice there have been a number of patients with fibromyalgia who do not have any other manifestations of depression, they have been the exceptions. The literature eschews the use of corticosteroids for treatment of the pain, but we have had occasion to see patients whose symptoms were relieved when these medications were used for other purposes.

Fibromyalgia remains a problematic illness, defined largely by a pattern of pain that justifies its name. Despite attempts to objectify the physical symptoms, psychiatric factors should not be overlooked. This condition is a favorite illness with physiotherapists, who claim that their physical measures are helpful, as they may well be. Rarely, a similar syndrome is the forerunner of what proves, after some days, with the onset of neurologic signs, to be a radiculitis, brachial neuritis, or outbreak of herpes zoster.

Other Myalgic States

An impressive polymyalgia follows excessive exercise. Often, the patient observes that aching pain occurs not at the time of activity but some hours or even a day or two later, resembling the discomfort following the excessive use of unconditioned muscles. The muscles are sore and there is an intolerance of exercise and physical exertion. The serum CK concentration is mildly to moderately elevated. This is a natural phenomenon and is self-limiting. When such a state persists indefinitely and a program of conditioning exercises does not alleviate the pain, it represents a special category of disease. In a few instances an increased sedimentation rate or other laboratory aids may clarify the diagnosis, and muscle biopsy may reveal a nonspecific interstitial nodular myositis or the giant cell arteritis associated with polymyalgia rheumatica. Whether or not patients on lipid-lowering statin medications are particularly susceptible to this problem is not clear. A few individuals go on to have the features of the previously described fibromyalgic syndrome. However, this cluster of symptoms most often occurs without explanation, and one can only suspect an obscure infection or a subtle aberration of muscle metabolism, presently impossible to demonstrate. Reference has been made in the literature to the controversial finding of a *myoadenylate deaminase deficiency* in some of these cases. There is also a group of patients who have idiopathic leg pain during rest after activity. Some families afflicted in this way are forced to live a sedentary existence. The condition does not respond to analgesics. In 2 cases, a deficiency of calcium ATPase was found and reportedly alleviated by a calcium channel blocker such as verapamil, 120 mg (Walton). It must be distinguished from the syndromes of painful legs and moving toes, and from the restless leg syndrome discussed in Chap. 18.

Before dismissing vague muscle aches as an excessive somatic concern, hypothyroidism, hyperparathyroidism, and renal tubular acidosis, hypophosphatemia, hypoglycemia, and the intrinsic phosphorylase or phosphofructokinase defects should be considered. Patients with these latter diseases often complain of soreness, stiffness, and lameness after strenuous muscular effort. The most valuable screening tests are the sedimentation rate and serum CK concentration. Some patients probably have an obscure metabolic myopathy, presently undiagnosable. In every reported series, such as that of Serratrice and coworkers, half of the cases with diffuse myalgia are of this uncertain type. This coincides with, or is more optimistic than, our own experience.

LOCALIZED MUSCLE MASSES

Masses may be found in one or many muscles in a variety of clinical settings, and the clinical findings in each one have a different significance.

Muscle or tendinous rupture is usually caused by a violent strain attended by an audible snap and then a bulge, which appears when the muscle contracts. A very focal weakening in contractile power and mild discomfort are usually noted by the patient. The biceps brachii and soleus muscles are most often affected. Treatment is by surgical repair; if that is delayed, little can be done for the condition.

Hemorrhage into muscle may occur as a consequence of trauma, as a complication of the use of anticoagulants, in hematologic diseases, in severe myotonia, or after a minor trauma to a patient with Zenker degeneration of muscle who is convalescing from typhoid fever or some other infection. Runners may acquire painful localized hematomas in leg muscles.

Tumors of muscle include *desmoid tumor* (a benign massive growth of fibrous tissue observed most often in parturient women and after surgery), *rhabdomyosarcoma* (a highly malignant tumor with strong liability to local recurrence and metastasis), *liposarcoma*, and *angioma*. Large neurofibromas or neurofibrosarcomas beneath large muscles such as the hamstring may be difficult to differentiate by physical examination or MRI from masses within the muscle. *Pseudotumorous* growths, sometimes massive, may follow injury to a muscle. Interlacing regenerating muscle fibers and fibroblasts compose the mass. Excision of the entire muscle had been undertaken in several cases in the belief that the growth was a rhabdomyosarcoma, whereas it is actually a benign reaction to trauma (Kakulas and Adams). Metastasis to muscle occurs, most often lymphomatous in our experience.

Thrombosis of arteries or, more often, of veins causes congestion and infarction of muscle. A special type of muscle infarction occurs in patients with complicated and poorly controlled diabetes mellitus (Banker and Chester). Usually it involves the anterior thigh, and occasionally other muscles of the lower limb. The symptoms are the sudden onset of pain and swelling of the thigh, with or without the formation of a tender, palpable mass. Recurrent infarction of the same or opposite thigh is characteristic. The stereotypical clinical picture and the striking MRI appearance obviate the need for diagnostic muscle biopsy. Extensive infarction of muscle is due to the occlusion of many medium-sized muscular arteries and arterioles, most likely the result of embolization of atheromatous material from eroded plaques in the aorta or iliac arteries. Recognition of this complication and immobilization of the limb are of prime practical importance, as muscle biopsy and early ambulation may cause serious hemorrhage into the infarcted tissue.

The *pretibial*, or *compartment syndrome*, also well recognized, follows direct trauma or excessive activity (marching, exercising of unconditioned muscles) or ischemic infarction due to arterial occlusion. There is swelling of the extensor hallucis longus, extensor digitorum longus, and anterior tibial muscles. Being tightly enclosed by the bones and pretibial fascia, the swelling leads to ischemic necrosis and myoglobinuria. Permanent weakness of this group of muscles can be prevented by incising the pretibial fascia and thereby decompressing the affected muscles. A similar compartment syndrome can occur in the forearm.

Myositis Ossificans

This condition involves the deposition of bone within the substance of a muscle. Two types are recognized. One is a localized form that appears in a single muscle or group of muscles after trauma, and the other is a progressive, widespread ossifying process, entirely unrelated to trauma, in many muscles of the body.

Localized (traumatic) myositis ossificans After a muscle tear, a single blow to the muscle, or repeated minor trauma, a painful area develops in the muscle. It is gradually replaced by a mass of cartilaginous consistency, and within 4 to 7 weeks a solid mass of bone can be felt and seen in CT or radiographs. This most frequently happens in vigorous adult men. The inner thigh muscles (in those who ride horses) and to a lesser extent the pectoralis major and biceps brachii are the most frequent locations. The mass tends to subside after several months if the patient desists from the activity that produced the trauma.

Generalized myositis ossificans This disease, first described by Munchmeyer in 1869, has since been referred to by his name or as *myositis ossificans progressiva*. It is rare, although Lutwak, in 1964, was able to collect 264 cases from the literature. The cause is unknown, but the disease is probably inherited as an autosomal dominant trait. It consists of widespread bone formation along the fascial planes of muscles and has its onset in infancy and childhood in 90 percent of cases. Biopsies of indurated swellings have revealed extensive proliferation of interstitial connective tissue in which little inflammatory cell reaction is found. Within a few weeks, the connective tissue becomes less cellular and retracts, compressing the adjacent muscle fibers. Osteoid and cartilage formation occur at a later stage, developing in the connective tissue and enclosing relatively intact muscle fibers.

Nearly 75 percent of all reported cases have been associated with congenital anomalies, the most frequent of which is a failure of development of the great toes or thumbs and less often, other digits. Less frequently, there is hypogenitalism, deafness, and an absence of upper incisors. The first symptom is often a firm swelling and tenderness in a paravertebral or cervical muscle. There is, in addition, a mild discomfort during muscle contraction, and the overlying skin may be reddened and slightly swollen. Trauma may be recalled as the initiating factor, but as the months pass, other muscles not injured in any recognizable way become similarly involved. At first, radiographs reveal no important changes, but within 6 to 12 months, calcium deposits are observed, and one can feel stony-hard masses within the muscles. As the disease advances, limitation of movement and deformities become increasingly evident. Calcified bridges between adjacent muscles and across joints lead to rigidity of the spine, jaw, and limbs; scoliosis; and limited expansion of the thorax. Ultimately, the patient is virtually "changed to stone." A genetic basis for one type, fibrodysplasia ossificans progressiva, has been determined.

The principal problem in diagnosis is to differentiate generalized myositis ossificans from *calcinosis universalis*. The latter usually occurs in relation to scleroderma or polymyositis and is characterized by calcium deposits in the skin, subcutaneous tissues, and connective tissue sheaths around the muscles; in myositis ossificans, there is actual bone formation within the muscles. The pathologic data are often too meager to justify this sharp distinction.

The prolonged ingestion of large doses of vitamin D may also result in the deposition of masses of calcium salts around muscles, joints, and subcutaneous tissue.

Calcific deposits, perhaps true ossification, may occur in the soft tissues around the hips and knees of paraplegics and rarely following a hemiplegia ("paralytic myositis ossificans") or other causes of prolonged immobilization such as casting.

Myositis ossificans may undergo spontaneous remissions and may stabilize for many years, during which the patient is capable of adequate function. In other cases, progression leads to marked debilitation and respiratory embarrassment, the final illness often being a terminal pneumonia or other infection.

The molecular basis for myositis ossificans is unknown, but it has been suggested that one causative defect is the overexpression of bone morphogenic protein. In mice, the forced expression of this protein induces heterotopic bone formation. It is likely that the primary problem arises either because of inappropriate expression of one element of the protein or of excessive binding between signaling proteins and their receptors.

Treatment

The administration of a diphosphonate (ethane-1-hydroxy-1,1-diphosphate [EHDP], 10 to 20 mg/kg orally), a compound that inhibits the deposition of calcium phosphate, has been said to cause regression of new swellings and to prevent calcification. Some of the calcium deposits in calcinosis universalis have receded in response to prednisone, and because of the unclear relationship of this disease to generalized myositis ossificans, it is probably advisable to try this form of therapy as well. Excision of bony deposits may be undertaken if it is certain that they are the cause of particular disabilities.

Disorders of the Neuromuscular Junction, Myotonias, and Disorders of Persistent Muscle Fiber Activity

Disorders of the neuromuscular junction, myotonias, and other disorders of persistent muscle fiber activity are discussed together because they can all cause weakness or changes in salience of the musculature but are not strictly speaking disease of muscle, instead having their origins in problems with the terminal motor axons or neuromuscular junction. Their pathophysiology and clinical features sometimes overlap with immune mechanisms that underlie a number of them.

DISORDERS OF THE NEUROMUSCULAR JUNCTION

Several disorders of the neuromuscular junction exist the most common of which is myasthenia gravis. Most of these disorders exhibit the characteristic and striking features of fluctuating weakness and fatigability of muscle. Some degree of weakness is usually present at all times, but it is made worse by activity. The weakness and fatigability reflect physiologic abnormalities of the neuromuscular junction that are demonstrated by clinical signs and by special electrophysiologic testing. As an aid to understanding the diseases discussed in this chapter, the reader should consult the discussion of the structure and function of the neuromuscular synapse given in Chap. 2.

Myasthenia Gravis

The cardinal feature of myasthenia gravis, usually referred to simply as myasthenia, is fluctuating weakness of voluntary (skeletal) muscles, particularly those innervated by motor nuclei of the brainstem, that is, ocular, masticatory, facial, deglutitional, and lingual. Manifest weakening during continued activity, quick restoration of power with rest, and dramatic improvement in strength following the administration of anticholinesterase drugs such as neostigmine are the other notable characteristics. Myasthenia is an immune disease in which circulating antibodies against components of the motor postsynaptic membrane and subsequent structural changes in that membrane explain virtually all the features of the disease.

Historical note Several students of medical history affirm that Willis, in 1672, gave an account of a disease that could be none other than myasthenia gravis. Others give credit to Wilks (1877) for the first description and for having noted that the medulla was free of disease, in distinction to other types of bulbar paralyses. The first reasonably complete accounts were those of Erb (1878), who characterized the disease as a bulbar palsy without an anatomic lesion, and of Goldflam (1893); for many years thereafter, the disorder was referred to as the *Erb-Goldflam syndrome.* Jolly (1895) was the first to use the name *myasthenia gravis*, to which he added the term *pseudoparalytica* to indicate the lack of structural changes at autopsy. Also, it was Jolly who demonstrated that myasthenic weakness could be reproduced in affected patients by repeated faradic stimulation of the motor nerve and that the "fatigued" muscle would still respond to direct galvanic stimulation of its membrane. Interestingly, he suggested the use of physostigmine as a form of treatment, but there the matter rested until Reman, in 1932, and Walker, in 1934, demonstrated the therapeutic value of the drug. The relationship between myasthenia gravis and tumors of the thymus gland was first noted by Laquer and Weigert in 1901, and in 1949, Castleman and Norris gave the first detailed account of the pathologic changes in the gland.

In 1905, Buzzard published a careful clinicopathologic analysis of the disease, commenting on both the thymic abnormalities and the infiltrations of lymphocytes (called *lymphorrhages*) in muscle. In 1973 and subsequently, the autoimmune nature of myasthenia gravis was established through a series of investigations by Patrick and Lindstrom, Fambrough, Lennon, and A.G. Engel (1977) and their colleagues (see in the following text).

The clear demonstration of an *immunologic mechanism* operative at the neuromuscular junction was the most significant development in our understanding of myasthenia gravis. Patrick and Lindstrom discovered that repeated immunization of rabbits with AChR protein obtained from the electric eel caused muscular weakness (contrary to what is stated in some books, their discovery was not accidental). Lennon and colleagues recognized this model as being similar to that of myasthenia gravis. Soon thereafter, Fambrough and coworkers demonstrated that the basic defect in myasthenia gravis was a marked reduction in the number of ACh receptors on the postsynaptic membrane of the neuromuscular junction. These

observations were followed by the creation of an experimental model of the disease and the demonstration that experimentally induced myasthenia had clinical, pharmacologic, and electrophysiologic properties identical with those of human myasthenia gravis (Engel et al, 1976a). It was also shown that humoral antibodies directed against protein components of AChR could transfer the myasthenic weakness to normal animals and that the weakness, as well as the physiologic abnormalities, could be reversed by the administration of anticholinesterase drugs. Thus, the accumulated evidence satisfied the criteria for the diagnosis of an autoantibody-mediated disorder (Drachman, 1990).

Epidemiology Certain *epidemiologic features* of the disease are of clinical interest. Its prevalence is variously estimated to be from 43 to 84 per million persons and the annual incidence rate is approximately 1 per 300,000. The disease may begin at any age, but onset in the first decade is relatively rare (only 10 percent of cases begin in children younger than 10 years of age). The peak age of first symptoms is between 20 and 30 years in women and between 50 and 60 years in men. Under the age of 40, females are affected two to three times as often as males, whereas in later life, the incidence in males is higher (3:2). Of patients with thymomas, the majority is older (50 to 60 years) and males predominate.

Familial occurrence of myasthenia is known, but it is rare. Many such cases prove to have one of the genetically determined myasthenic syndromes and not the acquired autoimmune form of disease (see further on). More common is a family history of one of the autoimmune diseases enumerated earlier. For example, in one series, 30 percent had a maternal relative with a connective tissue disease, suggesting that myasthenia gravis patients inherit a susceptibility to autoimmune disease (Kerzin-Storrar and associates). There have also been reports of the concurrence of myasthenia and multiple sclerosis, but this association is less certain. There is an increased representation of HLA-B8 and -DR3 haplotypes, as occurs in other autoimmune diseases, which are discussed further on.

Clinical Manifestations

Myasthenia gravis, as the name implies, formerly had a grave prognosis, perhaps less so today but still associated with considerable morbidity. As mentioned, repeated or persistent activity of a muscle group exhausts contractile power, leading to a progressive paresis, and rest restores strength, at least partially. These features, concentrated in the palpebral, ocular, and the oro-facial-lingual muscles, are the identifying attributes of the disease and their demonstration is usually enough to establish the diagnosis on clinical grounds.

The special vulnerability of the neuromuscular junctions in certain muscles gives myasthenia its highly characteristic clinical appearance. Usually, the eyelids and the muscles of eye movement, and somewhat less often, of the face, jaws, throat, and neck, are the first to be affected. Infrequently, the initial complaint is referable to the limbs or to breathing. Specifically, weakness of the levator palpebrae or extraocular muscles is the initial manifestation of the disease in about half the cases, and these muscles are involved eventually in more than 90 percent. Ocular palsies and ptosis are usually accompanied by weakness of eye closure, a combination that is virtually always indicative of the disease, although it may be observed in certain muscular dystrophies. Diplopia is quite common in myasthenia, but it does not correspond to the innervatory pattern of a nerve; instead, it is the result of asymmetrical weakness of several muscles in both eyes. As the disease advances, it spreads insidiously from the cranial to the limb and axial muscles, but there are instances of fairly rapid development, sometimes initiated by an infection, usually respiratory. In rare cases, the distal extremity muscles may be involved, such as the "myasthenic hand" described by Janssen and colleagues. Symptoms may first appear during pregnancy or, more commonly, during puerperium or in response to paralytic drugs used during general anesthesia.

Particular ocular signs are highly characteristic of myasthenia. For example, sustained upgaze (for 30 or more seconds) will usually induce or exaggerate ptosis and may uncover myasthenic ocular motor weakness, thereby marking it as "fatigable." Another characteristic sign, not as frequently elicitable as fatigable ptosis, was described by Cogan and is a twitching of the upper eyelid that appears a moment after the patient moves the eyes from a downward to the primary position ("lid-twitch" sign). Or, after sustained upward gaze, one or more twitches may be observed upon closure of the eyelids or during horizontal movements of the eyes. Repeated ocular versions when tracking a target or by an optokinetic stimulus may disclose progressive paresis of the muscles that carry out these movements. Unilateral painless ptosis without either ophthalmoplegia or pupillary abnormality in an adult will most often prove to be due to myasthenia. Usually, there is subtle ptosis of the other eye that can be revealed by manually elevating the more affected eyelid. Attempts by the patient to overcome ptosis may impart a staring expression of the opposite eye. Bright sunlight is said to aggravate the ocular signs and cold to improve them. The application of an ice pack over the eye often relieves the ptosis for a brief period.

Muscles of facial expression, mastication, swallowing, and speech are affected in 80 percent of patients at some time in the illness, and in 5 to 10 percent, these are the first or only muscles to be involved. Less frequent is early involvement of the flexors and extensors of the neck, muscles of the shoulder girdle, and flexors of the hips. (This pattern may be associated with a special autoantibody, as will be discussed later.) Of the trunk muscles, the erector spinae are the most frequently affected. In the most advanced cases, all muscles are weakened, including the diaphragmatic, abdominal, and intercostal, and even the external (skeletal muscle) sphincters of the bladder and bowel. As the disease progresses, the involvement of any group of muscles closely parallels their degree of weakness early in the disease. The clinical rule also holds that the proximal muscles are far more vulnerable than distal ones, as they are in most other forms of myopathy.

Another characteristic and understandable feature of myasthenic weakness is its tendency to increase as the day

wears on or with repeated use of an affected muscle group but curiously, patients seldom volunteer this information. A few patients report paradoxical worsening on awakening, especially if they have not taken medication during the night, but a larger proportion of patients are close to asymptomatic after a night's rest. In general terms, therefore, myasthenia gravis may be conceived as a fluctuating and fatigable oculofaciobulbar palsy.

Other features result from the topography and fatigability of the disease. The natural smile becomes transformed into a snarl; the jaw may sag so that it must be propped up by the patient's hand; chewing tough food may be difficult and the patient may have to terminate a meal because of the inability to masticate and swallow. It may be more difficult to eat after talking, and the voice fades and becomes nasal after sustained conversation. Women may complain of inability to fix their hair or makeup because of fatigue of the shoulders or of difficulty in applying lipstick because they are unable to purse and roll their lips. Weakness of the neck muscles causes fatigue in holding up the head. In cases with generalized weakness, there is difficulty in retaining flatus because of the weakness of the external rectal sphincter.

A peculiarity of myasthenic muscle contraction that may be observed occasionally is a sudden lapse of sustained posture or interruption of movement resulting in a kind of irregular tremor similar to that of normal muscle nearing the point of exhaustion. A dynamometer demonstrates the rapidly waning power of contraction of a series of hand grips and repetitive stimulation of a motor nerve at slow rates while recording muscle action potentials shows the same decremental strength in a quantitative fashion (see Fig. 2-15*A* and in the following text).

Weakened muscles in myasthenia gravis undergo atrophy to only a minimal degree or not at all. Tendon reflexes are seldom altered. Even repeated tapping of a tendon does not usually tax muscles to the point where contraction fails. Smooth and cardiac muscles are not involved and other neural functions are preserved. Weakened muscles, especially those of the eyes and back of the neck, may ache, but the pain is seldom an important complaint. Paresthesias of the face, hands, and thighs are reported infrequently but are not accompanied by demonstrable sensory loss. The tongue may display one central and two lateral longitudinal furrows (trident tongue), as pointed out originally by Buzzard; the tongue may be atrophic in the MuSK (muscle-specific tyrosine kinase) form of disease.

Patients with MuSK antibody, mostly women, have a special clinical syndrome of prominent oculobulbar weakness (Scuderi et al), or severe disease characterized by respiratory crises (see also Evoli et al). Others have reported a different pattern of mainly neck and proximal weakness that simulates a myopathy. Many of these patients are inadequately responsive to anticholinesterase treatment.

Clinical grading To facilitate the clinical staging of therapy and prognosis, the classification introduced by Osserman remains useful; it can be found in his monograph cited in the references and in previous editions of this book. This system has been replaced by a scheme suggested by a task force of the Myasthenia Gravis foundation, as reproduced here (Jaretzki et al).

Class I	Any ocular muscle weakness May have weakness of eye closure All other muscle strength is normal
Class II	Mild weakness affecting other than ocular muscles May also have ocular muscle weakness of any severity
IIa	Predominantly affecting limb, axial muscles, or both May also have lesser involvement of oropharyngeal muscles
IIb	Predominantly affecting oropharyngeal muscles, respiratory muscles, or both May also have lesser or equal involvement of limb, axial muscles, or both
Class III	Moderate weakness affecting other than ocular muscles May also have ocular muscle weakness of any severity
IIIa	Predominantly affecting limb, axial muscles, or bothMay also have lesser involvement of oropharyngeal muscles
IIIb	Predominantly affecting oropharyngeal muscles, respiratory muscles, or both May also have lesser or equal involvement of limb, axial muscles, or both
Class IV	Severe weakness affecting other than ocular muscles May also have ocular muscle weakness of any severity
IVa	Predominantly affecting limb and/or axial muscles May also have lesser involvement of oropharyngeal muscles
IVb	Predominantly affecting oropharyngeal muscles, respiratory muscles, or both May also have lesser or equal involvement of limb, axial muscles, or both
Class V	Intubation, with or without mechanical ventilation, except when employed during routine postoperative management. The use of a feeding tube without intubation places the patient in class IVb.

Others have proposed a classification based on a constellation of the age of onset, presence or absence of thymoma, antibody level against acetylcholine receptor (AChR), and association with human leukocyte antigen (HLA) haplotypes (Compston and colleagues). This system is as follows: (1) myasthenia gravis with thymoma—no sex or HLA association, high AChR antibody titer; (2) onset before age 40, no thymoma—female preponderance and an increased association with HLA A1, B8, and DRW3 antigens; (3) onset after age 40, no thymoma—male preponderance, increased association with HLA A3, B7, and DRW2 antigens, low AChR antibody titer. The last group includes a proportion of older men with purely ocular symptoms (formerly Osserman type I). Classifications such

as these are meant to capture certain types and contexts of myasthenia more than to convey the severity of illness.

Course and Prognosis

The course of the illness is extremely variable. Rapid spread from one muscle group to another occurs in some, but in others, the disease remains unchanged for years before progressing or there is no progression. Remissions may take place without explanation, usually in the first years of illness, but these happen in less than half the cases and seldom last longer than a month or two. If the disease remits for a year or longer and then recurs, it then tends to be steadily progressive. Relapse may also be occasioned by the same events that, in some cases, preceded the onset of the illness, especially infections.

The risk of severe respiratory compromise or death from generalized myasthenia gravis is greatest in the first year after the onset of the disease (Simpson). The second period of danger in progressive cases is from 4 to 7 years after onset. After this time, the disease tends to stabilize and the risk of severe relapse diminishes. Fatalities relate mainly to the respiratory complications of pneumonia and aspiration. The mortality rate in the first years of illness, formerly in excess of 30 percent, is now less than 5 percent, and with appropriate therapy, virtually all patients lead normal lives.

An aspect of interest is the timing and frequency of conversion from ocular and restricted oropharyngeal patterns of weakness to more widespread involvement including the diaphragm. An increasing duration of purely ocular myasthenia is associated with a decreasing risk of late generalization of weakness (Bever and coworkers). In a retrospective study of 108 patients, it was found that only 15 percent of the observed instances of generalization occurred more than 2 years after isolated ocular manifestations.

Later age at onset was also associated with a higher incidence of fatal respiratory crises. In general, patients whose disease begins at a younger age run a more benign course. Analysis of the course of an astonishing 1,036 patients for a mean duration of 12 years showed that the clinical manifestations remained confined to the extraocular muscles and orbicularis oculi in 16 percent (Grob and colleagues). Their data further indicated that localized ocular myasthenia present for only a month was associated with a 60 percent likelihood that the disease would generalize, but in those cases that remained restricted for more than a year, only 16 percent became generalized. Also informative in this series was that in 67 percent the disease attained its maximum severity within a year of onset, and in 83 percent, within 3 years. In contrast, in another study of 37 consecutive cases with only ocular signs, 17 had more widespread weakness within a period of 6 years (Weinberg et al). It has been stated that the progression of symptoms is more rapid in male than in female patients.

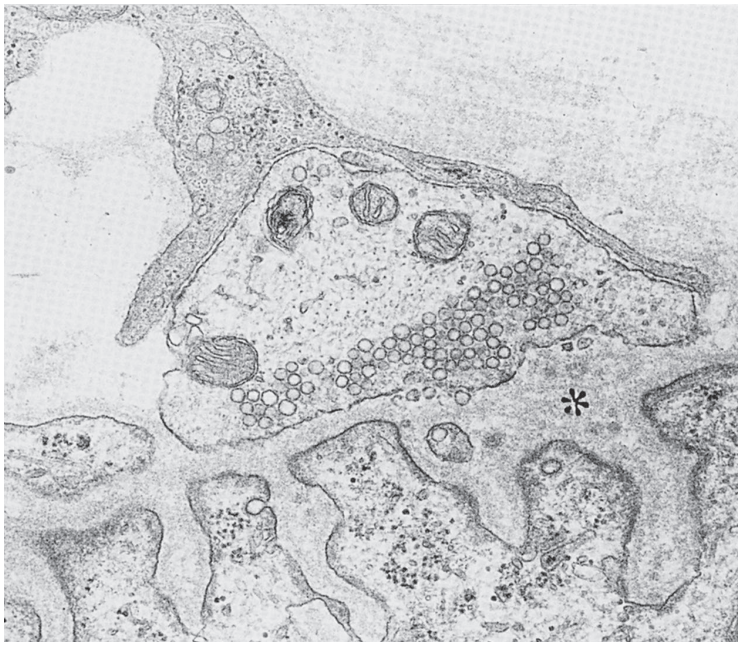
Occasionally, isolated muscle groups may occasionally remain permanently weak even when the ocular and generalized weakness has resolved. The muscles most often affected in this way are the anterior tibialis, triceps, and portions of the face.

The long-term outlook for children with myasthenia is better than it is for adults, and their life expectancy is only slightly reduced. Among a group of 149 children for an average of 17 years; 85 of them had thymectomies, one of the main treatments for myasthenia as discussed further on (Rodriguez and colleagues). Approximately 30 percent of the nonthymectomized and 40 percent of the thymectomized patients underwent remission and were free of symptoms, usually in the first 3 years of illness. Those children with bulbar symptoms and no ocular or generalized weakness had the most favorable outcome.

Thymic and Systemic Disorders Associated With Myasthenia

A nonneoplastic lymphofollicular hyperplasia of the thymic medulla occurs in 65 percent or more of cases of myasthenia and *thymic tumors* occur in 10 to 15 percent. Thymomas with malignant characteristics may spread locally in the mediastinum and to regional lymph nodes, but they rarely metastasize beyond these structures; when they do, the lungs and liver are usually affected. It should be emphasized that thymic enlargement and tumors may be missed in plain films of the chest and should be sought by CT with contrast.

A striking degree of hyperplasia of the medulla of the thymus characterized by lymphoid follicles with active germinal centers is found in the majority of cases. Hyperplasia is even more frequent in younger patients in the third and fourth decades. The cells in the centers of the follicles are histiocytes surrounded by helper T lymphocytes, B lymphocytes, and plasma cells; immunoglobulin G (IgG) is elaborated in the germinal follicles. These resemble the cellular reaction observed in the thyroid tissue of Hashimoto thyroiditis. Because the latter disease has been reproduced in animals by injecting extracts of thyroid with Freund adjuvants, it had long ago been suggested that the so-called thymitis of myasthenia gravis is the result of a similar autoimmune sensitization, but the inciting events for this process are entirely unknown. Immunosuppression with steroids causes the involution of the thymus.



With regard to thymic tumors, two forms have been described: one composed of histiocytic cells like the reticulum cells in the center of the follicles, and the other predominantly lymphocytic and considered to be lymphosarcomatous. Some of the tumors have a high proportion of spindle-shaped cells. Overlapping types have been common. Thymic tumors may be unattended by myasthenia, though myasthenia has eventually developed in all of the cases under our observation, sometimes 15 to 20 years after the tumor was removed surgically. The severity of myasthenic symptoms is said to be no different in patients with thymoma than it is from that in patients without a tumor (Bril and colleagues), but our impression has been that patients with tumors, particularly children, often have a peculiar clinical course. For example, we have observed unexpected sudden remissions and severe relapses, as well as resistance to medications.

Many contemporary studies, including more than 40 autopsies at our hospitals, have confirmed Erb's original contention that myasthenia gravis is a disease without a central nervous system lesion. The brain and spinal cord are normal unless damaged by hypoxia and hypotension from cardiorespiratory failure. Furthermore, the muscle

fibers are generally intact, although in fatal cases with extensive paralysis, isolated fibers of esophageal, diaphragmatic, and eye muscles may undergo segmental necrosis with variable regeneration (Russell). Scattered aggregates of lymphocytes (lymphorrhages) are also observed, as originally noted by Buzzard, but none of these changes in muscle explains the widespread and severe weakness.

The main ultrastructural alterations occur in the motor endplate. These changes, elegantly demonstrated by A.G. Engel and associates (1976a, 1977, 1987), consist of a reduction and simplification in the surface area of the postsynaptic membrane (sparse, shallow, abnormally wide, or absent secondary synaptic clefts) and a widening of the synaptic cleft (Fig. 46-1). The number and size of the presynaptic vesicles and their quanta of acetylcholine (ACh) are normal. The observation of regenerating axons near the junction, the many simplified junctions, and the absence of nerve terminals supplying some postsynaptic regions suggested to Engel and coworkers (1976a, 1977, 1987) that there was an active process of degeneration and repair of the neuromuscular junction, particularly of the postsynaptic side.

Although not directly relevant to myasthenia, it is of interest that a number of curious neurologic disorders occur in association with thymoma. Among our own patients were two with "limbic encephalitis" with memory

A

B

Figure 46-1. *A*. Endplate from a patient with myasthenia gravis. The terminal axon contains abundant presynaptic vesicles, but the postsynaptic folds are wide and there are few secondary folds. The loose junctional sarcoplasm is filled with microtubules and ribosomes. The synaptic cleft (*asterisk*) is widened. (From Santa et al by permission.) *B*. Normal endplate for comparison. (Courtesy of Dr. A.G. Engel.)

loss and confusion that could not be differentiated from the paraneoplastic variety of encephalitis (see Chap. 30), 1 case of midbrain encephalitis, 1 of Morvan's fibrillary chorea (see further on), and 1 of aplastic anemia. Some of these neurologic processes are associated with antibodies directed against voltage-gated potassium channels (VGKC). Such cases appear in the literature, and all are considered to have a humoral immune basis.

Of biologic and even greater clinical importance is the coexistence of myasthenia gravis and other autoimmune diseases. *Thyrotoxicosis* with periodic paralysis (5 percent of myasthenic patients), lupus erythematosus, rheumatoid arthritis, Sjögren syndrome, mixed connective tissue disease, anticardiolipin antibody, and (curiously) polymyositis have all been associated with myasthenia more often than can be explained by chance. A proportion of young women with myasthenia have moderately elevated titers of antinuclear antibody without the clinical manifestations of systemic lupus.

Etiology and Pathogenesis

Myasthenic weakness and fatigue are a result of the failure of effective neuromuscular transmission on the postsynaptic side. The greatly reduced number of receptors and the competitive activity of anti-AChR antibodies produce postsynaptic potentials of insufficient amplitude to discharge some muscle fibers. Blocked transmission at many endplates results in a reduction in the contractile power of the muscle. This deficiency is reflected first in the ocular and cranial muscles that are both the most continuously active and have the fewest AChRs per motor unit. Fatigue is understandable as the result of the normal decline in the amount of ACh released with each successive impulse.

Antibodies to AChR protein are present in more than 85 percent of patients with generalized myasthenia and in 60 percent of those with ocular myasthenia (Newsom-Davis, 1992). The presence of receptor antibodies has proved to be a reasonably sensitive and reliable test of the disease, as discussed later. The manner in which the antibodies that are directed against proteins in the intracellular compartment (such as anti-MuSK discussed later) causes weakness is not known.

Neuromuscular transmission is therefore impaired in several ways: (1) the antibodies block the binding of ACh to the AChR; (2) serum IgG from myasthenic patients has been shown to induce an increase in the degradation rate of AChR. This may be the result of the capacity of antibodies to cross-link the receptors; (3) antibodies cause a complement-mediated destruction of the postsynaptic folds (Engel and Arahata).

Although the evidence that an autoimmune mechanism is responsible for the functional disorder of muscle in myasthenia gravis is incontrovertible, the source of the autoimmune response has not been established. Because most patients with myasthenia have thymic abnormalities and a salutary response to thymectomy, it is logical to implicate the lymphoid reaction in this gland in the pathogenesis of the disease. Both T and B cells from the myasthenic thymus are particularly responsive to the AChR, more so than analogous cells from peripheral blood. Moreover, the thymus contains "myoid" cells (resembling striated muscle) that bear surface AChR. It is not known with certainty that thymic myoid cells are the source of immunologic stimulation in myasthenia gravis. The most obvious objection is that such cells are even more abundant in the normal than in the myasthenic thymus (according to Schluep et al). Another suggested pathogenesis, yet unconfirmed, is that a virus with a tropism for thymic cells might alter such cells and induce antibody formation. A viral infection might, at the same time, have a potential for oncogenesis, accounting for thymic tumors, but this is all speculative. Scadding and associates have suggested a different mode of thymic involvement; they have shown that thymic lymphocytes from patients with myasthenia gravis can synthesize anti-AChR antibody, both in culture and spontaneously.

Diagnosis

In patients who present with a changeable, specifically fatigable, diplopia or ptosis and the typical myasthenic facies—unequally drooping eyelids, relatively immobile mouth turned down at the corners, a smile that looks more like a snarl, a hanging jaw supported by the hand—the diagnosis can hardly be overlooked. However, only a few patients display this fully developed syndrome. Ptosis, diplopia, difficulty in speaking or swallowing, or weakness of the limbs is at first mild and inconstant and may be mistaken for cerebrovascular disease. However, the finding that sustained activity of small cranial muscles results in weakness (e.g., increasing droop of eyelids while looking at the ceiling or diplopia when fixating in lateral or vertical gaze or reading for 2 to 3 min) and that contraction improves after a brief rest is virtually diagnostic, even in the early stages of the disease. Any other affected group of muscles may be tested in a similar fashion. The characteristic ocular signs have already been described. For confirmation, the measurement of specific antibody (anti-AChR), electromyography, and certain pharmacologic tests described below are necessary. Several special clinical problems and associated conditions are summarized further on.

Electrophysiologic testing Characteristic of myasthenia is a rapid reduction in the amplitude of compound muscle action potentials during a series of repetitive stimulations of a peripheral nerve at a rate of 3 per second (*decrementing response* as shown in Fig. 2-15*A*). Reversal of this response by neostigmine or edrophonium has been a reliable confirmatory finding in most cases. A decremental response to stimulation can usually be obtained most often from the proximal limb muscles followed by the facial and, to a lesser extent, the hand muscles, which may or may not be clinically weak. During a progressive phase of the disease or during corticosteroid therapy, a slight initial incrementing response may be obtained, not to be confused with the marked incrementing response after voluntary contraction that characterizes the Lambert-Eaton syndrome (see further on).

Single-fiber electromyography (EMG) represents an even more sensitive method of detecting the defect in neuromuscular transmission. This technique demonstrates an inconstancy of the normally invariant interval between the

firing of muscle fibers connected to the same motor unit ("jitter"—see "Single-Fiber Electromyography" in Chap. 2) or complete blocking of successive discharges from single muscle fibers belonging to the same motor unit. The test requires a great deal of cooperation from the patient and that contraction of a muscle be sustained at just the right amplitude in order to isolate single muscle fibers from the same unit. It is also possible to detect such pairs of fibers by electrical stimulation of a nerve. Nerve conduction velocities and distal motor latencies are normal unless there is a coincident polyneuropathy.

Neostigmine test Almost as valuable as electrophysiologic testing is testing with the cholinesterase inhibitors neostigmine and, in the past, edrophonium, a more rapidly acting agent. These drugs prolong and exaggerate the effects of ACh in the synapse and thereby produce an increment in muscle power in the patient with myasthenia. Edrophonium is variably available in the United States at the time of this writing, but neostigmine affords a longer time for observation, as noted in the next paragraph. The tests are performed in the following manner. After the estimation of strength in a cranial (usually the levator palpebrae or an extraocular muscle) or limb muscle (by dynamometry), or vital capacity, neostigmine is injected intramuscularly in a dose of 1.5 mg. Atropine sulfate (0.8 mg) is generally given several minutes in advance to counteract the unpleasant muscarinic effects of neostigmine (salivation, sweating, bronchorrhea, borborygmi, bowel cramps, and, sometimes, diarrhea). Neostigmine may alternatively be given intravenously in a dose of 0.5 mg, but its effect is often too brief to be as useful. After intramuscular injection of neostigmine, objective improvement occurs within 10 to 15 min, reaches its peak at 20 min, and lasts up to 1 h, allowing for careful verification of the neurologic improvement. Many neurologists perform this test twice, once with an injection of saline as a control.

Alternatively, 1 mg (0.1 mL) of edrophonium is given intravenously; if this dose is tolerated and no definite improvement in strength occurs after 45 s, another 4 to 9 mg is injected. A total dose of 10 mg is rarely necessary. Most patients who respond do so after 3 to 5 mg has been administered. The mild muscarinic effects of edrophonium are blocked by pretreatment with atropine 0.8 mg subcutaneously as for neostigmine. The clinical effect of improved ptosis, extraocular movements, oropharyngeal function, arm and shoulder abduction, or vital capacity persists for no more than 5 min with edrophonium and 60 min with neostigmine.

One caution: with either drug, some patients deteriorate immediately, but briefly, as a result of an increase in pulmonary secretions. A positive test consists of visible (objective) improvement in muscle contractility, fusion of diplopia, or resolution of fatigable ptosis. Dynamometry and measurement of forced vital capacity serve as more objective markers of improvement or lack of effect. The report of subjective improvement alone is not dependable and one must be distrustful of equivocal test results, which may occur with ocular palsies due to tumors, thyroid disease, Guillain-Barré syndrome (GBS), progressive supranuclear palsy, or carotid aneurysms (pseudoocular myasthenia).

A negative test with an anticholinesterase agent does not entirely exclude myasthenia gravis but is a strong point against the diagnosis. In a small number of patients with periodic and purely ocular symptoms who later prove to have myasthenia gravis, the edrophonium and neostigmine tests (and electrophysiologic studies and AChR antibody measurements) may be entirely normal during the first or even after several acute episodes. Only later, for inexplicable reasons, do these tests become positive. Finally, the anticholinesterase-inhibiting drugs carry a small risk of inducing ventricular fibrillation and cardiac arrest so that testing should be carried out where emergency support is accessible.

Measurement of receptor antibodies in blood The detection of *anti-AChR antibodies* provides a reasonably sensitive and highly specific test for the diagnosis of myasthenia. The radioimmunoassay method of detection is accurate and widely used. Serum antibodies are found in 80 to 90 percent of patients with generalized myasthenia gravis and in approximately 60 percent of those whose symptoms are restricted to the ocular muscles (Vincent and Newsom-Davis). For the most part, adults with myasthenia whose sera are persistently negative for AChR antibodies do not differ clinically or electromyographically from those with antibodies with the exception noted below. Persistently negative AChR antibody tests are more frequently found in patients with ocular myasthenia than in patients with generalized weakness. Patients with thymoma and severe generalized myasthenia are practically always seropositive. Interestingly, the antibody titers usually remain elevated during clinical remissions.

Instances of "seronegative" disease are sometimes due to antibody production against unusual muscle epitopes that are located on or near the AChR; their detection requires a special panel of tests. However, the majority of such cases have been ascribed to IgG antibodies directed against an intracellular *muscle-specific kinase* (*MuSK*). This enzyme plays a role in supporting the normal structure of the postsynaptic membrane and in the arrangement of AChR, but its main function may be in developmental synaptic differentiation. The illness is possibly acquired late in life because of the high rate or turnover of the neuromuscular junction, with newly formed junctions being physiologically inadequate. The associated clinical syndrome differs from typical myasthenia and was discussed earlier. Also of interest, but not currently used in routine diagnosis, is the presence of antibodies directed against striated muscle in almost half of myasthenic patients and an even higher incidence (stated to be 85 percent) in patients who also have a thymoma. Rare instances of seronegative myasthenia with antibodies directed to cortactin, a protein in the pathway of MuSK has been described (Cortes-Vicente et al).

Each of the commonly used diagnostic tests, electrophysiology, edrophonium, and antibodies, proves to be about equally reliable. Kelly and coworkers obtained positive results with single-muscle-fiber recording in 79 percent, with the antireceptor antibody test in 71 percent, and with the edrophonium test in 81 percent. Combined, they confirmed the diagnosis in 95 percent of clinically suspected cases. Presumably, had the anti-MuSK receptor

antibody test been available, the sensitivity of serologic diagnosis would have been higher.

In keeping with the observation of some myasthenic patients that their weakness improves in the cold, a test has been devised in which an ice pack is placed over a ptotic eyelid for 2 min or to the limit of the patient's tolerance. Sethi and colleagues found that ptosis was diminished in 8 of 10 patients. In our patients, this effect has not been as consistently evident, but it may be a useful adjunctive test.

Other diagnostic tests performed routinely in essentially all patients with myasthenia gravis include CT of the chest (for the detection of thymic enlargement or thymoma), tests of thyroid function for reasons discussed further on, and in cases of uncertain diagnosis, magnetic resonance imaging of the cranium and orbits to exclude compressive and inflammatory lesions of the cranial nerves and ocular muscles.

Special Diagnostic Problems

We have encountered the following clinical problems in myasthenia:

1. *The concurrence of myasthenia gravis and thyrotoxicosis.* Thyrotoxicosis may produce a characteristic ocular myopathy and there is a tentative relation to periodic paralysis, as indicated in Chap. 45. There is no definite evidence that thyrotoxicosis aggravates myasthenia gravis; some clinicians have even observed an inverse relationship between the severity of the two conditions. Hypothyroidism, however, does worsen the myasthenic symptoms. The ophthalmoplegia of thyrotoxicosis can usually be distinguished by the presence of associated exophthalmos (early in the disease, exophthalmos may be absent), lack of ptosis, and the lack of definitive response to neostigmine. Polymyositis and inclusion body myopathy are differentiated from myasthenia by lack of involvement of extraocular muscles, but they may affect oropharyngeal muscles, as does myasthenia. Finding the signs of these diseases in combination with those of myasthenia indicates a concurrence of two independent autoimmune diseases.
2. *The patient with depression who complains of nonspecific weakness when actually referring to fatigability.* There is no ptosis, strabismus, or dysphagia, though an anxious individual may complain of diplopia (usually of momentary duration when drowsy) and also of tightness in the throat (globus hystericus). A number of such patients claim improvement with neostigmine, but the objective reversal is always uncertain. Conversely, myasthenia is as often mistaken for hysteria or other emotional illness, mainly because the physician is unfamiliar with myasthenia (or with hysteria) and has been overly impressed with the precipitation of the illness by an emotional crisis. Furthermore, fatigability is a feature of all of these conditions, but only in the psychiatric ones does it extend to the sphere of mental endurance. Those with myasthenia do not usually complain of fatigue of the mind, whereas these are frequent complaints in psychiatric conditions. A similar problem arises frequently in our services in judging breathlessness due to anxiety or cardiopulmonary disease in a patient with presumed myasthenia. Careful appraisal of the breathing pattern and determination of the vital capacity or other spirometric measurements are helpful here.
3. *Progressive external ophthalmoplegia and other restricted myopathies, including congenital myasthenic states.* These may be mistaken for long-established myasthenia gravis. It should be emphasized that the extraocular muscles and levator palpebrae may be permanently damaged by myasthenia and cease to respond to neostigmine. Another possibility is that restricted ocular myasthenia may not respond to anticholinesterase drugs from the beginning and the diagnosis of myasthenia is erroneously excluded. One must then turn to other muscles for clinical and electromyographic and serologic confirmation of the diagnosis.
4. *Myasthenia with dysarthria and dysphagia but without ptosis or obvious strabismus.* These may be confused with multiple sclerosis, polymyositis, inclusion body myopathy, stroke, motor neuron disease, or some other neurologic disease. Testing with an anticholinesterase inhibitor, single-fiber and repetitive stimulation recording, and measurement of antibodies usually clarifies the matter.
5. *The initial manifestations of botulism*—blurred vision, diplopia, ptosis, strabismus, and ophthalmoparesis—may be mistaken for myasthenia gravis of acute onset. In botulism, however, the pupils are usually large and unreactive, and the eye signs are followed in rapid succession by the involvement of bulbar, trunk, and limb muscles.
6. Similarly, the *oculopharyngeal-brachial* and *variants of GBS* in the early stages have many of the features of myasthenia, including ptosis, that may be partially responsive to anticholinesterase drugs. The loss of tendon reflexes, acral paresthesias, and areflexia, or the development of ataxia in the limbs make the diagnosis of GBS at once apparent and detailed electrophysiologic testing distinguishes the two conditions.
7. *Intoxication with organophosphate insecticides,* because of their capacity to induce a cholinergic crisis, may be confused with a myasthenic crisis (see further on).

Certain other small clinical points may be helpful in differentiating myasthenia from other diseases that affect the cranial musculature. A hanging jaw and hanging head are indicative of myasthenia, whereas complete or asymmetric facial paresis is typical of GBS. Botulism usually affects the pupillary convergence reaction, and GBS does so only when there is complete internal and external ophthalmoplegia; diphtheria affects mainly the accommodative reaction early on. The question of midbrain stroke as a consequence of basilar artery occlusion arises in a case with total ophthalmoplegia; it should be recalled that the level of consciousness is usually reduced if vertical gaze and pupillary reactions are lost in cases of basilar artery stroke; such is not the case in neuromuscular diseases. The myasthenic syndrome of Lambert-Eaton, discussed further on, only occasionally affects the ocular muscles but is identified by its other clinical and electrophysiologic features. Ocular paresis, as may occur in nemaline polymyopathy, oculopharyngeal dystrophy, and thyrotoxic ophthalmic

disease, come on too slowly in most cases to be confused with myasthenia gravis. On occasion, the eye movements in myasthenia simulate an internuclear ophthalmoplegia or other "central" sign, even to the extent of including nystagmus in an abducting eye.

Treatment

The treatment of this disease involves the careful use of two groups of drugs—anticholinesterases and immunosuppressants including corticosteroids and, in special acute circumstances, plasma exchange and intravenous immune globulin (IVIg). An elective thymectomy is appropriate in many patients, as discussed below. Consensus guidelines for the treatment of myasthenia were issued in 2016 (Sanders et al).

Anticholinesterase drugs The two drugs that give the best results in ameliorating myasthenic weakness are neostigmine (Prostigmin) and pyridostigmine (Mestinon), the latter being preferred by most clinicians and patients. The usual dose of pyridostigmine is 30 to 90 mg given every 6 h (typically a 60-mg pill is tried first); the oral dose of neostigmine ranges from 7.5 to 45 mg given every 2 to 6 h. Extended-action forms of both drugs are available but are given at bedtime mainly to patients who complain of weakness during the night or early morning hours. The dosage of these drugs and their frequency of administration vary considerably from patient to patient, but the maximal useful dosage of pyridostigmine rarely exceeds 120 mg given every 3 h (Drachman, 1990). Table 46-1 lists the approximate dose-equivalents of these various drugs.

For mild cases, and for patients in partial remission after thymectomy, and for some patients with purely ocular myasthenia, the use of anticholinesterase drugs may be the only form of therapy necessary for some period of time. Although these drugs seldom relieve symptoms completely (the response of ocular symptoms is typically incomplete), most such patients are able to function well.

Glucocorticoids For the patient with moderate to severe generalized weakness who is responding inadequately to anticholinesterase drugs, the long-term administration of corticosteroids is the most consistently effective form of treatment, as described in a large series of patients (Pascuzzi and colleagues). Small doses of corticosteroids (prednisone 15 to 25 mg daily) alone or in combination with azathioprine are also often adequate to control ocular myasthenia. However, one must be prepared to contend with the side effects of long-term glucocorticoid therapy and we hesitate to undertake such a program in children or patients with severe diabetes or other diseases that are likely to be aggravated. Because recent experience with the newer immunosuppressive agents was not incorporated into most prior series, the uniform use of steroids might not be correct.

Table 46-1

DOSE-EQUIVALENTS FOR DRUGS USED IN THE TREATMENT OF MYASTHENIA GRAVIS

	DOSE EQUIVALENT	ONSET	TIME TO MAXIMUM RESPONSE
Pyridostigmine (Mestinon)	60 mg (oral)	40 min	1 h
Neostigmine oral (Prostigmin)	15 mg	1 h	1.5 h
Neostigmine IM	1.5 mg	30 min	1 h
Neostigmine IV	0.5 mg	Immediate	20 min

The usual form of steroid therapy is prednisone (or corresponding doses of prednisolone), beginning with 15 to 20 mg/d and increasing the dose gradually until a satisfactory clinical response is obtained or until a daily dose of 50 to 60 mg is reached. It is important to be aware that with higher doses or more rapid elevations of the doses, worsening of weakness in the first weeks may occur and hospitalization and careful observation for respiratory difficulty may be advisable. Improvement after the initiation of corticosteroids occurs over a few weeks. Once the maximal effect from prednisone has been attained, the dosage can be reduced gradually over months to the lowest point at which it is still effective. Our practice has been to then attempt to institute an alternate-day schedule, which diminishes the side effects; some patients have done better with a modest difference in dose from 1 day to the next, rather than omitting a dose entirely on alternate days. Potassium supplements and antacids should be prescribed if needed, as with any chronic corticosteroid regime and consideration should be given to prophylaxis with antibiotics for *Pneumocystis* infection and bisphosphonate for osteoporosis if long-term treatment is anticipated. At the outset of steroid therapy, anticholinesterase drugs are given simultaneously; as the patient improves, the dosage of the latter may be adjusted downward.

Azathioprine and other immunosuppressive drugs *Azathioprine* is a useful adjunct to steroids in patients who cannot tolerate or fail to respond to prednisone. It has been possible to manage the disease reasonably well in a few patients with azathioprine alone, but there is no study to support this practice (see Palace et al, 1998). Treatment typically begins with 50 mg (1 tablet) bid for a few days; if this is tolerated, the dosage is raised to 2 to 3 mg/kg/d (150 to 250 mg daily). However, improvement occurs much more slowly than with corticosteroids and a significant response may not be evident for many months to a year (Witte et al). Liver function tests and blood cell count should be checked regularly. The Myasthenia Gravis Clinical Study Group found that the most severe forms of the disease, particularly those resistant to either prednisone or azathioprine alone, benefit from the combination of the two medications. Azathioprine is a prodrug of mercaptopurine, which is metabolized principally by thiopurine methyltransferase (TPMT). Approximately 3 per 100,000 persons are deficient in the enzyme, for which reason, some clinicians measure its level before initiating azathioprine in order to avoid bone marrow toxicity; it has not been our practice to do so. There are many variant alleles of TPMT and a larger number of patients have a partial deficiency of the enzyme or even excessive enzyme activity, but it has not been clear how to utilize this information in myasthenia. Azathioprine interacts with other drugs such as allopurinol and warfarin.

Cyclosporine is another immunosuppressive drug that has shown benefits in clinical trials (Tindall et al). It is

given in 2 divided doses daily, to a total of 6 mg/kg, but not often used currently because of serious side effects (hypertension, nephrotoxicity) and its high cost.

Mycophenolate is currently being used as an adjunct to corticosteroids and has been beneficial in several small trials but failed to demonstrate a similar effect in larger controlled studies. The clinical improvement, when it does occur, has generally occurred sooner than it does with azathioprine (Meriggioli et al). Diarrhea was the main adverse effect. Several experts in the field believe that mycophenolate is preferable to most of the adjunctive medications and, in some milder cases, may be effective alone but reconciling this view with recent failed trials is vexing.

Cyclophosphamide may be administered in intravenous pulses in severe cases, but the appropriate use of this potent agent is not clear and we have resorted to it infrequently (De Feo and coworkers). A regimen of high-dose cyclophosphamide (50 mg/kg/d for 4 consecutive days) followed by granulocyte-stimulating factor to "reboot" the immune system can also be considered in refractory cases (Drachman and colleagues). This approach has risks but may be justified if all other measures have failed. Liver function and white blood cell count require monitoring. On the basis of pilot trials, many other drugs, for example, tacrolimus, rituximab, and etanercept, have come into use in patients who are dependent on or resistant to corticosteroids, including those with antibodies to MuSK (Ponseti and colleagues; Diaz-Manera et al). Preliminary trial results have been reported with the use of an agent that blocks the neonatal IgG-Fc fragment (efgartigimod) and reduces antibody production (Howard et al), particularly in antiacetylcholine receptor antibody positive patients.

Plasma exchange and intravenous immune globulin For severe myasthenia that is refractory to treatment with anticholinesterase drugs and prednisone or during an acute period of worsening, one must resort to other measures. Striking temporary remissions (2 to 8 weeks) may be obtained by the use of *plasma exchange*. This form of treatment may be lifesaving during a myasthenic crisis. It also finds use before and after thymectomy and at the start of immunosuppressive drug therapy. Plasma exchange is also helpful in limiting the aforementioned weakness that is often induced by the institution of high-dose corticosteroids. The number and volume of exchanges required in these circumstances are somewhat arbitrary, but they tend to be less than those required for GBS; several exchanges of 2 to 3.5 L each (totaling approximately 125 mL/kg) performed over a week usually suffice. The removed plasma is replaced with albumin and saline. It has been estimated that a 2-L exchange will remove 80 percent of circulating antibodies and that this will be reflected in reduced ACh antibody levels in 3 to 5 days. There is only an approximate correlation between a reduction in the titer of anti-AChR antibody and the degree of clinical improvement. In a crisis requiring plasma exchanges and mechanical ventilation, it has been our practice to discontinue or curtail the use of anticholinesterase drugs and resume them as the patient is being weaned from the ventilator. Also, it may be that sensitivity to these drugs may be enhanced in the hours after an exchange so that their dosages must be adjusted accordingly.

A small number of patients respond so well to plasma exchange and find the side effects of steroids so intolerable that they choose to be maintained with 2 to 3 exchanges every several weeks or months. Immuno–adsorption, a technique similar to plasma exchange that removes antibodies and immune complexes by passing blood over a tryptophan column, is less cumbersome than conventional plasma exchange and has been effective, but experience with this procedure is limited.

IVIg is similarly, and possibly equivalently, useful in the short-term control of acutely worsening myasthenia. It's ease of administration favors it over plasma exchange. The usual dose is 2 g/kg given in divided doses over 3 to 5 days. Several small series suggest that the effect is equivalent to a series of plasma exchanges. However, plasma exchange and immune globulin have been subjected to only limited systematic study or comparison, and while these treatments are invaluable in deteriorated patients or those in crisis, they offer only short-term benefits. In two separate small studies, no difference was identified between IVIg and plasma exchange in myasthenic exacerbations, most cases of which were less severe than a typical crisis (Gajdos and colleagues, 1997; Barth et al). Also, no difference was identified in a trial of IVIg 1 g/kg/d given for 1 or 2 days.

Thymectomy This operation, first introduced by Blalock, is considered an appropriate procedure for many patients with generalized myasthenia gravis between puberty and 55 years of age. The surgery is performed electively and not during an acute deterioration of myasthenia. The remission rate after thymectomy is approximately 35 percent provided that the procedure is done in the first year or 2 after onset of the disease, and another 50 percent will improve to some extent (Buckingham et al). The remission rate is progressively lower, but not negligible if the operation is postponed beyond this time. In patients with myasthenia restricted to the ocular muscles for a year or longer, the prognosis is so good that thymectomy is unnecessary. The response to thymectomy is not evident for several months and is usually maximal by approximately 3 years. In favorably responding cases, levels of circulating receptor antibody are reduced or disappear entirely. If possible, thymectomy should be postponed until puberty because of the importance of the gland in the development of the immune system, but juvenile myasthenia is also quite responsive. The results are not as predictable in patients who harbor a thymoma.

A randomized trial has affirmed the usefulness of thymectomy (Wolfe and colleagues). Beyond the demonstration of effect of the procedure over 3 years when coupled with alternate day prednisone compared to alternate-day prednisone alone, certain of the outcomes of the trial were instructive but tentative due to the small number of patients enrolled: medical complications were lower in the surgical group as a result of reduced requirement for prednisone and immunosuppressive drugs, and the effects of the operation were clearer in women than in men. Viewing the Kaplan-Meier curves from that trial, it appears broadly that the effect of thymectomy was maximal at approximately 6 months and remained stable thereafter.

A suprasternal approach for removal of the gland has been developed and results in less postoperative pain and morbidity than occurs with a transsternal thoracotomy, but the transsternal operation may be preferable because it assures a more complete removal of thymic tissue. Thymectomy is best performed in a hospital where there is close collaboration between the thoracic surgeon and the neurologist. If the patient is weak preoperatively, a course of plasma exchange or immune globulin may be given preceding the surgical procedure. Large "stress doses" of corticosteroids seem to be unnecessary in most patients who have been taking these medications chronically. After operation, respiratory assistance must be available if needed. Neostigmine intramuscularly may be given every 3 to 6 h postoperatively. Usually, the dose requirement is about 75 percent of that taken before surgery. As improvement occurs, oral medications are resumed as remission is not anticipated for many months or longer, as noted above.

Thymectomy may also be a safe and effective treatment in elderly patients with myasthenia. In a study of 12 such individuals, complete remission in 9 and clinical improvement in the remainder (Olanow and associates). The improvement in older patients is less convincing than it is in the younger group, in part because the thymus is atrophic. Nonetheless, some of our patients who were older than age 60 years did benefit. The abovementioned clinical trial did not include patients over the age 65 years.

Removal of the thymus gland is also indicated in practically all patients in whom *thymoma* is detected by CT of the chest. The tumor can be locally invasive but rarely metastasizes. The operative approach is through the anterior thorax, with adequate exposure to remove all the tumor tissue. If the tumor cannot be removed completely, the remaining tissue should be treated with focused radiation. Local spread and lymph node invasion have been treated with combinations of chemotherapy including cisplatin, but it is not very satisfactory. Park and colleagues concluded from a large retrospective study of metastatic cases that chemotherapy offers some benefit in terms of survival, but this remains controversial.

Despite this endorsement of thymectomy for generalized myasthenia, it has remained an unproven therapy by a modern trial and attempts to recruit patients for such an endeavor have been difficult.

Myasthenic and Cholinergic Crisis

A rapid and severe deterioration of the myasthenia, termed *myasthenic crisis,* can bring the patient to the brink of respiratory failure in a matter of hours. A respiratory infection or excessive use of sedative medications or drugs with a potential for blocking neuromuscular transmission may precede the myasthenic crisis. We have encountered numerous cases in which oropharyngeal weakness has led to aspiration pneumonia, which, in turn, precipitated a crisis. Just as often, a precipitating event is not evident. Rarely a respiratory arrest is the first manifestation of crisis. Such events may occur at any time after the diagnosis of myasthenia, but half are evident within 12 to 18 months. In an early but still salient experience with 53 patients in myasthenic crisis at the Columbia-Presbyterian Medical Center, pneumonia was the most frequent precipitating event, but no cause could be determined in almost one-third of cases (Thomas et al).

Incipient respiratory failure is usually marked by a reduction of vital capacity, often accompanied by restlessness, anxiety, diaphoresis, or tremor. Once the diaphragm fails, movements of the chest wall and abdomen become paradoxical (the abdomen moves inward during inspiration) or there may be shallow excursions of the chest, alternating with paradoxical movements as discussed in Chap. 25, where the characteristics of neuromuscular respiratory failure are described. In an emergency, after clearing the airway, such a patient can be supported briefly by a tight-fitting face mask and manual bag (Ambu) breathing. The chest wall will be very compliant as a result of muscular weakness.

Management of the crisis entails timely and careful intubation followed by mechanical ventilation in a critical care unit that is equipped to attend to the medical and neurologic needs of such patients (Ropper). Respiratory failure in a few patients can be managed by the use of bilevel positive airway pressure (BIPAP), according to Rabinstein and Wijdicks, but in our experience, this has not been consistently effective in avoiding endotracheal intubation. One must cope with both the oropharyngeal weakness and secretions that endanger the airway and the diaphragmatic weakness. Anticholinesterase drugs, which exaggerate secretions, are best withdrawn at the time of intubation. A useful maneuver is to allow the patient to remain off cholinergic drugs for several days while on a ventilator; there is often a heightened response to the reinstitution of medications after this period. The use of plasma exchange or intravenous gamma globulin, as described earlier, is equivalently effective in hastening improvement and weaning from the ventilator. Some of our colleagues have used high-dose corticosteroid infusions in these circumstances, but this measure has not been particularly successful in our unit and, in the short run, carries the risk of inducing worsening of the weakness (Panegyres et al).

Patients with myasthenic crisis generally respond to plasma exchange or to immunoglobulin infusions in 1 or 2 days, but more often, a week or more is required for recovery after a full course of 4 to 5 exchanges or 3 to 5 g/kg IVIg given in divided daily doses. Whether the previously mentioned studies (e.g., Gajdos et al, 1997 and 2005) comparing the two treatments and comparing doses of IVIg in myasthenic exacerbations are pertinent to the crisis is unknown, but we almost always institute one or the other soon after it as it is apparent that respiratory failure is imminent or worsening.

It is generally best to wait 2 or 3 weeks before committing a patient to tracheostomy. When weaning from the ventilator is anticipated, anticholinesterase agents are reintroduced slowly, and treatment with corticosteroids can be instituted if necessary. Oral doses of 60 mg pyridostigmine or 15 mg neostigmine are roughly equivalent to 0.5 to 1 mg neostigmine intravenously and 1.5 to 2 mg intramuscularly, as noted in Table 46-1.

Most patients with myasthenic crisis take several weeks to recover, and a few of our patients have remained ventilator-dependent for months. In the extensive experience of 53 patients from Columbia-Presbyterian, half of the patients could be safely extubated within 2 weeks

and three-quarters by a month (Thomas et al). There were 7 deaths among 53 patients, reflecting the gravity of this syndrome even in the modern era of intensive care. Atelectasis, severe anemia, congestive heart failure, and clostridial diarrhea (associated with antibiotic use) portend a prolonged period of generalized weakness and intubation. From time to time, one encounters a patient in whom respiration and ambulation do not improve for many months after a myasthenic crisis. In our experience, these have been middle-aged or older patients, usually women, in whom an element of hyperthyroidism or hypothyroidism may have been operative. They become wasted as the proximal limb and axial muscles, including the diaphragm, fail to recover their power, even though the ocular and oropharyngeal muscles improve. The role of corticosteroids in producing a concomitant proximal myopathy is a consideration that can be solved by careful electrophysiologic examination.

If the response to anticholinesterase drugs is poor and progressively larger doses are not relieving symptoms, there is consideration of a *cholinergic crisis.* In our own experience with more than 80 patients of severe myasthenia in an intensive care unit, we have been persuaded of the occurrence of a cholinergic crisis only rarely. This consists of a relatively rapid increase in muscular weakness, usually coupled with the adverse muscarinic effects of the anticholinesterase drug (nausea, vomiting, pallor, sweating, salivation, bronchorrhea, colic, diarrhea, miosis, bradycardia). An impending cholinergic effect is betrayed by the constriction of pupils. If the blood pressure falls with bradycardia, 0.6 mg atropine sulfate may be given slowly by the intravenous route. Neostigmine or repetitive stimulation may be used to determine whether or not weakness is to the result of an excess of anticholinesterase medications. However, this test has been misleading and undoubtedly has contributed to an overestimation of the frequency and importance of the cholinergic crisis. Infection, or the natural course of the disease, has been a far more common cause of acutely worsening weakness and respiratory failure.

The only recourse in cases of long-standing and severe, intractable myasthenia is to continue an average dose of corticosteroids, immunosuppressive, and anticholinesterase medications with intermittent trials of immune globulin or plasma exchanges. This is also a desperate situation in which high-dose cyclophosphamide followed by a granulocyte-stimulating factor, as mentioned earlier, may result in slow improvement. Other agents such as rituximab may be tried. Whether thymectomy, undoubtedly risky in these sick patients, effects severe and long-established myasthenia is not known, but its effects, in any case, would be delayed.

Management of anesthesia and pregnancy in the myasthenic patient Surgical procedures of any type are often sufficiently stressful to produce decompensation of the disease. If the patient is unable to take medications orally, anticholinesterase agents may be given intramuscularly (approximately 1/30 of the oral dose of pyridostigmine and 1/10 the oral dose of neostigmine listed in Table 46-1). If corticosteroids were being used, they may be continued and the dose generally left unchanged; large "stress" doses are generally unnecessary, as mentioned earlier in the discussion of thymectomy. Neuromuscular blocking agents of the noncompetitive type may have a very prolonged effect in these patients and should be avoided as part of the anesthetic regimen. If they are necessary for some reason, a period of mechanical ventilation should be anticipated. In contrast, the dose of succinylcholine (which is not recommended) required to produce muscle relaxation may be larger than usual. Any drug, the use of which is contemplated in anesthetic and postsurgical management, should be checked against the list of agents that are capable of exaggerating myasthenic weakness (see further on).

Pregnancy is usually uncomplicated in patients with myasthenia, but some women who are partially treated for myasthenia and have generalized weakness may have difficulty in assisting with vaginal delivery. However, the use of intravenous cholinesterase inhibitors is contraindicated because of the possibility of inducing uterine contractions, and cytotoxic drugs are generally avoided during pregnancy because of the potential for fetal abnormalities. Also, magnesium is not recommended for the treatment of eclampsia because its neuromuscular blocking effects may worsen myasthenic weakness. Delivery usually proceeds normally, and breast-feeding is not thought to be a problem with regard to the transmission of AChR antibodies. Almost half of women with myasthenia have an exacerbation of varying degrees in the several weeks postpartum. A rapidly dropping level of alpha-fetoprotein has been implicated as this protein inhibits the binding of antiacetylcholine antibodies to postsynaptic receptors. The issues of neonatal myasthenia and of reduced intrauterine movements with arthrogryposis are considered later.

Other Disorders of Neuromuscular Transmission (Table 46-2)

Considered here are several disorders of neuromuscular transmission characterized clinically by muscular weakness and fatigability but differing in mechanism from autoimmune myasthenia gravis. The Lambert-Eaton myasthenic syndrome, neonatal myasthenia, congenital myasthenic syndromes, and myasthenic syndromes induced by drugs and toxins are the main disorders in this group. Two additional important diseases—botulism and organophosphate poisoning—are described in Chap. 41.

The Myasthenic-Myopathic Syndrome of Lambert-Eaton (Lambert-Eaton Syndrome)

This special form of neuromuscular disorder that in a few ways simulates myasthenia gravis is observed most often in patients with small cell carcinoma of the lung, was first described by Lambert, Eaton, and Rooke in 1956 and further by Eaton and Lambert in 1957. Unlike myasthenia gravis, the muscles of the trunk, shoulder girdle, pelvic girdle, and lower extremities are the ones that become weak and fatigable. The first symptoms are difficulty in arising from a chair, climbing stairs, and walking; the shoulder muscles are usually affected later. Although ptosis, diplopia, dysarthria, and dysphagia may occur, presentation with these symptoms is distinctly unusual. Increasing weakness after

Table 46-2

MAJOR DISORDERS OF THE NEUROMUSCULAR JUNCTION

MYASTHENIC SYNDROMES	CAUSAL AGENT OR GENE DEFECT	ONSET DECADE	TREATMENT	CLINICAL FEATURES
		ACQUIRED MYASTHENIC SYNDROMES		
Presynaptic				
Botulism (Chap. 41)	Peptide toxin from *Clostridium botulinum*	Any	Supportive; ventilation	Blurred vision, dysphagia, limb weakness
Lambert-Eaton myasthenic syndrome	Autoimmune reduction in calcium-mediated quantal release	Midlife	3,4-DAP Possibly IVIg	Truncal weakness, dysautonomic features Two-thirds have cancer
Synaptic				
Insecticides (Chap. 41)	Organophosphates (inhibits AChE)	Any	Remove toxins Atropine	Miosis, diarrhea, cramps, weakness Delayed sensorimotor neuropathy
Postsynaptic				
Myasthenia gravis	Autoimmune attack on postsynaptic membrane	Adult	AChE inhibitors, IVIg	Diplopia, ptosis
	Antibodies to AChR or MuSK protein		Other immunosuppressants	Limb weakness with exertion
Snake venom toxins (Chap. 41)	Multiple peptide toxins that lyse muscle, bind Na channels, K channels (acting both post- and presynaptically)	Any	Supportive Possibly AChE inhibitors	Acute weakness

exertion stamps the condition as myasthenic, but in direct contrast to myasthenia gravis, there may be a temporary increase in muscle power during the first few contractions. The tendon reflexes are often diminished, but complete abolition of the reflexes should raise the question of an associated carcinomatous polyneuropathy. Fasciculations are not seen.

An instructive review of this disease consisting of 50 well-studied cases described proximal leg weakness in all, arm weakness in 39, diplopia in 25, ptosis in 21, and dysarthria in 12. Symptoms were paresthesias, aching pain (suggesting arthritis), and a number of autonomic disturbances, such as dryness of the mouth, constipation, difficult micturition, and impotence (O'Neill and colleagues). This latter group of symptoms gives the syndrome an unmistakable stamp, as discussed further on under "Diagnosis." One should not be surprised to find other neurologic manifestations of neoplasia (e.g., polyneuropathy, polymyositis or dermatomyositis, multifocal leukoencephalopathy, cerebellar degeneration, as discussed in Chap. 30).

The onset of weakness is subacute and the course variably progressive. Males are affected far more often than females (5:1). The weakness may precede discovery of the tumor by months or years. Approximately 60 percent of cases are associated with small cell lung cancer, but small numbers have also occurred with carcinoma of the breast, prostate, stomach, and rectum and with lymphomas; in about one-third of patients, no tumor is found. Some cases are associated with other autoimmune diseases, but most are paraneoplastic or idiopathic. The condition may occur in children, usually with no relation to tumor. In tumor cases, death usually occurs in a few months or years from the effect of the neoplasm; the idiopathic ones fluctuate over the years.

The response to neostigmine and pyridostigmine is poor or at least unpredictable, and this finding in a myasthenic patient should bring the diagnosis of Lambert-Eaton syndrome to mind. In contrast, *d*-tubocurarine, suxamethonium chloride, gallamine, and other muscle relaxants have a deleterious effect and may cause fatality, just as in myasthenia gravis.

Conventional electrodiagnostic studies show no abnormality in the peripheral nerves. A single stimulus of nerve may evoke a low-amplitude muscle action potential (in contrast to myasthenia gravis, in which it is normal or nearly so) whereas at fast rates of stimulation (50 per second as shown in Fig. 2-15*B*) or following strong voluntary contraction (for 15 s or longer) there is a marked increase in the amplitude of action potentials (incrementing response hence the term "inverse myasthenia," which has been applied to Lambert-Eaton myasthenic syndrome [LEMS]). Single-fiber recordings show an increase in "jitter" as in myasthenia gravis, as described in Chap. 2.

Elmquist and Lambert, from a series of studies of excised muscle, deduced that there is a defect in the release of ACh quanta from the *presynaptic* nerve terminals, akin to the effects of botulinum toxin, magnesium excess, and neomycin. The presynaptic vesicles themselves appear to be normal in morphology and content. Also, in contrast to myasthenia gravis, the surface area of the postsynaptic receptor membrane in this syndrome is actually increased (Engel, 1976b).

The physiologic mechanism in Lambert-Eaton myasthenic syndrome is a loss of voltage-gated calcium channels on the presynaptic motor nerve terminal. The calcium channels become cross-linked and aggregated by IgG autoantibodies, ultimately reducing the number of functioning channels (Fukunaga et al). These antibodies against a specific component of the *presynaptic* membrane have the effect of reducing the presynaptic release of ACh, virtually the opposite of myasthenia gravis.

A serologic test for these antibodies (anti-VGKC) is available and is performed to confirm the diagnosis. Even in patients without detectable antibodies against

voltage-gated calcium channels, passive transfer experiments indicate the presence of a circulating factor with similar activity. Muscle biopsy is normal or shows only the same slight, nonspecific changes as in myasthenia gravis. The thymus is, of course, normal.

Recognition of the Lambert-Eaton syndrome should lead to a search for an occult tumor, particularly of the lung. A positron emission tomography (PET) scan of the body may be useful for this purpose, although CT of the lungs is usually adequate. If found, it should be treated; this alone may result in improvement in the neurologic syndrome. If none is found, the search should be repeated at regular intervals, as the tumors at first are small and may be inapparent even at autopsy. Numerous cases of the more typical paraneoplastic syndromes discussed in Chap. 30, such as cerebellar degeneration, may coexist with the Lambert-Eaton syndrome, most of them are a result of small cell lung cancer (see Mason and colleagues), while others are a result of idiopathic antibodies to the calcium channels.

Treatment Most patients with this disorder benefit mildly or moderately from the administration of 3,4-diaminopyridine (3,4-DAP), an agent that blocks potassium channels in the distal motor terminal, thus prolonging depolarizations and enhancing the release of ACh vesicles. The drug is given as 20 mg, up to 5 times a day, either alone or in conjunction with pyridostigmine (Lundh et al). It is not approved by the FDA in the United States and must be obtained from specialty pharmacies but, nonetheless, has replaced the formerly used guanidine hydrochloride that had hematologic and renal toxicity with long-term use. With regard to long-term relief, numerous regimens have been tried and favored by different groups. Several groups have claimed the best results in nontumor cases with repeated courses of plasmapheresis in combination with prednisone and azathioprine or prednisone alone (Streib and Rothner; Dau and Denys). IVIg has also been effective in a few reported cases. The benefit is a result of a reduction in calcium channel autoantibodies, but the mechanism whereby IVIg produces this effect could not be established (Bain and coworkers). Many clinicians prefer alternate-day administration of prednisone and azathioprine (prednisone 25 to 60 mg/d, and azathioprine 2–3 mg/kg body weight daily) supplemented intermittently as needed by IVIg. The response to treatment tends to be slow, over a period of months and sometimes up to a year. Some patients recover fully; in others, restoration of power is incomplete. The oral potassium channel blocker, amifampridine, has been approved for the treatment of LEMS in 6 to 17-year-olds and is supported by several clinical trial results (Oh et al). It has been tried as well in adults with LEMS and in congenital myasthenic syndromes but with less compelling evidence.

Diagnosis A syndrome of symmetrical weakness and fatigability of proximal muscles coupled with dry mouth, sphincter disturbances, aching muscles, and diminished reflexes are diagnostic. The illnesses with which it might be confused are myasthenia gravis, inclusion body myopathy, and polymyositis. There is a superficial resemblance to hysterical paralysis, where the patient may do better with encouragement on making a succession of voluntary contractions, and arthritis, where pain hampers the first movements more than the successive ones. Then the electrodiagnostic and specific serologic tests are of value.

Neonatal Myasthenia Gravis

An estimated 10 to 20 percent of babies born to mothers with myasthenia show transient signs of myasthenia (hypotonia, weak cry, and suck). This transitory phenomenon is apparent at birth and has a mean duration of about 2 to 5 weeks; recovery is usually complete within 2 months of birth (rarely longer), without later relapse. Uncommonly, the mother with myasthenia reports reduced intrauterine movements, suggesting a dangerous degree of myasthenia in the fetus. A few of these children will be born with arthrogryposis, the result of a sustained period of intrauterine immobility, and this complication tends to recur in subsequent births.

It has long been assumed that neonatal myasthenia is a result of the passive transplacental transfer of AChR antibodies. This explanation is not entirely satisfactory insofar as maternal AChR antibodies are transferred from mother to fetus in all AChR antibody-positive pregnancies and the incidence and severity of neonatal myasthenia gravis do not correlate with the severity or duration of the mother's illness or with the serum level of the maternal AChR antibody. In fact, neonatal myasthenia may occur when the mother is in remission.

Administration of plasma exchange and anticholinesterase drugs to the infant may be useful in hastening recovery from neonatal myasthenia.

Congenital Myasthenic Syndromes (See Table 46-3)

The congenital myasthenic syndromes are inherited defects in components of the presynaptic, synaptic, or postsynaptic junctional apparatus (Table 46-3). In the 1970s and 1980s, after the autoimmune basis of myasthenia gravis was established and its morphologic and physiologic features defined, the differences between this disease and familial infantile forms became evident. Since then, at least eight distinct and rare congenital myasthenic syndromes have been delineated on the basis of their electrophysiologic and ultrastructural features, and a number of others have been partially characterized. Broadly speaking, the defects involve resynthesis or packaging of ACh or a paucity of synaptic vesicles (presynaptic); deficient quantal release; a deficiency of endplate ACh esterase (synaptic); or kinetic abnormalities in the AChR channels or AChR deficiency (postsynaptic). It has been estimated that in three-fourths of the cases, the defect is postsynaptic.

These disorders are distinguished by neonatal onset, fluctuating and sometimes progressive weakness that may be quite severe, sometimes pronounced muscle hypotrophy, persistent ptosis, and seronegativity for anti-AChR and anti-MuSK antibodies. Moreover, heritability (typically autosomal recessive) is suggested by the familial occurrence of the disorders among siblings. The most important clue to the disease in the neonate is an increase in ptosis and in bulbar and respiratory weakness

Table 46-3

HEREDITARY AND CONGENITAL MYASTHENIC SYNDROMES

MYASTHENIC SYNDROME	CAUSAL AGENT OR GENE DEFECT	ONSET DECADE	TREATMENT	CLINICAL FEATURES
Presynaptics				
Episodic apnea	Choline acetyltransferase	1st	AChE inhibitors	Mild episodes of weakness; recurrent apnea
			Apnea monitor	Ptosis common
Paucity of synaptic vesicles	Unknown	1st	AChE inhibitors	Recurrent, sometimes pronounced weakness
Reduced quantal release of acetylcholine	Unknown	1st	AChE inhibitors and 3,4-aminopyridine	Wasting, respiratory failure, dysmorphism
Synaptic				
AChE deficiency	AChE Collagen tail for AChE	1st	None Avoid AChE inhibitors	Diffuse weakness, ptosis
DOK-7 "synopathy"	DOK-7 mutation	1st	None	Limb-girdle, ptosis
Postsynaptic				
Slow channel syndrome	AChR subunits	1st to 6th	Quinidine, AChE inhibitors	Ptosis, diffuse weakness, delayed motor milestones
			Avoid 3,4-DAP	Often show atrophy of dorsal forearms
Fast channel syndrome	AChR subunits	1st	3,4-DAP	Ptosis, recurrent weakness, motor development delays
Primary AChR deficiency	AChR subunits	1st	AChE inhibitors, 3,4-DAP	Ptosis, recurrent weakness, motor development delays
Rapsyn deficiency	Rapsyn	1st	AChE inhibitors, 3,4-DAP	Ptosis, recurrent weakness
Plectin deficiency	Plectin	1st	3,4-DAP	Myasthenic features, epidermolysis bullosa
Escobar syndrome	Defective fetal γ-AChR subunit	In-utero	Maturity with replacement of γ - with ε-AChR subunit	Arthrogryposis, respiratory failure, pterygium (webbing of skin)

AChE, acetylcholinesterase; AChR, acetylcholine receptor; DAP, diaminopyridine; .

with crying. Later in infancy, these symptoms, as well as fluctuating ocular palsies and abnormal fatigability, are brought out by other types of sustained activities. Motor milestones may be delayed. In some cases, myasthenic weakness and fatigability do not become evident until the second and third decades of life. Testing with anticholinesterase drugs is inconsistently positive in a few forms of congenital myasthenia, as mentioned further on, but it usually is negative.

Two of the congenital myasthenic diseases—*fast channel syndrome* and *slow channel syndrome*—are consequences of mutations in AChR subunits that accelerate (fast channel) and slow (slow channel) the kinetics of gating of receptor channel (Croxen et al). Another well-characterized type, usually causing arthrogryposis and recurrent apneic spells but occasionally having an adult-onset (as late as 48 years), has been traced to mutations in the "rapsyn" gene. The rapsyn protein plays a role in maintaining the integrity of the postsynaptic membrane (see Burke et al). Deficiency of the enzyme required to synthesize and package ACh in vesicles (choline acetyltransferase) causes a congenital myopathy with episodes of stress-induced apnea. In another type, the synaptic vesicles form poorly and are reduced in number. Being largely presynaptic defects, both of these disorders respond to acetylcholine esterase (AChE) inhibitors. In comparison, children with congenital myasthenia as a result of deficiency of AChE deteriorate markedly if given AChE inhibitors. Three disorders affecting postsynaptic structures (the fast-channel syndrome, AChR deficiency, and the myasthenic syndromes associated with deficiencies of rapsyn and plectin) also respond to AChE inhibition and 3,4-DAP, although both agents are hazardous in individuals with the slow-channel syndrome.

Another form of congenital myasthenia is caused by a recessive mutation in *DOK-7* that causes a simplified structure of the synapse but no alteration in AChRs (Beeson et al). The clinical features are of a limb-girdle pattern of weakness that causes a delay in walking after the child has reached other normal motor milestones and of ptosis from an early age (Palace and colleagues).

A further category of congenital syndromes of defects in the presynaptic quantal release of ACh linked to an intriguing prenatal myasthenic disease called *Escobar syndrome* (arthrogryposis, pterygia, and respiratory distress) has been traced to mutations in the gamma subunit of the AChR, a component expressed only in fetal life and replaced with maturity by the epsilon subunit (Milone and colleagues; Hoffmann and coworkers).

The studies of A.G. Engel have systematically defined and classified these disorders in a series of extensive investigations of more than 100 cases (Engel et al, 2003).

Myasthenic Weakness Caused by Antibiotics, Other Drugs, and by Environmental Toxins (See Chap. 41 and Table 46-2)

Many drugs can cause a myasthenic syndrome or a worsening of myasthenia gravis by their action on pre- or postsynaptic structures. In the case of a nonmyasthenic patient, this is most likely to happen in the presence of hepatic or renal disease that allows excessive accumulation of the causative agent. The myasthenic state in these conditions is acute and lasts hours or days, with full recovery provided that the patient does not succumb to respiratory failure.

The ocular, facial, and bulbar muscles are involved, just as in native myasthenia. The treatment is to provide respiratory support, discontinue the offending drug, and attempt to reverse the conduction block at the motor endplate by infusions of calcium gluconate, potassium, and anticholinesterases (Argov and Mastaglia).

There are more than 30 drugs in current clinical use (other than anesthetic agents) that may, under certain circumstances, interfere with the neuromuscular transmission in otherwise normal individuals. Of these, the most important is the aminoglycoside and quinolone antibiotics. Myasthenic weakness has been reported with 18 different antibiotics, but particularly neomycin, kanamycin (less so with gentamicin), colistin, streptomycin, polymyxin B, and certain tetracyclines (McQuillen et al; Pittinger et al). It has been shown that these drugs impair transmitter release by interfering with calcium ion fluxes at nerve terminals. The fluorinated quinolones (fluoroquinolones)—typified by ciprofloxacin—affect both pre- and postsynaptic activity. They are especially hazardous when given to patients with myasthenia, but they may be used if necessary to treat infections in patients who are already receiving ventilatory support.

Other agents—particularly the organophosphate insecticides and nerve gases—cause paralysis by binding to cholinesterase and blocking the hydrolysis of ACh. The endplate remains depolarized and is refractory to neural stimuli. The most notable of these agents are (1) botulinum toxin, which binds to cholinergic motor endings, blocking quantal release of ACh; (2) black widow spider venom, which causes a massive release of ACh, resulting in muscular contraction and then paralysis from a lack of ACh; (3) *d*-tubocurarine, which binds to AChR; (4) suxamethonium and decamethonium, which also bind to AChR; (5) organophosphates, which bind irreversibly to AChE; and (6) malathion and parathion, which inhibit AChE. The actions of all these agents except for the organophosphate "nerve gases" are transitory.

The administration of *d*-penicillamine has also caused an unusual type of myasthenia. The weakness is typical in that rest increases strength—as do neostigmine and edrophonium—and the electrophysiologic findings are also the same. In such cases, anti-AChR antibodies can be identified in the serum; hence, one must assume that this is a form of induced autoimmune myasthenia gravis (Vincent and associates). In these respects, it differs from the weakness caused by aminoglycosides (Swift). Rarely, typical autoimmune myasthenia gravis develops as part of a chronic graft-versus-host disease in long-term (2- to 3-year) survivors of allogeneic marrow transplants.

A large group of naturally occurring environmental neurotoxins is known to act at the neuromuscular junction and to induce muscle paralysis of a pattern like that of myasthenia gravis. Venoms of certain snakes, spiders, and ticks are common and well-known animal poisons, as are ciguatera and related toxins (from fish that have ingested certain dinoflagellates), curare (from plants), and *Clostridium botulinum*—all of which are discussed in Chap. 41. Poisoning by these natural neurotoxins constitutes an important public health hazard in many parts of the world (Senanayake and Roman).

MYOTONIAS, PERIODIC PARALYSES, AND STATES OF PERSISTENT MUSCLE FIBER ACTIVITY (CHANNELOPATHIES)

Myotonias were historically categorized as a special group of muscle diseases unified by the clinical sign of myotonia and were aligned in older classifications with muscular dystrophies. This view was based on myotonia as it was understood in the classic form of myotonic dystrophy, a subject discussed in Chap. 45. Similarly, before fundamental knowledge of their mechanism was revealed, periodic paralyses (better called *episodic paralysis*) were considered to be metabolic diseases of muscle. However, it has become evident that most diseases that feature prominent myotonia and the processes that cause episodic muscular paralysis are neither degenerative nor dystrophic. Clinical and electrophysiologic studies show that myotonia is an elemental feature of many nondystrophic conditions, foremost among them are the hyperkalemic form of periodic paralysis and myotonia congenita. Most of these diseases are caused by mutations in genes that code for chloride, sodium, calcium, or potassium ion channels in the muscle membrane, and they are referred to as *ion channel diseases* or *channelopathies* (see Ryan and Ptácek). Within this group, there are also instances of muscle conditions that display no myotonia but only periodic paralysis.

Given that these are disorders of muscle membrane excitability, it is not surprising that the primary defects are in voltage-dependent ion channels. By analogy, it was anticipated that ion channelopathies would be implicated in 2 other categories of disease in which there is altered membrane excitability, namely epilepsies and certain cardiac arrhythmias, and indeed, this has proven to be the case (see discussion in Chap. 15 on the epilepsies). In the process, several new forms of nondystrophic myotonia have been defined. Molecular studies have identified the fundamental defects in myotonias and episodic paralyses and clarified their relationships (Rüdel and associates; Hanna and colleagues; Cannon; Heatwole and colleagues). Table 46-4 summarizes the main features of the ion channel diseases affecting muscle and the individual members of the group are described as follows.

Chloride Channel Diseases

Myotonia Congenita (Thomsen Disease)

This is an uncommon disease of skeletal muscle that begins in early life and is characterized by myotonia, muscular hypertrophy, nonprogressive course, and dominant inheritance. It is distinctly different from myotonic dystrophy, which is characterized by a progressive degeneration of muscle fibers and has a different genetic basis. Thomsen disease is caused by one of several inherited molecular defects in the voltage-dependent chloride channel gene (*CLCN1*) (see Koch et al). It is interesting that most mutations behave as dominant traits, whereas others have either a dominant or recessive pattern of inheritance (see Table 46-4). The physiologic mechanism whereby these

mutations alter ion fluxes across the muscle membrane and cause myotonia is described further on.

History The disorder was first brought to the attention of the medical profession in 1876 by Julius Thomsen, a Danish physician who himself suffered from the disease, as did 20 members of his family over 4 generations. His designation of ataxia muscularis was not correct, but his description left no doubt as to the nature of the condition in that it featured "tonic cramps in voluntary muscles associated with an inherited psychical indisposition." The latter aspect of the condition was not borne out by subsequent studies and is now thought to be his erroneous speculation as to causality. In 1881, Strümpell assigned the name *myotonia congenita* to the disease, and in 1883, Westphal referred to it as *Thomsen's disease*. Erb provided the first description of its pathology and called attention to two additional unique features: muscular hyperexcitability and hypertrophy. In 1923, Nissen, Thomsen's great-nephew, extended the original genealogy to 35 cases in 7 generations, and in 1948, Thomasen's monograph is still a useful clinical reference.

Myotonia, a tonic spasm of muscle after forceful voluntary contraction, stands as the cardinal feature and is best represented in this disease. As emphasized in Chaps. 2 and 45, this phenomenon reflects the electrical hyperexcitability of the muscle membrane. The electrophysiologic representation of the spasm is shown in Fig. 2-19, and a description of the physiology can be found in Chap. 2. It is most pronounced after a period of inactivity. Repeated contractions "wear it out," so to speak, and the later movements in a series become more swift and effective. Rarely, the converse is observed—where only the later movements of a series induce myotonia (*myotonia paradoxica*); usually, this is a feature of another condition, cold-induced paramyotonia congenita (see further on). Unlike cramp, the myotonic spasm is painless, but after prolonged activity, nocturnal myalgia (a pinching-aching sensation in the overactive muscles) may develop and prove distressing. Close observation reveals a softness of the muscles during rest and the initial contraction appears not to be significantly slowed.

The disease, myotonia congenita, as mentioned above, is usually inherited as a dominant trait so that most often, other members of the family have been affected. Its congenital nature may be evident even in the crib, where the infant's eyes are noted to open slowly after it has been crying or sneezing and its legs are conspicuously stiff as the child tries to take its first steps. In other cases, the myotonia becomes evident only later in the first or second decade. The muscles are generously proportioned and may become hypertrophied but seldom to the degree observed in the recessive form of the disease described further on.

Despite their muscular appearance, these patients do not do well in athletic pursuits as a result of myotonia. When severe, myotonia affects all skeletal muscles but is especially prominent in the lower limbs. Attempts to walk and run are impeded to the extent that the patient stumbles and falls. Other limb and trunk muscles are also thrown into spasm, as are those of the face and upper limbs. One of the characteristic features is grip myotonia in which the patient is unable to release a handshake and must slowly open the fingers one at a time. Occasionally a sudden noise or fright may cause generalized stiffness and falling. Small, gentle movements such as blinking or elicitation of a tendon reflex do not initiate myotonia, whereas strong closure of the eyelids, as in a sneeze, sets up a spasm that may prevent the complete opening of the eyes for many seconds. Spasms of extraocular muscles occur in some instances, leading to strabismus. If the patient has not spoken for a time, there is sometimes striking dysarthria. Arising at night, the patient cannot walk without first moving the legs for a few minutes. After a period of rest, the patient may have difficulty in arising from a chair or climbing stairs. Loosening of one set of muscles after a succession of contractions does not prevent the appearance of myotonia in another area, nor in the same ones if used in another pattern of movement. Smooth and cardiac muscles are not affected and intelligence is normal. Lacking also are the narrow face, frontal balding, cataracts, and endocrine changes typical of myotonic dystrophy that is discussed in Chap. 45. Myotonia that is evident in infancy is far more likely to represent myotonia congenita than myotonic dystrophy, in which myotonia rarely has its onset in the first few years of life.

Myotonia can also be induced in most cases by tapping a muscle belly with a percussion hammer (percussion myotonia). Unlike the lump or ridge produced in hypothyroid or cachectic muscle (myoedema), the myotonic contraction involves an entire fasciculus or an entire muscle and, unlike the phenomenon of idiomuscular irritability (contraction of a fascicle in response to striking the muscle), it persists for several seconds. If tapped, the tongue shows a similar reaction. An electrical stimulus delivered to the motor point in a muscle induces a prolonged contraction (Erb myotonic reaction). In Thomsen disease, as in virtually all forms of myotonia, the stiffness is somewhat exaggerated in the cold. On a cold day, affected individuals may have a prolonged grimace with closed eyes after a sneeze. We encountered two brothers with this disorder who described diving into a cool swimming pool on a hot summer day and having to lie nearly motionless at the bottom of the pool for several seconds until the muscle stiffness abated enough to allow them to swim to the top. However, as mentioned, prominent cold-induced myotonia is more characteristic of paramyotonia congenita (see later).

Biopsy reveals no abnormality other than enlargement of muscle fibers, and this change occurs only in hypertrophied muscles. As often happens in fibers of increased volume, central nucleation is somewhat more frequent than it is in normal muscle. The large fibers contain increased numbers of normally structured myofibrils. In well-fixed biopsy material examined under the electron microscope, no significant morphologic changes have been identified (Schröder and Adams).

Myotonia levior was the name applied by DeJong to a dominantly inherited form of myotonia congenita in which the symptoms are milder and of later onset than those of Thomsen disease. In 2 patients of a myotonia levior family, a mutation of the same chloride ion channel (CLCN1) that is implicated in Thomsen's disease has been identified (Lehmann-Horn and coworkers, 1995). Thus it appears that myotonia levior is simply a mild form of Thomsen disease.

Diagnosis In patients who complain of spasms, cramping, and stiffness, myotonia must be distinguished from several of the disorders of persistent muscle activity described further on and in Chap. 45. None of these disorders displays percussion myotonia or the typical electromyogram (EMG) abnormality of myotonic discharge. The only possible exceptions are the Schwartz-Jampel syndrome of hereditary stiffness combined with short stature and muscle hypertrophy and stiff man syndrome, which are discussed further on and in Chap. 45.

Uncertainty in diagnosis arises in patients who have only myotonia in early life and later prove to have classic (type 1) myotonic dystrophy or who notice myotonia in adulthood with mild proximal weakness and are found to have type 2 myotonic dystrophy. The myotonia in myotonic dystrophy is usually mild and in several families that we have followed, some degree of weakness and the typical facies of myotonic dystrophy could be appreciated even in early childhood. This is not the case in the less-frequent type 2 myotonic dystrophy in which there are no dysmorphic features (also called proximal myotonic myopathy [PROMM]; see Chap. 45 and further on). In paramyotonia congenita there is also myotonia of early onset, but, again, it tends to be mild, involving mainly the orbicularis oculi, levator palpebrae, and tongue; the diagnosis of paramyotonia is seldom in doubt because of the worsening with continued activity and prominent cold-induced episodes of myotonia and paralysis.

In patients with very large muscles, one must consider not only myotonia congenita but also familial hyperdevelopment, hypothyroid myopathy, the Bruck-de Lange syndrome (congenital hypertrophy of muscles, mental retardation, and extrapyramidal movement disorder), Becker myotonia, Duchenne dystrophy, and most of all, hypertrophic myopathy (hypertrophia musculorum vera); this last disease is of interest because the aberrant protein (myostatin) and gene defect have been characterized. Muscle hypertrophy is not a feature of myotonic dystrophy. The demonstration of myotonia by percussion and EMG study usually resolves the problem, although, in exceptional cases of Thomsen disease, the persistence of contraction may be difficult to demonstrate. In hypothyroidism, the EMG may show bizarre high-frequency (pseudomyotonic) discharges; however, true myotonia does not occur, myoedema is prominent, and, along with other signs of thyroid deficiency, there is slowing of contraction and relaxation of tendon reflexes not seen in myotonia congenita.

Treatment Quinine is effective in reducing myotonia but is now used infrequently because of the (low) risk of causing torsade de pointes. Procainamide, 250 to 500 mg qid, and mexiletine, 100 to 300 mg tid, are beneficial in relieving the myotonia, but they, too, have fallen out of favor for various reasons. Phenytoin, 100 mg tid, is useful in some cases. The cardiac antiarrhythmic drug tocainide (1,200 mg daily) has also proved effective, but it sometimes causes agranulocytosis and is no longer recommended. A trial has shown that mexiletine may be useful in a group of rare nondystrophic myotonias (Statland et al).

Generalized Myotonia (Becker Disease)

This is the second form of congenital myotonia, inherited as an autosomal recessive trait. Like the dominant Thomsen form, it is caused by an allelic mutation of the gene encoding the chloride ion channel of the muscle fiber membrane. The clinical features of the dominant and recessive types are similar except that myotonia in the recessive type does not become manifest until 10 to 14 years of age, or even later, and tends to be more severe in the dominantly inherited variety. The myotonia appears first in the lower limbs and spreads to the trunk, arms, and face. Hypertrophy is invariably present. There may be associated mild distal weakness and atrophy; this was found in the forearms in 28 percent of Becker's 148 patients and in the sternocleidomastoids in 19 percent. Dorsiflexion of the feet was limited and fibrous contractures were common. Weakness may also be present in the proximal leg and arm muscles. The most troublesome aspect of the disease is the transient weakness that follows initial muscle contraction after a period of inactivity. Progression of the disease continues until about 30 years of age, and the course of the illness thereafter remains unchanged (Sun and Streib). In contrast to Thomsen disease, creatine kinase (CK) may be elevated. Testicular atrophy, cardiac abnormality, frontal baldness, and cataracts—the features that characterize myotonic dystrophy—are conspicuously absent.

Sodium Channel Diseases

The main diseases in this category are *hyperkalemic periodic paralysis* and *paramyotonia congenita*. The derivative disorders *normokalemic periodic paralysis*, *acetazolamide-responsive myotonia*, *myotonia fluctuans*, and *myotonia permanens* are variants of hyperkalemic periodic paralysis. All of them are caused by mutations in the gene encoding the alpha subunit of the membrane-bound voltage-gated sodium channel in skeletal muscle (*SCN4A*).

Hyperkalemic Periodic Paralysis

The essential features of this disease are an episodic generalized weakness of fairly rapid onset and a rise in serum potassium during attacks. Weakness appearing after a period of rest that follows exercise is particularly characteristic. This type of periodic paralysis was first described and distinguished from the more common (hypokalemic) form by Tyler and colleagues in 1951. Five years later, Gamstorp described two additional families with the disorder and named it *adynamia episodica hereditaria*. As further examples were reported, it was noted that in many of them, there were minor degrees of myotonia, which brought the condition into relation with paramyotonia congenita (see further on). Hyperkalemic periodic paralysis is associated with a defect in the alpha subunit of the sodium channel gene (Fontaine et al, 1990). It is now appreciated that there are distinct variants of hyperkalemic periodic paralysis that are genetically distinct. All are associated with membrane hyperexcitability because of delays in sodium channel inactivation following membrane depolarization, as discussed later.

Clinical Manifestations

The pattern of inheritance is autosomal dominant, as noted, with onset usually in infancy and childhood. Characteristically, attacks of weakness occur before breakfast and later in the day, particularly when resting following exercise. In the latter case, the weakness appears after 20 to 30 min of becoming sedentary. The patient notes difficulty that begins in the legs, thighs, and lower back and spreads to the hands, forearms, and shoulders over minutes or more. Only in the severest attacks are the neck and cranial muscles involved; respiratory muscles are usually spared. As the muscles become inexcitable, tendon reflexes are diminished or lost. Attacks usually last 15 to 60 min, and recovery can be hastened by mild exercise. After an attack, mild weakness may persist for a day or 2. In severe cases, the attacks may occur every day; during late adolescence and the adult years, when the patient becomes more sedentary, the attacks may diminish and even cease entirely. In certain muscle groups, if myotonia coexists, it is difficult to separate the effects of weakness from those of myotonia. Indeed, when an attack of paresis is prevented by continuous movement, firm, painful lumps may form in the calf muscles. Usually, however, the presence of myotonia can only be detected electromyographically. Some patients with repeated attacks may be left with permanent weakness and wasting of the proximal limb muscles.

During the attack of weakness, serum K rises, often, but not always, up to 5 to 6 mmol/L. This is associated with increased amplitude of T waves in the electrocardiogram (ECG) and a fall in the serum Na level (because of the entry of Na into the muscle). With increased urinary excretion of K, the serum K falls and the attack terminates. Between attacks, serum K is usually normal or only slightly elevated.

The attacks of paralysis are virtually alike in all clinical variants of the disease. In the paramyotonic form discussed below, the attacks are associated with paradoxical myotonia (myotonia induced by exercise and also by cold).

The provocative test, undertaken under careful supervision when the patient is functioning normally, consists of the oral administration of 2 g of KCl in a sugar-free liquid repeated every 2 h for 4 doses if that many are necessary to provoke an attack. The test is given in the fasting state, ideally just after exercise. The weakness typically has a latency of 1 to 2 h after the administration of K. The patient must be carefully monitored by ECG and frequent serum estimations of serum potassium. The test should never be undertaken in the presence of an attack of weakness, or when there is reduced renal function, or in those with diabetes requiring insulin.

The treatment of this syndrome is the same as that for paramyotonia congenita, described further on.

Normokalemic periodic paralysis This form of episodic paralysis resembles the hyperkalemic form in practically all respects except that serum potassium does not increase out of the normal range, even during the most severe attacks. However, some patients with normokalemic periodic paralysis are sensitive to potassium loading (Poskanzer and Kerr); other kindreds are not (Meyers et al). The disorder is also transmitted as an autosomal dominant trait and the basic defect has proved to stem from the same mutation as that of hyperkalemic periodic paralysis of which it may be considered a variant.

Paramyotonia Congenita (Eulenburg Disease)

Clinical manifestations In this disease, attacks of periodic paralysis are associated with myotonia, which may be paradoxical in type—that is, developing during exercise and worsening as the exercise continues. In addition, a widespread myotonia, often coupled with weakness, is induced by exposure to cold. In some patients, the myotonia can be elicited even in a warm environment. The weakness may be diffuse, as in hyperkalemic periodic paralysis, or limited to the part of the body that is cooled. As commented in the earlier sections, cold exaggerates many types of myotonia to some extent, but this property is most characteristic of paramyotonia, and it is in this condition that cold-induced weakness persists for up to several hours once started, even after the body is rewarmed. Percussion myotonia can be evoked in the tongue and thenar eminence. Myotonia that is constantly present in a warm environment diminishes with repeated contraction, whereas myotonia induced by cold increases with repeated contraction (paradoxical myotonia) (Haass and colleagues).

Like hyperkalemic periodic paralysis, paramyotonia congenita is transmitted in an autosomal dominant manner and both diseases have been linked to the same gene (*SCN4A*), which encodes the alpha subunit of the muscle membrane sodium channel; the two mutations are allelic.

Laboratory findings In both hyperkalemic periodic paralysis and paramyotonia congenita, the serum K is usually above the normal range during bouts of weakness, but paralysis has been observed at levels of 5 mEq/L and lower. Each patient appears to have a critical level of serum K, which, if exceeded, will be associated with weakness. (This has led some authors to term the periodic paralysis as potassium dependent.) The administration of KCl, raising serum K to above 7 mEq/L, a level that has no effect on normal individuals, invariably induces an attack. As mentioned earlier, the ECG must be monitored during such provocative testing. The EMG shows myotonic discharge in all muscles, even at normal temperatures. The CK may be elevated.

In vitro studies of muscle from patients with cold-induced stiffness and weakness have shown that as the temperature is reduced, the muscle membrane is progressively depolarized to the point where the fibers are inexcitable (Lehmann-Horn et al, 1987). A sodium channel blocker (tetrodotoxin) prevents the cold-induced depolarization. In patients with paramyotonia, but not in those with hyperkalemic periodic paralysis, a diminution of the compound muscle action potential in response to the cooling of muscle occurs, largely settling the argument as to whether the two syndromes (hyperkalemic paralysis and paramyotonia) are the same or different (Subramony and colleagues).

Some patients with paramyotonia, like those with certain other forms of periodic paralysis, may, in later life, slowly develop a myopathy that causes persistent weakness. In some cases, this is sufficiently severe that it mimics

the pattern of late-onset limb-girdle muscular dystrophy. However, in the case of paramyotonia there are relatively few histologic changes, primarily vacuoles in some of the muscle fibers and minimal evidence of myofiber degeneration.

Treatment Most patients with hyperkalemic periodic paralysis and its variants benefit from prophylactic use of the carbonic anhydrase inhibitor acetazolamide, 125 to 250 mg bid or tid (paradoxically, as it has a tendency to produce potassium retention). Acetazolamide reduces the frequency of attacks and may provide some relief from myotonia. There are no controlled studies of acetazolamide in these disorders, but trials of the related carbonic anhydrase inhibitor, dichlorphenamide demonstrated a reduced frequency of paralytic spells in both hyper- and hypokalemic forms of periodic paralysis (Tawil et al; Sansone et al, 2016). However, in some patients, the attacks of hyperkalemic paralysis and of paramyotonia congenita are too infrequent, too brief, or too mild to require continuous treatment.

The administration of diuretics such as hydrochlorothiazide (0.5 g daily), keeping the serum K below 5 mEq/L, also prevents attacks but risks inducing dangerous degrees of hypokalemia. When the myotonia is more troublesome than the weakness, mexiletine 200 mg tid is perhaps the best alternative because it prevents both cold- and exercise-induced myotonia, but it does not influence the frequency of acute attacks. Some additional benefits may be gained by adding inhaled beta-adrenergic agonists such as albuterol or salbutamol. Some studies suggest that one agent in this class, clenbuterol, may have a direct effect in blocking the sodium channel, independent of its activation of adrenergic receptors. Procainamide or the lidocaine derivative tocainide, in doses of 400 to 1,200 mg daily, is also useful for myotonia (tocainide carries a small risk of agranulocytosis).

For the treatment of an acute and severe episode, intravenous calcium gluconate (1–2 g) often restores power. If, after a few minutes, this treatment is unsuccessful, intravenous glucose or glucose and insulin and hydrochlorothiazide should be tried so as to reduce the serum potassium concentration.

Other Sodium Channel Disorders

Several other clinical presentations of hereditary periodic paralysis have been linked to mutations of the gene encoding the alpha subunit of the skeletal muscle sodium channel and probably represent variants of the disease. One of these has been designated *myotonia fluctuans* because muscle stiffness fluctuated in severity from day to day (Ricker and colleagues, 1994). In other respects, the clinical features resemble those of myotonia congenita, including provocation of attacks of myotonia by exercise. The muscle stiffness is only slightly sensitive to cold but is markedly aggravated by the ingestion of potassium and, interestingly, never progresses to muscular weakness or paralysis. *Myotonia permanens* is the name given to a severe, persistent myotonia and marked hypertrophy of muscles, particularly of the neck and shoulders. The EMG discloses continuous muscle activity. This disease was discovered in the course of genotyping a patient who earlier had been reported as an example of "myogenic" Schwartz-Jampel syndrome, but it affects the same channel as in hyperkalemic periodic paralysis (Spaans and associates).

Trudell and colleagues studied 14 patients from a large kindred with autosomal dominant myotonia, the main feature of which was periodic worsening of myotonia accompanied by muscle pain and stiffness, most severe in the face and hands. The symptoms were enhanced by cold (suggesting paramyotonia) and severe stiffness and palpable rigidity followed within 15 min of the ingestion of potassium, but neither of these measures provoked muscle weakness. Muscle biopsy disclosed a normal ratio of types 1, 2A, and 2B fibers, further distinguishing this disorder from typical myotonia congenita, where 2B fibers may be reduced in number. All patients in this family who were treated with the carbonic anhydrase inhibitor acetazolamide had a dramatic resolution of symptoms within 24 h, hence the name *acetazolamide-responsive myotonia*. This disorder has been linked to the same molecular alteration of the sodium channel gene as occurs in hyperkalemic periodic paralysis (Ptácek et al, 1994b).

Rosenfeld and coworkers described yet another form of *painful congenital myotonia* attributable to a novel mutation in the sodium channel alpha-subunit gene (*SCN4A*). Affected members of this family experienced debilitating pain, particularly severe in the intercostal muscles. Also, the pain was resistant to treatment with acetazolamide and other antimyotonic drugs (mexiletine and tocainide) and could not be provoked by ingestion of potassium-rich foods, differing from even rarer similar cases that are acetazolamide responsive.

Finally, in regard to disorders of the sodium channel, it should be mentioned that the marine toxins (ciguatoxin, tetrodotoxin, saxitoxin) discussed in Chap. 41, produce their effects on the peripheral and central nerves by blocking sodium channels but have a little obvious effect on muscle function.

Pathophysiology of Myotonia and Hyperkalemic Periodic Paralysis (See Also Chap. 2)

In both myotonia congenita and hyperkalemic paralysis, the absence of major morphologic changes and the prominence of the myotonic phenomenon in individual muscle fibers are consistent with a disorder of the sodium channel. This is also compatible with the observation that myotonia persists after the administration of curare, thereby exonerating neural input as the source of myofiber hyperexcitability.

The electromyographic pattern of a myotonic muscle reveals highly characteristic discharges that persist following the cessation of voluntary contraction. The tension of the myotonic muscle fibers is slow to diminish as a result of these greatly prolonged trains of muscle action potentials (see Fig. 2-19). Some of these afterdischarge potentials are the size of fibrillations, but others are as large as normal motor units. Thus myotonia can be distinguished electrophysiologically from contracture (e.g., that encountered in McArdle disease, in which the muscle is electrically silent). In experiments conducted in the 1940s, Denny-Brown and Foley, stimulating single muscle fibers directly, found that

myotonic discharges could be elicited only by a volley of stimuli and not by a single stimulus. They also noted that the series of myotonic potentials progressively diminished in size. Percussion elicits myotonia by imparting a brief but relatively intense repetitive excitation of the muscle membrane.

The biophysical basis of myotonia is now well understood in terms of the functioning of chloride and sodium channels in the muscle membrane and internal structures. The correspondence between mathematical models of the electrical properties of the membrane and the clinical features of the myotonic and periodic paralyses is quite remarkable. During the normal action potential in all neural and muscular tissue, membrane depolarization is terminated by two events: the depolarization-induced inactivation of the sodium channel (which ends the inward sodium current) and the subsequent action of the outward potassium current. In muscle, the termination of an action potential requires an additional factor. Because of its large size, excitation of the muscle fiber involves depolarization that propagates not only along the cell surface but also radially into the center of the muscle cell through the transverse tubules (T tubules). The tubules are very narrow structures whose internal spaces are in continuity with the extracellular space. When the repolarizing outward potassium current is activated, potassium ions flood into the tubules from the muscle cytoplasm. By itself, this tubular K accumulation would depolarize the muscle membrane and prolong excitation. Normally, this does not occur because there is a large opposing chloride conductance in the tubules that counteracts the influence of potassium accumulation.

The first clues to the importance of the chloride channel in this electrical stabilizing process were demonstrated in vitro studies of myotonic goat muscle that showed reduced chloride conductance in the transverse tubular system (Bryant, 1979). Subsequent studies of muscle from patients with myotonia congenita demonstrated a similarly low chloride conductance (Lipicky and Bryant). That a mutation in a muscle chloride channel could produce myotonia was confirmed in a mouse model by Jentsch and Steinmeyer and colleagues (see Koch et al), who subsequently also described the first human chloride channel (*CLCN1*) mutations.

As indicated, an essential event for normal repolarization of an excitable membrane is the rapid inactivation of the inward sodium current. This process of rapid, complete sodium channel inactivation is impaired by the sodium channel mutations implicated in hyperkalemic periodic paralysis. The mutations cause imperfect inactivation of the channel and lead to aberrant and early reopenings. Repolarization is then incomplete, rendering the muscle cell more readily re-excited; it is this hyperexcitability that causes the myotonia of hyperkalemic periodic paralysis. The problem becomes self-reinforcing because, as the membrane fails to repolarize fully, its electrolytic inactivation becomes increasingly less effective. If this process is not aborted, the result is such excessive depolarization that the muscle cell ultimately becomes unexcitable—a state that corresponds to the paralytic phase of hyperkalemic periodic paralysis. These features are evident in hyperkalemic muscle in vitro (Cannon et al) and can be recapitulated in computer simulations of aberrant channels. Presumably, over several hours, a variety of compensatory mechanisms (e.g., activation of Na-K adenosine triphosphatase [ATPase] pumps) restores the baseline excitability of the muscle membrane.

Calcium Channel Diseases

Hypokalemic Periodic Paralysis

This is the best-known form of periodic paralysis. The history of the disease is difficult to trace, but the first unmistakable account was probably that of Hartwig in 1874, followed by the accounts of Westphal (1885) and Oppenheim (1891). Goldflam (in 1895) first called attention to the remarkable vacuolization of the muscle fibers that is characteristic of the process (Talbott; Layzer; Lehmann-Horn and associates, 2004). In 1937, Aitken and associates described the occurrence of low serum potassium during attacks of paralysis and the reversal of the paralysis by the administration of potassium, thus setting the stage for subsequent differentiation from the hyperkalemic forms of periodic paralysis.

The usual pattern of inheritance is autosomal dominant with reduced penetrance in women (male-to-female ratio of 3 or 4:1). The mutation was localized to a region containing the gene that encodes the alpha subunit of the calcium channel of skeletal muscle and missense mutations in the responsible gene (*CACNA1S*) have been identified (Fontaine and coworkers, 1990 and 1994). The subunit, which is part of the dihydropyridine receptor complex, is located in the transverse tubular system. This region is believed to act both as a voltage sensor that controls calcium release from the sarcoplasmic reticulum, thus mediating muscle excitation–contraction coupling, and as a calcium-conducting pore. How precisely the reduced calcium channel function relates to hypokalemia-induced attacks of muscle weakness is not fully known, but most of the mutations affect the protein in a way that would allow a cation leak (Matthews et al). Approximately 10 percent of cases, however, are due to a mutation in the earlier discussed sodium channel, SCN4A.

Clinical manifestations In our experience, this disease has become clinically apparent after adolescence and has been much more severe in males. We note, however, that in Talbott's review of 152 cases, there were 40 in which symptoms began before the 10th year of life and 92 before the 16th year. The typical attack comes on during the second half of the night or the early morning hours, after a day of unusually strenuous exercise; a meal rich in carbohydrates favors its development. Excessive hunger or thirst, dry mouth, palpitation, sweating, diarrhea, nervousness, and a sense of weariness or fatigue are mentioned as prodromata but do not necessarily precede an attack. Usually, the patient awakens to discover a mild or severe weakness of the limbs. However, diurnal attacks also occur, especially after a nap that follows a large meal. The attack evolves over minutes to several hours; at its peak, it may render the patient so helpless as to be unable to call for assistance. Once established, the weakness lasts a few hours if mild or several days if severe.

The distribution of the paralysis varies. Limbs are affected earlier and often more severely than trunk muscles, and proximal muscles are possibly more susceptible than distal ones. The legs are often weakened before the arms, but exceptionally the order is reversed. The muscles most likely to escape are those of the eyes, face, tongue, pharynx, larynx, diaphragm, and sphincters, but on occasion, even these may be involved. When the attack is at its peak, tendon reflexes are reduced or abolished and cutaneous reflexes may also disappear. As the attack subsides, strength generally returns first to the muscles that were last to be affected. Headache, exhaustion, diuresis, and occasionally diarrhea may follow the attack. Myotonia is not seen; indeed, clinical or EMG evidence of myotonia essentially excludes the diagnosis of hypokalemic periodic paralysis.

Attacks of paralysis tend to occur every few weeks and tend to lessen in frequency with advancing age. Rarely, death may occur from respiratory paralysis or derangements of the conducting system of the heart. Such fatal cases were reported mainly in the era before modern intensive care.

Atypical forms include weakness of one limb or certain groups of muscles, bibrachial palsy (inability to lift one's arms or to comb one's hair), and transient weakness during accustomed activities such as walking. Some of our patients had a talipes deformity from early life. During middle adult life, a number of patients have developed a severe, slowly progressive proximal myopathy, with vacuolated and degenerated fibers and myopathic action potentials, in some instances long after attacks of periodic paralysis had ceased.

Laboratory findings The attacks are accompanied by a reduction in serum K levels, as low as 1.8 mEq/L, but usually at levels that would not be associated with muscle weakness in normal subjects. The fall in serum K is associated with little or no increase in urinary K excretion. Presumably, large quantities of K enter the muscle fibers during an attack, but this explanation may not be complete. Some episodes occur with near-normal levels of K, and weakness persists for a time after the serum level has been restored. The serum K levels return to normal during recovery. Although the shifts in K are of undoubted importance in the pathogenesis of muscle weakness, the marked sensitivity to small reductions of serum K suggests that other factors are operative and that the fall in K may be a secondary phenomenon.

As in hyperkalemic paralysis, the muscular weakness in this disease is associated with a decrease in the amplitude, and eventual loss, of muscle action potentials, and there is a failure of excitation by supramaximal stimulation of peripheral nerve or by strong voluntary effort. A decline in strength precedes the loss of motor unit potentials and the failure of propagation of action potentials over the surface of the fiber. The polarization potentials of muscle fibers measured by intracellular recordings are initially normal despite the failure of impulse propagation by the sarcolemma. One would expect the muscle fiber to be hyperpolarized as K moves into it, but it actually becomes depolarized, likely due to increased Na conductance (Rüdel and associates). ECG changes also begin at levels of K that are slightly below normal (about 3 mEq/L); they consist of prolonged PR, QRS, and QT intervals and flattening of T waves.

Diagnosis at a time when the patient is normal may be facilitated by provocative tests. With the patient carefully monitored, including the use of ECG, the oral administration of 50 to 100 g of glucose or loading with 2 g of NaCl every hour for 7 doses, followed by vigorous exercise, brings on an attack, which then can be terminated by 2 to 4 g of oral KCl (the opposite of what pertains in hyperkalemic periodic paralysis).

Pathologic changes The muscle fibers are uniformly somewhat large, but the most striking change, particularly in the late degenerative phases of the disease, is vacuolization of the sarcoplasm. The myofibrils are separated by round or oval vacuoles containing clear fluid, presumably water, and a few periodic acid-Schiff (PAS)-positive granules. There are pathologic changes in myofibrils and mitochondria as well, and focal increases in muscle glycogen. Isolated muscle fibers may undergo segmental degeneration. Electron microscopic studies have shown that the vacuoles arise as a result of proliferation and degeneration of membranous organelles within the sarcoplasmic reticulum and transverse tubules (Engel, 1970).

Treatment A low-sodium diet (less than 160 mEq/d), avoidance of large meals and of exposure to cold, and acetazolamide 250 mg tid may be helpful in preventing attacks. That acetazolamide reduces attacks is somewhat surprising as it is kaluretic, but it may work through the production of acidosis; a few patients have worsened with the drug. Patients who are unresponsive to acetazolamide may be treated with the more potent carbonic anhydrase inhibitor, dichlorphenamide, 50 to 150 mg/d, or with the potassium-sparing diuretics spironolactone or triamterene (both in doses of 25–100 mg/d), but caution must then be exercised with the simultaneous administration of oral potassium supplements. The daily administration of 5 to 10 g of KCl orally in an unsweetened aqueous solution prevents attacks in many patients, and apparently, this program can be maintained indefinitely. If this approach fails, a low-carbohydrate, low-salt, high-K diet combined with a slow-release K preparation may be effective.

For an acute attack, 0.25 mEq KCl/kg should be given orally, or if this is not tolerated, some other K salt may be tried. This dose may be insufficient and if there is no improvement in 1 or 2 h, KCl may have to be given intravenously: 0.05 to 0.1 mEq/kg initially in a bolus at a safe rate, followed by 20 to 40 mEq KCl in 5 percent mannitol, avoiding glucose or NaCl as the carrier solution. For the late-progressive polymyopathy that follows many severe attacks of periodic paralysis, strength can be restored with long-term administration of dichlorphenamide (Dalakas and Engel). Regular exercise (not too strenuous) to keep the patient fit is desirable.

Secondary Kalemic Periodic Paralyses

In addition to the hereditary kalemic paralyses described earlier, transitory episodes of weakness are associated with a number of acquired derangements of potassium metabolism (mainly hypokalemia); these include thyrotoxicosis, aldosteronism, 17α-hydroxylase deficiency (Yazaki et al), barium poisoning (Lewi and Bar-Khayim), glycyrrhizic

acid ingestion (a substance in licorice that has mineralocorticoid activity), and abuse of thyroid hormone (Layzer). Other forms of secondary hypokalemic weakness occur in patients with chronic renal disease (including renal tubular acidosis from Sjogren syndrome) and adrenal insufficiency or loss of potassium, as occurs with excessive use of diuretics or laxatives (the most common cause in practice). Renal failure with hyperkalemia can also induce considerable weakness.

Thyrotoxicosis With Periodic Paralysis

This is a special form of secondary hypokalemic periodic paralysis and occurs mainly in young adult males (despite the higher incidence of thyrotoxicosis in women), with a strong predilection for those of Japanese and Chinese origin (Pothiwala). A study in Japan showed that 8.9 percent of men with thyrotoxicosis had periodic paralysis, but this was the case in only 0.4 percent of women (Okinaka and associates); in China, the corresponding figures were 13.0 and 0.17 percent (McFadzean and Yeung). The paralytic disorder is unrelated to the severity of hyperthyroidism. In patients with familial forms of periodic paralysis, the induction of hyperthyroidism is said not to increase the frequency or intensity of attacks. Therefore, it seems likely that thyrotoxicosis has unmasked another type of hereditary periodic paralysis, although a familial occurrence in thyrotoxic cases is exceptional. Clinically, the attacks of paralysis are much the same as those of familial hypokalemic type except for a greater liability to cardiac irregularity. As in the familial form, the paralyzed muscles are electrically inexcitable. Potassium chloride restores power in paralytic attacks, and treatment of hyperthyroidism prevents their recurrence.

Hypokalemic Weakness in Primary Aldosteronism (Conn Syndrome)

Hypokalemic weakness because of hypersecretion of the major adrenal mineralocorticoid aldosterone was first described by Conn and associates in 1955. In primary aldosteronism, the cause of the hypersecretion is in the adrenal gland itself, usually an adrenal cortical adenoma, less often adrenal cortical hyperplasia. Although the disorder is uncommon (occurring in approximately 1 percent of unselected hypertensive patients), its recognition is essential for effective treatment. Persistent aldosteronism is frequently associated with hypernatremia, polyuria, and alkalosis, which predispose to attacks of tetany as well as to hypokalemic weakness. In an analysis of 145 patients with primary aldosteronism, it was found that persistent muscular weakness was a major complaint in 73 percent; intermittent attacks of paralysis occurred in 21 percent; and tetany in another 21 percent (Conn and associates 1964). These manifestations were much more frequent in women than in men, in contrast to the preponderance of men among patients with hypokalemic periodic paralysis of familial type. Rarely, as already noted, primary aldosteronism is produced by the chronic ingestion of licorice; this is due to its content of glycyrrhizic acid, a potent mineralocorticoid (Conn et al, 1968).

The muscle fibers of patients with primary aldosteronism show necrosis and vacuolation. Ultrastructurally, the necrotic areas are characterized by the dissolution of myofilaments with degenerative vacuoles; nonnecrotic fibers contain membrane-bound vacuoles and show dilatation of the sarcoplasmic reticulum and abnormalities of the transverse tubular system, suggesting that vulnerability of the latter structures may be responsible for the muscle fiber necrosis (Atsumi et al).

Malignant Hyperthermia

This dramatic syndrome is observed during general anesthesia in susceptible individuals, some of whom clearly have a channelopathy. It is characterized by rapidly rising body temperature, extreme muscular rigidity, and a high mortality rate. Since the original report by Denborough, as larger experience was gained with this entity, it proved in some cases to be a metabolic myopathy inherited as a dominant trait, rendering the individual vulnerable to any volatile anesthetic agent, particularly halothane, and to the muscle relaxant succinylcholine. The fundamental cause, in a proportion of cases, is an aberration in a component of the *ryanodine calcium channel*. Malignant hyperthermia has been estimated to occur approximately once in the course of every 50,000 administrations of general anesthesia.

Clinical Manifestations

The full clinical picture is striking, but anesthesiologists have become adept at detecting its earliest stages and aborting the process. As halothane or similar inhalational anesthesia is induced, or succinylcholine is given for muscular relaxation, the jaw muscles unexpectedly become tense rather than relaxed and soon rigidity extends to all of the muscles. Thereafter, the body temperature rises to 42°C or 43°C and there is tachypnea and tachycardia. Blood pH may fall to 7 or below. There may be gross myoglobinuria and serum CK reaches extraordinarily high levels. Circulatory collapse and death may ensue in approximately 10 percent of cases, or the patient may survive with gradual recovery. In some cases, there is the same sequence of events (increased temperature and acidosis) without muscular spasm. In cases of early death, the muscle may appear normal by light microscopy. With survival for several days, samples of muscle reveal scattered segmental necrosis and phagocytosis of sarcoplasm without inflammation. Patients with a particular congenital myopathy (central core myopathy), and those with King-Denborough syndrome, mentioned later, have a propensity to malignant hyperthermia, as noted in Chap. 45.

Pathophysiology and Etiology

The pathogenesis of malignant hyperthermia has been the subject of numerous investigations. During the rigor phase, oxygen consumption in muscle increases threefold and serum lactate, 15- to 20-fold. Muscle from most affected individuals is abnormally sensitive to caffeine, which induces contracture in vitro. It has been postulated that halothane acts in a manner similar to caffeine—that is, to release calcium from the sarcoplasmic reticulum and prevent its reaccumulation, thus interfering with the relaxation of the muscle. The essential physiologic change is one of increased intracellular calcium.

Insight into the disease has been gained from a breed of pigs, inbred for muscular development, in which muscle spasm (true contracture) and hyperthermia follow the administration of anesthetic agents. These swine have an inherited defect in the ryanodine receptor, a protein component of the calcium channel of the sarcoplasm that is sensitive to both caffeine and ryanodine. However, one of several similar defects in ryanodine is found in somewhat fewer than 20 percent of people with susceptibility to malignant hypothermia. It is presumed that other yet unidentified allelic mutations of this receptor protein or another that controls the structure of the calcium channel account for the remainder of cases. The cause of the high fever is unknown; it is probably caused by muscle spasm, but the effect of the anesthetic on heat-regulating centers has not been excluded.

Clues as to which patients are at risk for this condition come from several sources. Other members of the family may have difficulties or have died during anesthesia. Some susceptible individuals exhibit myopathic and musculoskeletal abnormalities (Isaacs and Barlow). One such dysmorphic constellation consists of short stature, ptosis, strabismus, highly arched palate, dislocated patellae, and kyphoscoliosis, which have been present in several families (King-Denborough syndrome, see Denborough et al). As mentioned just above and in Chap. 45 on the congenital myopathies, central core (sometimes called multicore) myopathy is frequently complicated by malignant hyperthermia. This is understandable insofar as both disorders have been linked to the gene encoding the ryanodine receptor; the two diseases are a result of allelic variations (Quane et al). It has been pointed out that another rare muscle disease (Evans myopathy, named after the affected family) may also be a predisposing condition. It is inherited as an autosomal trait and may be asymptomatic until the anesthetic reaction, but some patients have wasting of the distal thigh muscles and an elevation of serum CK concentration (see Harriman et al).

Diagnostic testing Various tests for susceptibility to malignant hyperthermia can be considered in the appropriate circumstances. One method involves in vitro exposure of a muscle biopsy specimen to halothane and to caffeine and the detection of muscle contracture with both agents (Denborough). This test may be considered in individuals with a suspected prior episode of malignant hyperthermia (after 6 months) and in those with a family member with a prior episode but without a known genetic mutation. It is performed only in a few centers, which are listed at http://www.mhaus.org. Genetic testing of the *RYR1, CACNA1s,* and *STAC3* genes may also be considered, particularly in individuals with a confirmed or highly suspicious episode or those with a positive caffeine halothane contracture test.

Treatment

This consists of discontinuation of anesthesia at the first hint of masseter spasm or rise of temperature. The intravenous administration of dantrolene, which inhibits the release of calcium from the sarcoplasmic reticulum, may be lifesaving. An infusion of 1 mg/kg is given initially and increased slowly until symptoms subside, the total dosage not exceeding 10 mg/kg. Other measures should include body cooling, intravenous hydration, sodium bicarbonate infusion to correct acidosis, and mechanical hyperventilation to decrease acidosis. Thereafter, halothane and other volatile anesthetic agents and succinylcholine should be avoided in such individuals and surgical procedures, if necessary, should be done with other agents, such as propofol, nitrous oxide, fentanyl, thiopental (or other barbiturate), or local anesthesia. Intravenous dantrolene (2.5 mg/kg given slowly 1 h prior to anesthesia) prevents the syndrome, but this is not a preferred option in patients with the disorder.

Neuroleptic Malignant Syndrome

This state, in which hyperthermia occurs as an idiosyncratic reaction to neuroleptic drugs, is also accompanied by widespread myonecrosis. It shares some features with malignant hyperthermia but is a distinct entity, as discussed in Chap. 41.

Potassium Channel Diseases

The discovery of several types of seizure disorders based on inherited defects of the potassium channel has elicited considerable interest and only recently was it appreciated that one form of periodic paralysis, Andersen disease, is associated with the VGKC.

Andersen-Tawil Disease

Andersen and coworkers first drew attention to a distinct form of potassium-sensitive periodic paralysis characterized by the triad of periodic potassium-sensitive weakness, ventricular dysrhythmias with long QT syndrome, and dysmorphic features (micrognathia, short stature, scaphocephaly, hypertelorism, broad nose, low-set ears, and short index fingers). Sometimes called "Andersen disease," it is not to be mistaken for the glycogen storage disease of the same name, which is discussed in Chap. 45.

A study of five kindreds pointed out that attacks of paralysis can be associated with hypo-, normo-, or hyperkalemia and that a prolonged QT interval is an integral feature of the disease (and sometimes the only sign in a given family) (Sansone and colleagues, 1997). Most cases of Andersen disease are a consequence of dominant-negative mutations in the gene *KCNJ2* that encodes a type of K channel (Plaster and colleagues). In vitro studies indicate that the mutation impairs the ability of preformed channels to migrate to the membrane surface and also impedes the current-carrying capacity of the potassium channel system. This defect would be expected to impair the repolarization of the muscle membrane, thereby making both skeletal and cardiac muscle hyperexcitable.

Morvan Syndrome (Chorée Fibrillaire)

This disease is characterized by continuous muscle fiber activity, sometimes referred to as "neuromyotonia," and therefore may also be considered among similar disorders of constant muscle activity that are discussed further in the chapter. It is associated with specific antibodies directed against VGKC. One of these antibodies is anti-contactin-associated protein-like 2 (Caspr2) antibodies that produce a syndrome of neuromyotonia, often associated with some

combination of memory loss and confusion, sleep disturbances, neuropathic pain, autonomic instability, and focal seizures (Irani and colleagues; Serratrice and Azulay; Thieben and colleagues). This disorder is most common in older men with a median age of 65 years. The presentation tends to be more slower than other autoimmune encephalitis syndromes, often presenting over the course of many months. In some patients, there is isolated neuromyotonia without the other clinical features. It is typically not associated with cancer and most patients have good responses to immunotherapy (Ligouri and colleagues). Some cases have an associated thymoma and its removal may be curative.

OTHER DISEASES AFFECTING MUSCLE MEMBRANE EXCITABILITY

In addition to the above disorders, various seizure syndromes (see Chap. 15) and a category of spinocerebellar ataxias are also attributable to mutations of ion channels and are addressed in other sections of the book. Also mentioned here for completeness are several diseases that result from secondary dysfunction of these same ion channels. Most of these conditions are acquired and autoimmune in nature, for example, the Lambert-Eaton myasthenic syndrome that results from an autoimmune attack on calcium channels discussed earlier, the Isaac syndrome that results from an autoimmune attack on potassium channels, producing neuromyotonia, anti-VGKC and anti-NMDA encephalitis (see Chap. 30), and erythromelalgia that implicates a sodium channel (see Chap. 10). Thus, ion channels, being ubiquitous in all excitable tissues, might be expected to produce a large variety of diseases that affect central and peripheral nervous structures. Despite this, each of the genetic and acquired processes has remarkably specific features that are pertinent only to the channel as expressed in a single tissue.

Physiologic Contracture Caused by Phosphorylase Deficiency (McArdle Disease) and Phosphofructokinase Deficiency (Tarui Disease)

Contractures are examples of an entirely different type of painful shortening and hardness of muscle. In both these diseases, an otherwise healthy child, adolescent, or adult begins to complain of weakness and stiffness, and sometimes pain on using the limbs. Muscle contraction and relaxation are normal when the patient is in repose, but strenuous activity, especially under conditions of ischemia, causes the muscles to shorten gradually because of a failure of relaxation. The contracted muscles in these disorders—unlike muscles in cramp, continuous muscular activity syndromes, or myotonia and other involuntary spasms—no longer use energy, for which reason they are almost silent electrically in the EMG. This condition is spoken of as *physiologic contracture*. McArdle and Tarui diseases are discussed more fully in a later section.

Pseudomyotonia

This phenomenon is observed in *hypothyroidism*, where the muscle fibers contract and relax slowly, a response readily demonstrated in the tendon reflexes, particularly the Achilles reflex. The muscles are large and subject to myoedema. When contracted, they may show waves of slow contraction. The basis of this disorder appears to be slowness in the reaccumulation of calcium ions in the endoplasmic reticulum and in the disengagement of actin and myosin filaments. The EMG may show afterpotentials following voluntary contraction, but they do not resemble the typical waning discharges ("myotonic runs"; Fig. 2-19) of true myotonia.

A closely related syndrome, wherein painless contracture is induced by exercise, consists of normal muscle contraction is normal, but the relaxation phase becomes increasingly slow during exercise (Lambert and Goldstein; Brody). The slow relaxation has also been attributed to a decreased uptake of calcium by the sarcoplasmic reticulum. In some cases, the disease is transmitted as a recessive trait with a mutation that impairs the function of a sarcoplasmic reticular calcium ATPase. In other instances, the disease is transmitted as a dominant trait that is not genetically linked to calcium ATPase. This latter process may be more closely aligned with muscular dystrophies and is mentioned in Chap. 45 under that heading.

Tetanus (See Tetanus in Chap. 41)

This toxic disorder is characterized by persistent spasms of skeletal muscles, owing to the effect of the tetanus toxin on spinal neurons (Renshaw and other cells), the natural function of which is to inhibit the motor neurons. As the condition develops, activities that normally excite the neurons (i.e., voluntary contraction and startle from visual and auditory stimulation) all evoke involuntary spasms. Sleep tends to quiet them, and they are suppressed by spinal anesthesia and curare. The EMG shows the expected interference pattern of muscle action potentials. Once the muscle is involved in persistent contraction, it is said that the shortened state is not abolished by procaine block or severance of nerve (in animals), but this type of myostatic contracture has not been demonstrated in humans.

The effect of tetanus toxin on the spinal inhibitory neurons is analogous to that of strychnine. There is also an action of the toxin at the neuromuscular junction, which has been more difficult to evaluate in the face of its powerful central action. Having injected this toxin locally in animals, Price and associates demonstrated its localization at motor endplates. It binds with ganglioside in the axon membrane and is transported by retrograde flow to the spinal cord, where it induces local tetanus effects. Neurons that innervate slow-twitch type 1 muscle fibers are more sensitive than those supplying fast-twitch type 2 fibers. Presynaptic vesicles increase in number, ACh is blocked, and terminal axon injury may paralyze muscle fibers. Fibrillation potentials and axonal sprouting follow. The similarities to stiff person syndrome are mentioned further on.

Black Widow Spider Bite (See also Chap. 41)

The toxin produced by this spider within a few minutes of the bite leads to a striking syndrome of cramps and spasms and then a painful rigidity of abdominal, trunk,

and leg muscles. The spasms are followed by weakness. There is also vasoconstriction, hypertension, and autonomic hyperactivity. If death does not occur in the first 24 to 48 h, recovery is complete. The spider venom has a presynaptic localization and rapidly releases quanta of ACh. The vesicles became depleted. There is some evidence that the venom prevents endocytosis of the vesicles by inserting itself into the presynaptic membranes, causing a disturbance of ionic conductance channels (Swift).

Treatment consists of calcium gluconate infusions and diazepine. Intravenous magnesium sulfate also helps to reduce the release of ACh and control the convulsions that sometimes occur. There is antiserum that is available in regions where such envenomation is frequent; it shortens the illness considerably.

States of Persistent Muscle Activity

This is an interrelated group of clinical states, all characterized by some degree of regional continuous muscular activity that, in some cases, cannot be fully differentiated from one another. From a clinical perspective, we have found it is useful to categorize them into groups that are caused by (1) hyperexcitability of the peripheral motor nerves (fasciculations and myokymia), (2) centrally mediated hyperexcitability of motor output (Isaacs syndrome, stiff man syndrome), and (3) nonmyotonic hyperexcitability of muscle (rippling muscle disease, Schwartz-Jampel syndrome).

Hyperexcitability of Peripheral Nerve

This comprises a set of disorders in which peripheral motor nerve activity is augmented such that there are excessive, sometimes sustained contractions of the motor unit. Its mildest manifestation is benign fasciculation. In more severe form, the manifestations include neuromyotonia, Isaacs disease, and a disease of potassium-gated ion channels (Morvan disease, or Morvan fibrillary chorea discussed below) that may also involve the brain. These processes are not generally familial and several lines of investigation suggest an acquired autoimmune nature (Newsom-Davis). For example, all but benign fasciculations are associated more often than might be expected with other autoimmune diseases such as myasthenia gravis and some respond to autoimmune therapies such as plasmapheresis, the patient's serum possesses antibodies to either VGKCs as mentioned or, less frequently, to nicotinic ACh receptors (Vernino and Lennon).

Benign Fasciculations

A few random fasciculations in the muscles of the calf, small muscles of the hand or of the face, or elsewhere are seen in most normal individuals. They are of little significance but can be a source of worry to physicians and patients who have read that fasciculations are an early sign of amyotrophic lateral sclerosis. A simple clinical rule is that fasciculations in relaxed muscle are not indicative of motor system disease unless there is associated weakness, atrophy, or reflex change.

Healthy individuals experience intermittent twitching of a muscle (or even part of a muscle), such as one of the muscles of the thenar eminence, eyelids, calves, or orbicularis oculi. They may continue for days. Electromyographically, benign fasciculations tend to be more constant in location and more frequent and rhythmic than the ominous fasciculations of amyotrophic lateral sclerosis, but such distinctions are not entirely reliable. The physiology of fasciculations is discussed in Chap. 2 and illustrated in Fig. 2-20. Quantitative study of the motor unit size may be helpful in these circumstances by demonstrating normally modeled units in the benign form and abnormally large units because of reinnervation in the case of motor neuron disease.

Occasionally, benign fasciculations are widespread and may last for months or even years. In several of our patients, they have recurred in bouts separated by months and lasting several weeks. No reflex changes, sensory loss, nerve conduction, EMG abnormality (other than fasciculations), or increase in serum muscle enzymes are found. Low energy and fatigability in some of these patients may suggest an endogenous depressive illness, yet the fasciculations are not explained by this mechanism. Patients commonly report a sense that the muscles affected by the twitching are weak, but this cannot be confirmed by testing and several of our patients, curiously most of whom have been physicians, complained of equally troubling migratory zones of paresthesias. Pain of aching or burning type may increase after activity and cease during rest. Fatigue and a sense of weakness are frequent complaints. We suspect that this fasciculatory state reflects a disease of the terminal motor nerves, for a few of our patients have shown slowing of distal latencies, and Cöers and associates have found degeneration and regeneration of motor nerve terminals in similar cases. However, most such cases are of benign nature and settle down in a matter of weeks or months. Large series show that the condition, even after years, does not progress to spinal muscular atrophy, polyneuropathy, or amyotrophic lateral sclerosis (Hudson and colleagues; Blexrud et al). It should be acknowledged, however, that there are infrequent patients with seemingly benign fasciculations in whom the EMG shows some abnormal features (e.g., rare fibrillations) in numerous muscles and who later develop the other features of motor neuron disease. Carbamazepine, and to a lesser extent phenytoin and other antiepileptic drugs, has been helpful in reducing the fasciculations and sensations of weakness in a proportion of cases and numerous other medications have been reportedly helpful.

Cramp-Fasciculation Syndrome

This is probably a variant of the above-described benign entity in which fasciculations are conjoined with cramps, stiffness, and systemic features such as exercise intolerance, fatigability, and muscle aches. Although affected individuals may be to some degree disabled by these symptoms, the prognosis is good. The salient finding on physiologic studies is that stimulation of peripheral nerves results in sustained muscle firing due to prolonged trains of action potentials in the distal motor nerve. This phenomenon may be brought out in special electrophysiologic testing (Tahmoush and colleagues). In effect, this is a mild form of neuromyotonia, which is described

further on. In a small number of patients with cramp-fasciculation syndrome, it is possible to demonstrate the presence of autoantibodies directed against voltage-gated axonal potassium channels. Carbamazepine or gabapentin may be beneficial.

There are, in addition to these benign states, several syndromes of abnormal muscle activity. The main ones are myokymia, a state of successive contractions of motor units imparting an almost continuous undulation or rippling of the overlying body surface, and several syndromes of continuous muscle fiber activity described below.

Myokymia

This state of abnormal rippling muscle activity may be generalized or limited to one part of the body such as the muscles of the shoulders or of the lower extremities. It is observed most often with demyelination of peripheral nerve following injury, and thus it is neuropathic in nature. The common underlying conditions are multiple sclerosis or GBS affecting the facial nerve and radiation damage to the brachial or lumbar plexus. In the EMG, myokymic discharges consist of repetitive firing of 1 motor unit, firing at 5 to 60 Hz and recurring regularly at 0.2- to 10-s intervals. The driving impulses arise in the most peripheral parts of the axon of chronically damaged nerves. In some patients, cramping is associated, and those muscles about to cramp may twitch or show premonitory spontaneous rippling contractions; the cramping may be associated with sweating. Thus, myokymia, fasciculation, and cramping seem to be related but not clinically identical conditions.

Continuous Muscle Fiber Activity (Isaac Syndrome)

The relation of myokymia to the state called continuous muscle fiber activity is ambiguous. Sporadically in the neurologic literature, there have been descriptions of patients whose muscles, at some point, begin to "work" continuously (see Isaacs). Terms such as *neuromyotonia* and *widespread myokymia with delayed muscle relaxation* are additional names that have been applied to what is essentially the same condition. At the moment, there is little reason to distinguish one from another except in gradations of severity. In each case, the excessive and spontaneous activity can be attributed to hyperexcitability of terminal parts of motor nerve fiber, possibly as a result of a partial loss of motor innervation and compensatory collateral sprouting of surviving axons (Cöers et al; Valli et al). The association of this type of disorder to anti-voltage gated potassium channels has been mentioned in relation to thymoma and to Morvan's syndrome.

Twitching, spasms, and rippling of muscles (myokymia) are evident, the latter being the main clinical sign. In advanced cases, there is generalized muscle stiffness and a sense of weakness. Complaints of muscle aching are usual, but severe myalgia is uncommon. The tendon reflexes may be reduced or abolished. Any muscle group may be affected. The stiffness and slowness of movement make walking laborious ("armadillo" syndrome); in extreme cases, all voluntary movement is blocked. The muscle activity persists throughout sleep. The continuous visible and painful cramps of the above-described Satoyoshi disease may be difficult to distinguish from myokymia clinically, but they represent a different phenomenon. General and spinal anesthesia do not always suppress the muscular activity, but curare does; nerve block usually has no effect or may reduce the activity, as in the case described by Lütschg and colleagues. The EMG findings are much the same as those described earlier.

Special types of myokymia arise in childhood or adult life, sometimes in association either with a polyneuropathy or rarely with an inherited type of episodic ataxia that is variably responsive to acetazolamide or remits spontaneously (see Chap. 5). An inherited form of continuous muscle fiber activity has been traced to a mutation of the peripheral nerve K channel (Gutmann and Gutmann). In addition to the association with polyneuropathy, a state of continuous muscular activity has also been described in association with lung cancer and thymoma, in which cases an immune mechanism has been inferred, as noted above in Morvan syndrome (see reviews by Newsom-Davis and Mills and the discussion of paraneoplastic syndromes in Chap. 30).

Treatment Phenytoin or carbamazepine often abolishes the continuous muscular activity and cause a return of reflexes. Acetazolamide has been helpful in other cases (Celebisoy et al). Many of the idiopathic cases will improve spontaneously after several years, however, plasma exchange may be tried if the symptoms are intractable.

Stiff Person Syndrome

This is a condition of persistent and intense spasms, particularly of the proximal lower limbs and lumbar paraspinal muscles. It was originally described by Moersch and Woltman in 1956 as stiff man syndrome. Since then, many examples have been reported all over the world and the term *stiff person syndrome* has been used to indicate its occurrence in both women and men. For lack of a better place in the book to discuss it, it is included here with other processes that cause muscular spasms and cramps.

The onset is insidious, usually in middle life. No genetic predisposition is known. At first, the stiffness and spasms are intermittent, then gradually, they become more or less continuously active in the proximal leg and axial trunk muscles and increasingly painful. The spasms impart a robotic appearance to walking and an exaggerated lumbar lordosis. Attempts to move an affected part passively yield an almost rock-like immobility, perceptibly different from spasticity, paratonia, or extrapyramidal rigidity. Muscles of respiration and swallowing and those of the face may be involved in advanced cases, but trismus, a common feature of tetanus, does not occur. We have observed brief periods of cyanosis and respiratory arrest during episodes of intense spasm, and one of our patients died during such an episode. The eye muscles are rarely affected.

As the illness progresses, any noise or other sensory stimulus or attempted passive or voluntary movement may precipitate painful spasms of all the involved musculature. The tendon reflexes are normal if they can be tested. The affected muscles, particularly the lumbar paraspinals and

glutei, are extremely taut when palpated and eventually, they become hypertrophied. It is this axial spasm that is most characteristic of the disease and gives rise to a characteristic lumbar lordosis. We have experience with one unusual instance of this disease that caused the obverse, namely, flexion spasm of the abdominal musculature with a bent-over camptocormia.

A similar stiffness of one limb (*stiff limb syndrome*) has been differentiated from the generalized variety (Barker et al; Saiz et al; Brown et al), but most of the localized cases have antibodies to glutamic acid decarboxylase (GAD), as described below. The limited form of the condition begins in 1 leg and spreads to its opposite but remains isolated to the lower extremities, similar to localized tetanus.

A central origin of the muscle spasms is indicated by their disappearance during sleep, during general anesthesia, and with a proximal nerve block. The electrophysiologic features differ from those of myokymia and continuous muscle fiber activity syndrome in that the EMG in stiff man syndrome consists entirely of activated but normally configured motor units, with no evidence of distal motor nerve disturbance.

Of interest is the finding that about two-thirds of the cases of stiff man syndrome display circulating autoantibodies that are reactive with GAD, the synthesizing enzyme for gamma-aminobutyric acid (GABA; Solimena et al). On several occasions, the test for this antibody has become positive after samples taken over 2 years were negative. An antibody to the glycine receptor (GlyR) has been identified in a subset of patients with stiff man syndrome with anti-GAD antibodies (McKeon and colleagues), rare cases of which have included a fatal encephalopathy and myoclonus (Turner et al) and a few patients with a special cervical pattern of stiffness have had anti-amphiphysin antibodies (Murinson and Guarnaccia). In all these rare cases, anti-GAD antibody is usually also present and paraneoplastic versions of each syndrome are known, as commented below.

Reduced spinal GABA presumably creates an imbalance between the spinal inhibitory (gabanergic) input and the excitatory input to alpha motor neurons. This interpretation is supported by the fact that the spasms worsen under the influence of drugs that enhance aminergic activity, thereby facilitating long-latency spinal reflexes or that inhibit catecholaminergic or gabanergic transmitters. An autoimmune mechanism is further suggested by the high incidence of insulin-dependent diabetes (present eventually in almost all the cases under our care) with detectable antibodies to islet cells; a few patients have thyroiditis, pernicious anemia, or immune-mediated vitiligo.

There are rare paraneoplastic varieties of stiff man syndrome, mostly accompanying breast cancer and associated in some cases with circulating antibodies directed against amphiphysin or gephyrin, proteins associated with synaptic GABA receptors. Some of the cases related to the antiamphiphysin antibodies also display more conventional types of paraneoplastic neurologic disorder such as encephalopathy or opsoclonus (see Chap. 30). Also reported, perhaps not surprisingly, have been instances of a variable cerebellar syndrome with stiff-man and high titers of anti-GAD antibodies (Rakoevic et al).

The stiff man syndrome must be distinguished from tetanus (see "Tetanus" in Chap. 41 and further on), Isaacs syndrome, and the rare syndrome of subacute myoclonic spinal neuronitis, described in Chaps. 32 and 42. In both the stiff man syndrome and myoclonic spinal neuronitis, the intense spasms and stiffness of muscles are a result of the disinhibition of interneurons in the gray matter of the spinal cord.

The syndromes of continuous muscle activity are usually distinguishable clinically and electromyographically from extrapyramidal and corticospinal abnormalities such as dystonia, dyskinesia, and rigidity, although early phases of axial dystonic disorders and stiff man syndrome have similarities.

Treatment

In the stiff man syndrome, diazepam in doses of up to 50 to 250 mg/d, increased gradually, is most effective; clonazepam, vigabatrin, or baclofen is sometimes effective as well. In keeping with the presumed autoimmune mechanism of most cases, plasma exchange, high-dose corticosteroids, or intravenous gamma globulin are helpful in some patients, albeit for only several weeks or months before another infusion is required. Several of our patients have required intravenous gamma globulin for several years at intervals of 6 to 12 weeks but nevertheless became disabled if the dose of diazepam was reduced below 100 mg/d. A small randomized trial of IVIg has demonstrated the efficacy of this treatment, with benefits varying in duration from 6 weeks to 1 year (Dalakas and colleagues, 2001). The typical dose is 0.4 mg/kg daily for 4 or 5 consecutive days. Immunosuppression with rituximab is being used increasingly on the basis of case reports and small series, but a small randomized trial has been negative (Dalakas et al, 2017). For intractable cases, particularly when one limb is involved, propofol has been anecdotally effective in doses that do not produce sedation (Hattan et al).

Congenital Neonatal Rigidity

A "stiff infant" syndrome, observed by Dudley and colleagues in four families of mixed heritage, probably should be included in this general category. The condition came to medical attention because of respiratory distress as the result of a generalized muscular rigidity beginning at about 2 months of age. The rigidity spread slowly from cervical muscles to those of the trunk and limbs, and, as it persisted, slight hypertrophy developed. The use of respiratory aid and a feeding gastrostomy enabled the infants to survive. The rigidity slowly diminished in the second year of life. The clinical course was unlike that of tetanus. In fatal cases, there were zones of fiber loss, with fibrosis in skeletal and cardiac muscles and a greater than normal variation in fiber size. Altered Z lines were observed with electron microscope in some fibers.

Primary Hyperexcitability of Muscle

At least three varieties of primary muscle disorders are known, not myotonic in nature, that produce continuous muscle activity. The first described below is because of a defect in the muscle membrane; the second has been found to be a disease of the extracellular matrix of muscle.

The third disorder, Brody disease, is only mentioned here for completeness as it is quite rare, even in comparison to the other unusual disorders in this section.

Rippling Muscle Disease

Ricker and Burns and their associates described a rare familial disorder (autosomal dominant) in which muscles display an unusual sensitivity to stretch, manifest by rippling waves of muscle contraction. Percussion of muscles yields a pronounced and painful local mounding. The activation is a type of myokymia. Similar familial and sporadic cases have been traced to a defect in caveolin, a protein otherwise implicated in one of the muscular dystrophies (Vorgerd). An autoimmune process was implicated in some other cases (Ashok Muley and Day). The EMG discloses neither myotonic discharges nor the action potentials of cramp, indicating that the basic abnormality is in the muscle membrane.

Schwartz-Jampel Syndrome

A syndrome characterized by continuous muscle fiber activity with stiffness and blepharospasm, accompanied by obvious dysmorphic features (dwarfism, pinched face with low-set ears, blepharophimosis, high-arched palate, receding chin, diffuse metaphyseal and epiphyseal bone dysplasia with flattened vertebrae), was described by Schwartz and Jampel in 1962. It has been reported under other names including *myotonic chondrodystrophy*. There may be percussion myotonia. Intelligence is usually preserved. The stiff muscles disturb gait most obviously.

The muscle stiffness is the result of frequent, almost continuous muscle activity with a combination of normal motor units and high-frequency discharges and afterdischarges similar to those seen in Isaacs syndrome. The discharges can be demonstrated to arise from muscle fibers themselves as the activity is not obliterated by curare. Agents such as procainamide, which block sodium channels in muscle, inhibit the discharges, just as they do in some other myotonic disorders (Spaans and associates).

The disorder is usually inherited as an autosomal recessive trait that is caused by mutations in perlecan, a heparin-sulfate proteoglycan that is bound to the basement membranes of skeletal muscle and cartilage. Loss of function of the protein perturbs the organization of the basement membrane leading to an altered clustering of ACh esterase and abnormal expression of ion channels. Electron microscopic studies of muscle have yielded inconsistent findings: dilated T system, Z-band streaming, dilatation of mitochondria, and signs of denervation (Fariello and colleagues).

PART 6

PSYCHIATRIC DISORDERS

47

Anxiety, "Functional" and Personality Disorders

The relationship between psychiatry and neurology, at one time unified specialties, has been problematic for well over a century. With the emergence of numerous theories of the nature of mental life and of the mind, came corresponding systems for the treatment of psychiatric disease. Most of these systems, typified in the past by psychoanalysis, seemed to have little in common with neurologic ideas about the structure and function of the brain. Freed from the model of the main mental disease that was the result of structural damage to the brain, syphilitic general paresis, psychiatry was able to turn to matters that were less anchored in medicine. With the emergence of a biologic psychiatry based on neurochemistry, genetics, and functional imaging of the brain, it would seem that the gap between diseases of the mind and of the brain is closing. However, neurologists should view some of these modern ideas with at least some skepticism. For example, the observation of brain function by the use of imaging methods, and disruption of that function in disease, is not the equivalent of the disease itself and certainly cannot capture the experience through which mental disease is manifest. To dissociate an individual's personal history and experiences, aspects of life that probably cannot be quantified or visualized, from diseases of the mind remains an artifice now, as it was in the time of the classic philosophers. This potential division between mind and brain, or "dualism," is particularly apparent when one begins to analyze the normal internal stream of thought that dominates daily life rather than the disordered thoughts of mental disease states. Hughlings Jackson was of the opinion that the brain provides a platform for thinking but is not explanatory of it, a property of mind he termed "emergent." This leaves open the possibility of a science of the mind that is separate from the science of the brain.

Moreover, the separation of quirks of personality and character traits, probably reflecting the biologic diversity of the development of the brain, from genuine disease will remain eternally problematic. Even the margins between disease and mental dysfunction in everyday life have been disputed and have given rise to numerous "shadow syndromes" of psychologic origin that are subject to change with popular culture and fashion. This serves as an appropriate introduction to a chapter that formerly used the term "Neuroses" and has been mostly renamed "Anxiety Disorders" in acquiescence to modern terminology. Likewise, what had been called "hysteria" for over a century, has pejorative connotations and is biologically incorrect (in so far as symptoms were attributed to a wandering uterus), and has been ambiguously renamed "functional disorder" or "psychogenic disorder," both meant to strongly imply to the absence of an anatomical explanation but this is no to say the patient has volitional control over the symptoms.

In every society, there are many troubled individuals who are neither mentally ill nor developmentally impaired. They differ from other people in being plagued by feelings of inferiority or self-doubt, suspicion about the motives of others, low energy, inexplicable fatigue, shyness, irritability, moodiness, sense of guilt, or unreasonable worries and fears. They suffer as a result of these feelings or they behave in ways that are upsetting to those around them and to society at large. Yet none of these conditions precludes partaking in the everyday life, such as attending school, working, marrying, and raising a family. As these conditions were more carefully documented in the early part of the last century, they came to be called *neuroses*, and those that created societal difficulties were called *psychopathies,* and more recently, personality disorders and *sociopathies*.

The question of the purity and homogeneity of these mental states creates an ongoing polemic in psychiatry, medicine and society. The neuroses as a group appeared to be so diverse as to require subdivision in former editions of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) into no less than seven different types before the term was expunged in 1980. We take a neutral position on the value of DSM not out of iconoclasm but because the definitions in that system are changed frequently, are subject to considerable controversy, and often do not accord with neurobiologic ideas of brain function. In any case, readers may wish to consult the most current DSM where appropriate, to gain insight into the evolving thinking of the psychiatric community.

Even in the modern era, a discussion of non-psychotic mental disorders is not complete without including the ideas of Sigmund Freud and his psychoanalytically minded colleagues. Freud separated neuroses and psychoneuroses and both subjects became enmeshed in psychoanalytic theory. The assumption about neurosis was that an undercurrent of anxiety arising from unconscious conflict explained the neuroses as well as the psychopathies.

The term psychoneurosis was reserved for neurosis that had an additional aspect based in a brain (physical) trait—but the two differed very little. Later, psychiatrists uncommitted to psychoanalytic theory attributed these states to social forces leading to maladaptive behavior from childhood. Many of these notions were not acceptable to biologically oriented physicians, with the result that the term *psychoneurosis* was expunged from later editions of the DSM, and *neurosis* was replaced by *anxiety disorders*, *phobic states*, and *obsessive-compulsive disorder* as alluded to above. These terms are at present applied to mental disorders with the following characteristics: (1) symptoms that are distressing to the affected individual and regarded by the person as unacceptable or alien; (2) intactness of reality testing (the patient's evaluation of the relationship between himself and the outside world); (3) symptomatic behavior that does not seriously violate social norms, although personal functioning may be moderately impaired; (4) a disturbance that has its onset early in life and is enduring—not a transitory reaction to stress; and (5) the absence of a discernible medical cause or structural disease of the brain. The foregoing definition of anxiety and its allied disorders has the virtue of being descriptive without committing one to any theory of causation.

The genesis of the anxiety, phobic, and obsessive states remains elusive. It is generally conceded that they do not arise de novo. The antecedents are thought in some quarters to be abnormalities in personality development, strongly influenced by genetic factors and molded by stressful events in the life of the individual (Noyes et al), introduced by Engel in 1977 as the biopsychosocial theory of mental health and mental illness. Traits of this nature undoubtedly arise in several individuals from the same family. Thus, any discussion requires a brief digression into the origins of normal personality development and departures from it. It is clear from the interactions of daily life that minor forms of anxiety contribute to the makeup of the normal personality.

PERSONALITY DISORDERS

Chapter 27 introduced the concept of *personality* and its development. There it was pointed out that the term embraces the totality of a person's mental attributes, observable behavior, and reportable subjective experience—the sum of which distinguishes one individual from all others. It includes elements of what might be called the individual's character that is defined by intelligence, drives, temperament, and sentiments—in short, all forces from within the organism that determine a person's reactions to the prevailing environment. The term *character* is almost synonymous with personality but is less useful in medicine because of its emphasis on interpersonal and ethical aspects and its moralistic connotation. Pertinent to this subject matter is the assumption that in approximately 15 percent of the general population, certain personality traits are so pronounced as to be distressing to the individual and disturbing to others, even though the patient is not manifestly sociopathic or psychotic.

The roots of personality features such as boldness and timidity, novelty seeking and excitability, level of energy and motor activity, fearfulness and fearlessness, social adaptability and rigidity or stubbornness are already evident in the first months of life. Monozygotic twins are alike (but not absolutely identical) in these respects, even when reared apart. Gesell and his colleagues, in their studies of infants in the middle of the last century (see Chap. 27), observed individual differences that are apparently innate; each of these characteristics is likely to be at least partly genetically determined. The personalities that result are as individual as fingerprints. One example of a biologic and genetic basis of a human personality trait, albeit to a limited degree, has been found in the expression of thrill seeking, exploration, and excitability. For example, early work in the field pointed to polymorphisms of a dopamine receptor gene accounts in small measure for the genetic variability of this personality type (Cloninger and colleagues, 1996). Findings such as these have been reproduced for similar polymorphisms that contribute to the traits of timidity, anxiety, and obsessiveness. The notion, expressed by authors such as Kandel, that genetics will explain a large part of mental function and mental illness sounds reasonable enough, but the data to establish this are far from complete.

The interesting and somewhat related construct of a "national character" is embedded in social discourse but has not been extensively studied. It is mentioned here to allow for a more complete picture of the concept of character. A survey has indicated that mean personality traits in 49 cultures do not correspond to general stereotypes and are therefore probably simply contrivances for maintaining national identity (Terracciano and colleagues). Similar comments can be proffered regarding sex differences in personality that are embedded in cultural stereotypes but these sex personality profiles have more data to suggest a degree of uniformity and validity in differences between men and women in all cultures.

An unsolved problem is whether each of the personality types accepted by the American Psychiatric Association is predictive or determinative of a later mental disorder. (DSM-5 lists 10 types of personality disorder; Table 47-1 lists 12 that are more granular). In this regard, two broad groups of personality disorders can be recognized. In one group—comprising the paranoid, schizoid, cyclothymic, and obsessive-compulsive personality types—there are similarities to major types of psychiatric illness. Thus, among patients who develop paranoid schizophrenia, a considerable number will have had attributes described under "paranoid" or "schizoid" personality type." In fact, it may be difficult to judge where the personality disorder leaves off and the schizophrenic illness began. Similarly, it may be that from several family studies that the cyclothymic personality is related to bipolar disease. Obsessive-compulsive personality is related not only to obsessive-compulsive disorder, as one might expect, but also to depressive disease. The notion of clusters of personality traits has been introduced and may be more useful in clinical work than are the discrete personality types (Tyrer). The co-occurrence of types of personality disorders is common has led to an new classification system using a "dimensional" approach that gauges the maladaptive aspects of behavior that are shared across types (Sharp). Borderline personality (see below) anchors many of the other types.

Perhaps most problematic in classification, but seen regularly in medical practice, is the "borderline personality

Table 47-1

PERSONALITY DISORDERS

TYPE	CHARACTERISTICS
Paranoid	Chronic wariness, suspiciousness, litigiousness, hypersensitivity, jealousy, envy; lack of insight or humor, tendency to blame others; sense of self-importance and entitlement
Cyclothymic	Recurring periods of depression (low energy, pessimism, hopelessness, despair) and elation (high energy, ambition, enthusiasm, optimism) not readily explained by circumstances
Schizoid	Isolation, seclusiveness, secretiveness, discomfort in relationships; often eccentric and lacking in energy; few friends; detachment; inability to express ideas and feelings, especially anger
Explosive	Outbursts of rage and aggression not in keeping with usual personality, often in response to minor provocation; sense of loss of control followed by regret
Obsessive-compulsive (anankastic)	Chronic worries about standards; excessive concern about self-image; tension in relationships, leading to isolation; inability to relax and excessive inhibitions; overly meticulous, conscientious, and perfectionist; predisposition to depression and obsessive-compulsive neurosis
Hysterical	Immaturity, histrionic behavior, excitability, emotional instability, sexualization of relationships, low frustration tolerance, and shallow interpersonal ties; dependency
Asthenic	Chronic weakness, easy fatigability, sense of vulnerability, oversensitive to physically and emotionally taxing situations, little ambition or aggression; low energy level; anhedonia
Passive-aggressive	Obstructive behavior, stubbornness, intentional errors or omissions; intolerance of authority with struggles over control, often creating difficulties in medical settings; externalization of conflicts and blaming others for untoward events
Inadequate	Chronic inability to meet ordinary life demands in the absence of mental retardation; severe dependency on others; tendency to become institutionalized or to become dependent on institutions
Antisocial	Unsocialized or antisocial behavior in conflict with society; selfishness, callousness, impulsiveness, lack of loyalty, and little guilt; low frustration tolerance; tendency to blame others, long history of interpersonal and social difficulties and arrests
Passive-dependent	Lack of self-confidence, indecisiveness, tendency to cling to and seek support from others
Immature	Ineffectual responses to social, psychologic, and physical demands; lack of stamina; poor adaptation to ordinary situations; a "loser"
Borderline	Poorly regulated emotions, self-injury, dysphoria, unstable interpersonal relationships
Narcissistic	Grandiosity, fantasies of power, success, idealized love, and belief that he or she is special or unique and can only be understood by or associate with others of high status

disorder." As with other personality types, the pattern of behaviors is pervasive and lifelong in the affected individual. An ensemble of poorly regulated emotions, impulsive and aggressive actions, and repeated self-injury form the core aspects of the disorder. These patients typically express a range of emotional "pains" and a sense of dysphoria, often rapidly changing from one mood to another without provocation. Interpersonal relationships are unstable as a result of fear of being left alone combined with argumentativeness. These are among the most distressing individuals for families and physicians to deal with and little success has been achieved in treatment. The potential biologic roots of the borderline personality disorder are difficult to determine (Lieb and colleagues) and difficulties in treating these people are well known (Gunderson), currently limited mainly to various types of insight-oriented psychotherapies.

As all personality disorders involve problems in self-regulation and maintenance of stable relationships an approach to understanding and classification, as alluded to above, has been to assess the severity of maladaptive traits such as disordered self-identity and interpersonal functioning across domains of functioning such as detachment, antagonism and psychoticism (Sharp). The defining features of the personality disorders therefore fall short of meeting the criteria for serious mental illness. Yet, an understanding of these personal peculiarities may be of great help to the physician. This knowledge makes it possible to appreciate their role as sources of perennial complaint, self-concern, and family discord, and to explain a patient's reactions that have interfered with diagnostic and therapeutic procedures during a medical illness. It is, however, quite common for extremes of personality to create depression and anxiety, either of which is amenable to medical and psychotherapeutic treatment. As a final comment, one should never underestimate the power of maturation to ameliorate the turmoil of adolescence and to settle the young mind.

ANXIETY DISORDERS (SEE ALSO CHAP. 23)

Although considered to be the most frequent of mental disturbances, the anxiety disorders are among the least understood. They were established as clinical entities in the late 19th century, but there are still major unresolved issues with respect to their nature, classification, and etiology. Descriptively, they are meant to include (1) anxiety disorder; (2) phobic disorder, which includes phobia of illness, social phobia, and agoraphobia; (3) obsessive-compulsive states; (4) functional disorder (formerly hysteria); and (5) hypochondriasis. Older classifications included additional types called neurasthenia (dysthymia or depressive neurosis), which is now considered with the depressive illnesses, and "depersonalization neurosis" (dissociative disorders), which is a form of functional illness. Although each of these syndromes is clinically separable when occurring in pure form, experience shows that many patients suffer from symptoms of more than one type. In recent classifications, all the neuroses have been again subsumed in three broad categories: (1) *anxiety disorders* (which include panic states, with and without agoraphobia, and the phobic and obsessive-compulsive neuroses); (2) *somatoform disorders*

(comprising hysterical neurosis, or conversion disorder, and hypochondriasis); and (3) *dissociative disorders*.

An interesting view of the relative frequency and expression of mental disorders of the day (but still pertinent) was provided by an analysis of 1,045 consecutive psychiatric consultations at the New England Center Hospital during the years 1955 and 1956 in which the dominant psychiatric syndrome in approximately 20 percent of patients was an anxiety state. Other epidemiologic studies continued to disclose a strikingly high incidence of anxiety disorders in the general population (Winokur and Coryell). Lifetime prevalence figures indicate that at least 11 percent of the population is so affected—that is, an estimate of 25 million persons in the United States. Such information as is available suggests that the incidence of the anxiety disorders is much the same in an urban population (midtown New York) as it is in a rural one (Stirling County, Nova Scotia), indicating that socioeconomic, racial, and cultural factors may be of limited importance. Furthermore, in times of calamity or societal stress, such as the bombing of London, or the (of course, not comparable) COVID epidemic the incidence of neurotic symptoms was said not to have increased. Thus, it is probably an oversimplification to view neuroses as merely by-products of life in civilized society or reactions to environmental stress (see also Chap. 23). This raises the issue alluded to earlier and discussed more extensively further on;, the role of background personality traits in promoting extreme and persistent anxiety after a traumatizing event (posttraumatic stress disorder, PTSD; see Chap. 23).

The symptoms of the anxiety disorders typically arise in late childhood, adolescence, or early adult life. Admittedly, symptoms may be recognized for the first time after this age, but a good clinical rule is to suspect any mental illness that appears for the first time after the age of about 40 years to be either a depression or a dementia rather than a personality trait or disorder.

ANXIETY AND PANIC ATTACKS

As mentioned, the term *anxiety neurosis* was introduced by Freud to describe a syndrome of general irritability, anxious expectation, anxiety attacks, and somatic accompaniments or equivalents of anxiety (breathlessness, chest pain, asthenia). In anxiety disorders, this symptom complex constitutes the entire illness. However, parts or all of this constellation also appear with many psychiatric diseases—bipolar disease, schizophrenia, hysteria, and phobic neurosis. Its closest link is with depression, which it resembles in another respect, namely, a strong hereditary factor, as pointed out by Cohen and White in 1949.

Clinical Presentation

Anxiety disorder in its fullest form is a chronic state, punctuated by recurrent attacks of acute anxiety or panic. The acute attacks are the hallmark of the disorder, and some psychiatrists were in the past reluctant to make a diagnosis of anxiety (neurosis) in their absence. Because of the clinical features of panic attacks and particularly their episodic nature, which can simulate an acute medical condition, they are of special interest to neurologists and general physicians. At times, anxiety may be inferred from observing the activities of young children and is reported as a form of nervousness by older children and adolescents, but more often in this age group there are physical complaints at times of transition or stress.

The most extreme form of anxiety is the panic attack. In their full form they are prone to begin after adolescence. They generally begin with ill-defined distressing feelings that may include dread and foreboding. The patient is assailed by a sense of strangeness, becomes frightened, in extreme cases by the prospect of imminent death (*angor animi*) or of losing his mind or losing self-control. There may be a feeling of smothering. “I am dying” or “I can’t breathe” are characteristic expressions of alarm and panic. The heart races, breathing comes in rapid gasps, the pupils may be dilated, and the patient may sweat or tremble. The palpitation and breathing difficulties are so prominent that a cardiologist is often consulted. Some of our psychiatric colleagues have identified breathlessness or a suffocating feeling as central to the diagnosis of panic (and attribute psychologic meaning to the symptom), but this is not sustained by our observations of affected patients. The symptoms abate spontaneously after 15 to 30 min, leaving the patient shaken, tense, perplexed, and often embarrassed. There is no confusion, and after the episode there is full memory of the event.

Most anxiety attacks are of lesser severity with complaints of apprehension, slight faintness, palpitations, or a feeling of postural instability referred to by the patient as dizziness. Breathlessness, vague chest or upper abdominal discomfort, a palpitating sensation as if the heart were beating too hard, and a generalized “washed out” feeling (asthenia) are other common symptoms. More than 50 years ago Cohen and White listed the following symptoms in order of frequency in the patients they observed with anxiety attacks: palpitation, 97 percent; easy fatigue, 93 percent; breathlessness, 90 percent; nervousness, 88 percent; chest pain, 85 percent; sighing, 79 percent; dizziness, 78 percent; apprehensiveness, 61 percent; headache, 58 percent; paresthesias, 58 percent; weakness, 56 percent; insomnia, 53 percent; unhappiness, 50 percent. What is evident from this listing is that the experience of anxiety is a polysymptomatic physical syndrome. This was the basis of the James-Lang theory of emotion—that the physical-sensory experience was the central one and the emotional experience followed. It is not surprising, therefore, that many patients with chronic or recurrent symptoms first consult a physician not with a complaint of “anxiety” but with symptoms referable to the cardiorespiratory system or gastrointestinal system (dyspepsia, loss of appetite, or “irritable colon”).

Many patients experience a constant uneasiness that the spells may reoccur, especially in public; hence the patient may be fearful of leaving home lest help not be available should an attack occur (agoraphobia). Except in minor details, it is notable that the attacks are alike in any one individual. Between attacks, most patients feel relatively well but many complain of the symptoms of anxiety and asthenia in lesser but persistent fashion.

Hyperventilation is a special, although not invariable, feature of the anxiety attack. Hyperventilation itself, by reducing the PCO_2, will cause giddiness, paresthesias of the fingers, tongue, and lips, and, at times, frank tetany. However, contrary to what is stated in some textbooks, in only a minority of patients does a 3-min period of deep breathing reproduce the symptoms of an anxiety or panic attack. Nonetheless, this maneuver may be used to assist the patient in describing certain aspects of an attack.

Attacks in minor form, without the full force of the physical accompaniments may occur at infrequent intervals or several times a day. Much to the patient's surprise, they usually occur in situations where there are no easily recognizable sources of fear, as when the patient is sitting quietly at home or has just awakened from sleep. In other instances, a trying or upsetting experience induces an attack, which is nonetheless excessive for the condition that provoked it. In some patients, attacks are brought on consistently by confinement to a closed space (claustrophobia)—an elevator, for example—or by crowded surroundings, as in a church, restaurant, or theater. An anxiety state frequently follows an accident and then may be a source of ongoing disability (Modlin), a condition more akin to posttraumatic stress disorder. Similar spells of anxiety are also a prominent feature of the postconcussive and posttraumatic stress syndromes.

From the patient's life history, two patterns of anxiety disorder are discernible. In one, there is a nearly lifelong history of poor exercise tolerance, little stamina, and inability to do heavy physical work or participate in vigorous sports, tenseness, nervousness, and intolerance of crowds, that is, what had in the past been called neurasthenia (or nervous exhaustion), named by the neurologist George Beard in 1869 and renamed innumerable times by others as a result of its widespread applicability in all branches of medicine. When these symptoms arose during military service, they were designated, since the American Civil War as *neurocirculatory asthenia*, "irritable heart," or "soldier's heart."

The course of anxiety traits is variable. A 20-year follow-up study showed that symptoms were still present in 88 percent but persisted in being moderately or severely disabling in only 15 percent (Wheeler and associates). Most affected patients were able to work and to enjoy a reasonably normal family and social life. Their only liability to further psychiatric illness was to later anxious depression, whereas so-called psychosomatic illnesses and other psychiatric illnesses did not occur more frequently than in the general population. Those with uncomplicated anxiety neurosis rarely commit suicide.

Etiology and Pathogenesis

Anxiety disorder has been attributed to a genetic propensity, to a "constitutional weakness" of the nervous system, to social and psychologic factors, and to physiologic and biochemical derangements; but none of these factors provides a completely satisfactory explanation of the primary problem.

The onset of both acute and chronic anxiety, as mentioned, is rare before 18 years or after 35 to 40 years of age (average age of onset 25 years). The condition in some series is twice as frequent in women as in men and there is clearly a high familial incidence. In one study (Wheeler et al) there was a prevalence of 49 percent among the grown children of patients with anxiety neurosis, compared with 5 percent in the general population. There was a concordance rate of 40 percent in identical twins, compared with 4 percent in dizygotic twins in one study (Slater and Shields). Among the relatives of index cases, mothers suffered from anxiety neurosis more often than did fathers; in the latter, alcoholism was more frequent than in the population at large (Modlin). A clear pattern of inheritance has not been established, but it approximates that of autosomal dominance with incomplete penetrance. The psychodynamic theories that attempted to provide a unified explanation of these diverse anxiety states (Nemiah) cannot be totally dismissed.

The symptoms of an anxiety resemble those of fear in many ways, although nearly always the former is longer in duration and less distinct. The most important difference, however, is that the cause of fear is known to the patient, whereas that of anxiety is not. The most extreme but not inconceivable interpretation of anxiety is the James-Lange theory of emotion, mentioned earlier, which attributes the psychologic experience entirely to the accompanying physical symptoms.

On the physiologic and biochemical side, it has been observed that anger provokes an excessive secretion of norepinephrine, whereas fear is accompanied by increased secretion of epinephrine. Actually, fear activates the autonomic nervous system as a whole and the increase in epinephrine is more than counterbalanced by a parasympathetic discharge. Attention has been focused on overactivity of the locus ceruleus and upper brainstem nuclei as possible anatomic substrates of anxiety (Judd et al). Other studies have implicated serotonergic centers. Evidently, the responsiveness of the autonomic nervous system in these patients remains heightened and a number of stimuli (cold, pain, muscular effort) may produce abnormal responses in pulse, respiration, oxygen consumption, and work performance. An interesting but not uniformly affirmed abnormality (noted by Cohen et al) was that the blood lactic acid levels in response to exercise are higher than normal. The presence of these changes does not necessarily mean that they are causal; they are as likely secondary to other factors such as poor physical condition and apprehension associated with the syndrome. Nevertheless, some investigators have found that infusions of lactic acid can trigger panic attacks in persons with anxiety neurosis (Liebowitz et al). Subsequently, numerous other theories of causation have been proposed based on the reported provocation of panic attacks by a number of different substances—carbon dioxide, yohimbine, gamma-aminobutyric acid (GABA), isoproterenol, and others. None provides a comprehensive biologic explanation for anxiety or panic attacks.

Studies correlating cerebral function and blood flow indicate that when panic is induced by an intravenous injection of sodium lactate, there is an immediate increase in blood flow to the cortex of both temporal lobes. In states of fear, the tips of the temporal lobes and the amygdaloid nuclei are known to become activated. In the relaxed

period between panic attacks, the right limbic system and the parahippocampal gyrus have been abnormally active in some studies. As with the aforementioned biochemical models, these seem to be more reflections of brain activity in response to the psychic experience than they are explanations. Nevertheless, parts of the limbic system are presumably involved in an essential way in the production and perpetuation of anxiety and its related states.

The discovery that the benzodiazepines bind to specific sites of the GABA receptor complex and that the sedative and amnesic effects (α_1 subunit) of these drugs seem to be separable from their anxiolytic effects (α_2 subunit) raises the possibility that abnormalities of the GABA system directly underlie anxiety. However, there is only indirect evidence for this mechanism. Of potentially greater importance is the finding of genetic polymorphisms that relate to the presence of anxiety states, such as one in the serotonin transporter gene (Lesch et al). It has been estimated that allelic differences in this gene contribute perhaps 10 percent to the overall anxiety tendency. One presumes that there are numerous additional genes that participate in a similar way. Others have not found this association or have found it only in patients with generalized anxiety and not in those with panic attacks. Consequently, the relationship of genetic polymorphisms to anxiety states cannot be stated at this moment, but a heritable component seems highly likely.

Differential Diagnosis

Shorn of the psychologic components of apprehension and fear, the anxiety and panic attack consists essentially of an excessive autonomic, mainly sympathetic, discharge. Some of the autonomic symptoms are therefore duplicated by pheochromocytoma. The prominence of chest discomfort and respiratory distress during an acute anxiety attack may be mistaken for myocardial ischemia, in which case the patient is often subjected to a series of studies of cardiac function. Another form of the illness—in which nondescript dizziness, vague difficulty with visual clarity, and fear of losing consciousness are the most prominent features—may be mistaken for a vestibular problem (see "Nonvertiginous Types of Dizziness" in Chap. 14) or for epilepsy. In contrast, headache is surprisingly, an infrequent experience and the diagnosis should be suspect if it is a prominent feature. Other medical diseases that may be brought to mind by isolated elements of an anxiety state are pulmonary embolism, cardiac arrhythmias, hypoglycemia, hypoparathyroidism, alcohol, drug, nicotine withdrawal and especially, complex partial seizures. The autoantibody syndrome associated with NMDA antibodies and some instances without these antibodies may have anxiety as its opening feature. In regard to seizures as imitators of anxiety, however, loss of consciousness, incontinence, and clonic or myoclonic movements do not occur in anxiety spells. Adherence to the diagnostic criteria of these disease states readily permits their differentiation from acute anxiety, but diagnosis may be difficult if the symptoms are brief.

Of equal importance is the relationship of anxiety to depression. A large proportion of patients with depression have symptoms of anxiety. Indeed, some psychiatrists believe that anxiety disorder is accounted for mainly by a variant of depression. As has been mentioned, an anxiety state appearing for the first time after the 40th year usually proves to be primarily a depression, although it may be that a predisposing personality trait is involved. The presence of symptoms such as overwhelming fatigue, self-deprecation, and feelings of hopelessness and, of course, ideas of self-destruction make depression the fundamental diagnosis, with anxiety an associated feature (anxious depression). As mentioned, a very small number of patients with a condition diagnosed as pure anxiety neurosis have committed suicide, but this does not hold if depression is the central illness.

Schizophrenia may also make itself apparent initially with prominent anxiety symptoms. Here the diagnosis rests on finding the characteristic thought disorder of schizophrenia, which may emerge only with time and after several interviews.

Treatment

Anxiolytics and antidepressants are generally effective in suppressing panic attacks and creating a sense of well-being but their continued use comes with risks of dependence and withdrawal. Among these, the benzodiazepine alprazolam had been favored by some psychiatrists, but lorazepam and clonazepam are almost as effective and are considered less likely to cause dependence, but this has not been clearly documented. In mild cases, the benzodiazepines may be used intermittently rather than several times daily, but they tend to be less useful once a panic attack has become established. Panic attacks tend to recur when the medications are discontinued, even after prolonged (6 to 12 months) administration. Any reduction in the amount of these medications should be gradual as withdrawal symptoms simulate panic or anxiety spells.

Tricyclic antidepressants and drugs that raise serotonin concentrations in the nervous system (selective serotonin reuptake inhibitors [SSRIs]) may also be effective in the prevention of panic attacks and agoraphobia, but their onset of action is delayed for weeks. They become useful for symptoms of anxiety that recur or persist for more than several months. The doses are similar to those used to treat depression, and small differences between the agents in this class do not seem to be clinically important (see Chap. 48). Buspirone, a specific serotonin 5-HT_2 agonist, has been promoted as effective in the treatment of anxiety and as a surrogate for benzodiazepines, but to us, its benefit has seemed to be slight. It is important to point out that during the initial weeks of administration of antidepressants, the underlying anxiety symptoms may worsen, and an anxiolytic may be required until the antidepressant becomes effective. Propranolol, 10 to 20 mg tid, or a long-acting form of adrenergic blocker, can reduce many of the autonomic accompaniments of anxiety and is useful to some patients.

Psychiatric consultation is, of course, invaluable. Behavioral therapy (progressive exposure of the patient to panic-provoking situations) is said to be beneficial,

particularly if agoraphobia is a major symptom. Relaxation activities, including biofeedback and meditation, help many patients, although persistence is required in performing these exercises at least once daily and they are less helpful once a panic attack has begun. Cognitive-behavioral therapy, which is discussed in relation to the treatment of depression in Chap. 48, also appears to be useful in the treatment of panic disorder (Andreasen and Black).

A cardiac consultation and some simple tests (electrocardiogram, chest films) are often needed to reinforce to the patient the benign nature of the cardiac and respiratory symptoms and to alleviate fear of heart disease. These and other concepts of the treatment of anxiety were discussed decades ago by Goodwin and Guze and are still valid. Anxiety symptoms arising in relation to a particular threatening event in an individual not previously prone to anxiety carry the best prognosis, but the symptoms may be prolonged, a feature of posttraumatic stress disorder.

PHOBIC DISORDER

In this state, patients are overwhelmed by an intense and irrational fear of some animal, object, social situation, or disease. Although acknowledging that there are no grounds for a particular fear (hence it is not a delusion) and that such provocative stimuli are for the most part innocuous, the patient is nonetheless powerless to suppress it. This disorder was known to Hippocrates, who drew a distinction between normal and morbid fears. Westphal, in 1871, was the first to give morbid fears the status of a disease.

Unlike an anxiety attack, a phobia focuses on a specific object or situation. The patient is chronically fearful of a particular animal or situation and becomes extremely anxious or panic stricken and incapacitated when placed in a situation that evokes the phobia. These situations are avoided at all costs. As a result, it may be impossible for the patient to leave the house or neighborhood unaccompanied or at all, mingle in a crowd, walk across a bridge, or travel by air. This fear of being in places or situations from which escape might be difficult or extremely embarrassing is spoken of as *agoraphobia*. (Agoraphobia, however, is a secondary feature of other psychiatric disorders, the most frequent being anxiety with panic attacks as already mentioned.) The most common phobia—and one that is not disabling for the most part—is claustrophobia, the fear of being confined in a closed space such as an elevator or a magnetic resonance scanner. Other phobias are those of high places, dogs, cats, insects, dirt, sprays and other contaminants, air travel, HIV, cancer, insanity, and death. Feelings of helplessness, pessimism, and despondency, the hallmarks of a depressive illness, result after years of phobic suffering. Often there are obsessive-compulsive tendencies as well, and some patients are hypochondriacal. Phobias are essentially *obsessive fears* and are somehow allied with anxiety disorders. The present authors have observed a number of patients whose phobic (or obsessive-compulsive) states became greatly exaggerated as an endogenous depression developed. Recovery from the depression returned them to their earlier and milder phobic state.

OBSESSIVE-COMPULSIVE DISORDER

Like the pure phobic states, a state dominated by obsessions (thoughts) and compulsions (acts) is infrequent, occurring in less than 5 percent of patients seeking help in a psychiatric outpatient clinic, but it can be extremely disabling. Minor compulsions (e.g., not stepping on cracks in the sidewalk), like minor phobias, are common in children, cause little or no distress, and disappear in later life. A few, such as rechecking a locked door or a gas stove, may persist throughout life. Also, certain habits and rigid, obsessional ways of thinking, stubbornness, extreme punctuality, and excessive attention to detail may be persistent but excite little attention medically unless they interfere with a diagnostic procedure or the treatment of a medical disease.

Obsessive-compulsive disorder begins in adolescence or early adult years, although treatment may not be sought until middle age. The two sexes are equally affected. The onset is usually gradual and often cannot be accurately dated, but in some cases, it is precipitated by a particular event in the patient's life, such as the death of a relative. The family history often discloses a high incidence of obsessional or phobic personality in other members. There is usually a prevailing undercurrent of insecurity and anxiety.

Obsessions are imperative and distressing thoughts that persist in the patient's mind despite a desire to resist and to get rid of them. They take various forms; among them are *intellectual obsessions*, in which phrases, rhymes, ideas, or vivid images (these are often absurd, blasphemous, obscene, and sometimes frightening) constantly intrude into consciousness; *impulsive obsessions*, in which the mind is dominated by an impulse to kill oneself, to stab one's children, or to perform some other objectionable act; and *inhibiting obsessions*, in which every act must be ruminated on and analyzed before it is carried out—a state that is cleverly called *doubting mania*. Every effort at distraction fails to rid the patient of the obsessive thought. It engulfs the individual's mind, rendering the person dysphoric and, often, inefficient. Probably the most disturbing obsessions are the impulsive ones, in which patients constantly struggle with the fear that they will put some terrible thought into action. Even as they tell of the obsession, they reveal a severe underlying anxiety and seek reassurance that they will not yield to it. Fortunately, such patients rarely obey their pathologic impulses. Phobias, as mentioned earlier, are considered by some authorities to be essentially obsessive fears and are included in this category of neurosis.

Compulsions are acts that result from obsessions. These are single acts or a series of acts (rituals) that the patient must carry out to put his mind at ease. Examples are repeated checking of the gas jets or the locks on doors, adjusting articles of clothing, repeated hand washing, using a clean handkerchief to wipe objects that have been touched by others, tasting foods in specific ways, and touching or arranging objects in a particular sequence. The most common of these obsessions and compulsions center

around contamination concerns that lead to repeated hand washing or bathing. Other obsessions and compulsions can be identified as clusters of thoughts that derive from the above-mentioned concern about harm to oneself or to others and consequent checking on others. Less common clusters involve excessive focus on symmetry, precision, and ordering, and on saving and hoarding.

Certain motor disturbances—namely, habit spasms or tics—are, in a sense, *motor compulsions*. They consist of repetitious movements of the shoulders, arms, hands, and certain of the facial muscles (see Chap. 4). One feature that separates quasivoluntary tics from involuntary movements of extrapyramidal type is the patient's feeling that the tics must be carried out to relieve an inner tension. Unlike compulsions, however, tics are not usually based directly on obsessive thoughts—except perhaps the Gilles de la Tourette syndrome, in which multiple tics are combined with compulsive utterances, often offensive ones (see later).

In all these obsessions and compulsions and in the phobias, patients recognize the irrationality of their ideas and behaviors, yet are powerless to control them. It is this insight into the obsessional experience and the struggle against it that distinguish obsessions from delusions. After the condition has persisted for a time, they may become depressed and suffer from typical anxiety attacks.

Mechanisms of Obsessive Disorder

For many years, psychodynamic conceptualizations held sway of obsessional states as the product of intrapsychic conflicts. Only relatively recently has a more reasonable neurobiologic model been advanced. These are largely derived from the findings of functional imaging, which have been quite consistent in demonstrating increased metabolic activity in the orbitofrontal cortex, cingulate, and, to a lesser extent, striatum. The orbitofrontal cortex and amygdala were reported to be shrunken in other cases. In a study of 13 patients who developed elements of obsessiveness and compulsive disorder after incurring focal brain lesions, lesions have been found in diverse loci, including the cingulate, frontal, and temporal cortices, as well as the basal ganglia (Berthier and colleagues).

Additional insight into obsessive-compulsive disorder may be obtained from the many cases in which acquired striatal damage may be linked to obsessional behavior. One such entity is a poststreptococcal tic disorder termed *PANDAS* (pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections), discussed in Chap. 4. This disorder is presumably related to another extrapyramidal condition, Sydenham chorea, in which tics and similar movement disorders, as well as obsessive behavioral abnormalities, have long been known to coexist. Functional imaging studies in patients with PANDAS have yielded variable findings but generally there has been increased activity in the caudate nucleus and orbitofrontal cortex in association with the patient's compulsive thoughts.

The *Gilles de la Tourette syndrome* of multiple tics, including vocal ones, beginning in childhood or adolescence and lasting more than a year, has a strong component of obsessive-compulsive disorder in more than half of patients. Both disorders occur in a pattern of inheritance that is close to an autosomal dominant trait with incomplete penetrance (Kurlan). Because dopamine antagonists (Haldol was the first of these to be tried systematically, by Shapiro) have been beneficial in the management of the Tourette syndrome, a number of etiologic hypotheses revolve around serotonergic and dopaminergic neurotransmitter systems (Baxter). The neurochemical alterations in obsessive-compulsive disorder have been based in part on the responses to medications, notably to the serotonin reuptake inhibitors, as noted further on. These agents are found to be of therapeutic benefit, as are stereotactic neurosurgical lesions in the cingulate gyri (see further on). More extensive comments on the Gilles de la Tourette syndrome are found in Chap. 4.

Treatment

This is best left to the experienced psychiatrist. At the least there should be a trial of therapy using behavioral modification techniques. In the case of phobic neurosis, the aim is to reduce the patient's fear to the extent that exposure to the phobic situation can be tolerated. One form of therapy is *systematic desensitization*, which consists of increasing and graded exposure of the patient to the object or situation that arouses the fear. Psychotherapy can consist of repeated explanation, reassurance, and guidance in dealing with symptoms. As with phobic neurosis, several reports have indicated that compulsive rituals can sometimes be reduced by the techniques of behavior therapy as discussed in Chap. 48.

Certain medications, particularly the SSRI types such as fluoxetine, are considered to be effective in reducing obsessions and compulsions in more than half of patients. The less selective agent, clomipramine, is also effective, as were the commonly used tricyclic antidepressants in the past, but clomipramine is not nearly as well tolerated as are the conventional SSRI drugs (Stein).

In the past, cingulotomy produced symptomatic improvement in both phobic and obsessional neuroses and was considered a reasonable procedure. This measure is largely outdated as the implantation of electrical stimulating electrodes (deep brain stimulation) in this region or in the subthalamic nucleus has proved effective for intractable and disabling obsessive compulsive disorder but without affecting the degree of anxiety and at the expense of a moderate number of surgical complications (Mallet et al).

FUNCTIONAL NEUROLOGICAL DISORDERS (HYSTERIA, BRIQUET DISEASE; SOMATIZATION DISORDER; PSYCHOGENIC NEUROLOGIC DISORDER)

This subject is of great importance to neurologists and general physicians because of its frequency. Any sense that this was a disorder of the Victorian era belies modern experience. What has changed for the better is the reduced stigmatization of the disorder and a more straightforward, non-judgmental approach to treatment.

Although a disorder of this nature has been known since ancient times, many writers credit the first description of the syndrome to the French physician Briquet in 1859. Charcot later elaborated certain manifestations of the disease, particularly those with a theatrical aspect, and thereby interested Freud and Janet in the problem. Charcot demonstrated that the symptoms could be produced and relieved by hypnosis. There have been many extensive expositions of Charcot's work in this field and his consideration of hysteria as an organic disease, perhaps allied with epilepsy but representing in any case a "functional" disorder of brain. One of the authors of this text has devoted a large part of a book to the subject (Ropper and Burrell). Charcot's acolyte, Janet postulated a *dissociative state* of mind to account for certain features, such as trances and *fugue states*, a term that has reappeared in modern psychiatry. Freud and his followers conceived of hysterical symptoms as a product of "ego defense mechanisms" in which psychic energy, generated by unconscious sexual conflicts, was "converted" into physical symptoms. This latter concept was widely accepted, to the point where the term *conversion* became incorporated into the nomenclature of the neuroses and the terms *conversion symptoms* and *conversion reaction* came to be equated with the disease hysteria. We see no merit in this dichotomy, based on unsubstantiated psychodynamic theory, of a conversion type as separate from a dissociative type of hysteria, as claimed by the DSM classification (Nemiah).

In clinical neurology one encounters two types of psychogenic neurologic disorders, both identified as having no possibility of explanation in disease of the nervous system: (1) a chronic illness marked by multiple and often dramatically presented symptoms and somatic abnormalities of "classic hysteria," predominantly in women (there is potential sexism and acquisition bias in this categorization but we report our and our colleagues contemporary experience) and (2) an illness predominantly of men but also of women who develop physical symptoms or remain inexplicably disabled for the purpose of obtaining compensation, influencing litigation, avoiding military duty or imprisonment, or for the manipulation of some other interpersonal or societal situation. This latter state has been called *compensation neurosis*, *compensation hysteria*, or *hysteria with sociopathy*, in other words, *malingering*.

Briquet Syndrome

There is also a chronic and episodic condition of repeated bouts of functional neurologic and medical symptoms in the past accounted for 1 to 2 percent of admissions to a neurologic service and a greater number of outpatient visits but now is represented mainly by psychogenic seizures and convulsions, "psychogenic nonepileptic seizures," or PNES (see further on and Chap. 15). The more general chronic form that does not include epileptic-like attacks usually has its onset in the teens or early twenties, mainly in young women; a very few cases begin before puberty. Once established, the symptoms recur intermittently, although with reduced frequency, throughout the adult years even to an advanced age. No doubt there are cases of lesser severity in which symptoms occur only a few times or perhaps only once. The patient may be seen for the first time during middle life or later, and the earlier history may not at first be forthcoming. Careful probing almost invariably reveals that the earliest manifestations of the chronic form of illness had appeared before the age of about 25 years.

Other important data are also revealed by eliciting a careful history. During late childhood and adolescence, the normal activities of the patient, including education, had often been interrupted by periods of ill-defined illness. In the past, rheumatic fever, and in the current era, chronic fatigue, Lyme disease, sick building syndrome, or multiple environmental allergy may be carried as explanatory diagnoses from other physicians or the patient's research on the Internet. Later in life, problems in work adjustment and marriage are frequent. Notable in many cases is a high incidence of marital incompatibility, separation, and divorce. The patient's life history is punctuated by symptoms that do not conform to recognizable patterns of medical and surgical disease. For these ailments, many forms of therapy including surgical operations may have been performed.

In the past, rarely had adult life been reached without at least one abdominal operation for vague abdominal pain, persistent nausea and vomiting, or an obscure gynecologic complaint. Often the indications for the surgical procedures were unclear; moreover, the same symptoms or others often recurred to complicate the convalescence. The biographies of these patients are replete with disorders that center about menstrual, sexual, and procreative functions. Menstrual periods may be painfully prostrating, irregular, or excessive. Sexual intercourse may be painful or unpleasant. Pregnancies may be exceedingly difficult; the common vomiting of the first trimester may persist all through the gestational period, with weight loss and prostration; labor may be unusually difficult and prolonged, and all manner of unpredictable complications are said to have occurred during and after parturition.

Briquet syndrome in its fullest form is a polysymptomatic disorder, implicating at some time and in some patients, almost every organ system. In a study of 50 unmistakable cases of hysteria (as compared with a control group of 50 healthy women), the most frequent symptoms were headache, blurred vision, lump in the throat, loss of voice, dyspnea, palpitation, anxiety attacks, anorexia, nausea and vomiting, abdominal pain, unusual food allergies, severe menstrual pain, urinary retention, painful intercourse, paresthesias, dizzy spells, nervousness, and easy crying (Purtell and colleagues).

The mental examination of the patient with hysteria demonstrates a lack of precision in relating the details of the illness. Questions regarding the chief complaint usually elicit a narration of a series of incidents or problems, many of which prove to have little or no relevance to the question. Memory defects (amnesic gaps) are apparent while the history is being taken; the patient appears to have forgotten important segments of the history, some of which had been clearly described in the past and are part of the medical record. The description of symptoms is dramatic and not in accord with the facts as elicited

from other members of the family. Often, a rather casual demeanor is manifest, the patient insisting that everything in her life is quite normal and controlled, when, in fact, the medical record is checkered with instances of dramatic and unexplained illness. This calm attitude toward a turbulent illness and seemingly disabling physical signs is so common that it had been singled out as an important characteristic of hysteria, *la belle indifference*. Other patients, however, are obviously tense and anxious and report frank anxiety attacks. Emotional reactions are superficial and scenes that are disturbing to others are quickly forgotten. Claims of early life sexual or physical abuse are common and often prove to be true, or sometimes are not valid; when present, they probably play a role in the genesis of some cases (see further on).

The so-called stigmata of hysteria—that is, corneal anesthesia; absence of gag reflex; spots of pain and tenderness over the scalp, sternum, breasts, lower ribs, and ovaries—had in the past been suggested by the examiner and are not helpful in diagnosis. The relative value of various features of the history, examination and psychological profile that may be of value in diagnosis have been summarized (Lazare), and the psychiatric features are not definitive. The variation and pleomorphism of the physical signs are limited only by the patient's ability to produce them by voluntary effort. Some features that were common in the past, such as *arc de circle*, in which the patient arches the back and supports the body by the heels and back of the head, however, are not possible to obtain except by voluntary means and probably can be considered characteristic, if rare. Sometimes the patient's physical signs are an imitation of those of another member of the family ("folie à deux") or are evoked by a stressful event in the patient's personal life. However, this may not be disclosed at the time of the first examination. Although many in the past had commented on the rather youthful, girlish appearance and coquettish ("seductive") manner of the patients, these by no means characterize patients in the current era.

Special Neurologic Syndromes of Functional Origin

A few functional syndromes occur with regularity that physicians may expect to encounter them. Most are neurologic in nature. They constitute some of the most puzzling diagnostic problems in medicine.

Hysterical Pain

This is a fraught area but pain due to functional disorder may involve any part of the body; generalized or localized headache, "atypical facial pain," vague abdominal pain, and chronic back pain with camptocormia are the most frequent and troublesome. In many of these patients the response to analgesic drugs has been unusual or excessive, and some of them are addicted. The hysterical patient may respond readily to a placebo as though it were a potent drug, but it should be pointed out that this is a notoriously unreliable means of distinguishing hysterical pain from that of other diseases. A greater error is to mistake the pain of osteomyelitis or visceral tumor—before other symptoms have developed—for a manifestation of hysteria. There are several helpful diagnostic features of hysterical pain: (1) the patient's inability to give a clear, concise description of the type of pain; (2) the location of the pain does not conform to the pattern of pain in the familiar medical syndromes; (3) the dramatic elaborations of its intensity (speaking in inflated metaphors—"like a giant knife stabbing") and its effects on the body ("tearing my limb off"); (4) its persistence, either continuous or intermittent, for long periods of time; (5) the assumption of bizarre postures; and, most important; and (6) the coexistence of other clinical features or previous attacks of hysterical nature.

Functional Vomiting

This is often combined with pain and tenderness in the lower abdomen and had many times in the past resulted in unnecessary appendectomies and removal of pelvic organs in adolescent girls and young women. The vomiting often occurs after a meal, leaving the patient hungry and ready to eat again; it may be induced by unpleasant circumstances. Some of these patients can vomit at will, regurgitating food from the stomach like a ruminant animal. Vomiting may persist for weeks with no cause being found. Weight loss may occur, but seldom to the degree anticipated. As remarked earlier, the usual first-trimester vomiting of pregnancy may continue throughout the entire 9 months. Anorexia may be a prominent associated symptom and must be differentiated from anorexia nervosa–bulimia, another closely related disease of young women. Factitious self-induced vomiting is more aligned with malingering.

Psychogenic Seizures (PNES), Trances, and Fugues (See Also Chap. 15)

These conditions seem to be no less frequent than in the days of Charcot, when *la grande attaque d'hysterie* was often exhibited before medical audiences, but it is quite familiar to neurologists and one of the main concerns of epileptologists. To witness an attack is of great assistance in diagnosis but electroencephalogram (EEG) monitoring is often required for certainty. The lack of an aura, initiating cry, hurtful fall, or incontinence; the presence of peculiar movements such as grimacing, squirming, thrashing and flailing of the limbs, side-to-side motions of the head, *arc de circle*, and striking at or resisting those who offer assistance; the retention of consciousness during a motor seizure that involves both sides of the body; a long duration of the seizure, its abrupt termination by strong sensory stimulation, lack of postictal confusion, and failure to produce a rise in creatine kinase—are all typical of the psychogenic attack. Sometimes hyperventilation will initiate an attack and is therefore a useful diagnostic maneuver. Both epilepsy, particularly of frontal-lobe type, and functional seizures may occur in the same patient, a combination that invariably causes difficulty in diagnosis as discussed in Chap. 15.

Hysterical trances or fugues, in which the patient wanders about for hours or days and carries out complex acts may simulate temporal lobe epilepsy or any of the conditions that lead to confusional psychosis. The most reliable point of differentiation comes from observation of the patient, who, if hysterical, is likely to indicate a degree of alertness and promptness of response not seen in temporal

lobe seizures or confusional states. Following the episode, an interview with the patient—under the influence of hypnosis, strong suggestion, or midazolam (formerly used was amobarbital [Amytal])—will often reveal memories of what happened during the episode. This helps to exclude the possibility of an epileptic spell.

Functional Paralyses, Gait, Sensory Loss, and Tremors (See Also Chaps. 3, 4, and 6)

Hysterical palsies may involve an arm, a leg, one side of the body, or both legs. If the affected limb can be moved at all, muscle action is weak and tremulous. Movements are slow, tentative, and poorly sustained; often it can be demonstrated that the strength of voluntary movement is proportional to the resistance offered by the examiner, thus imparting a "give-way" character, as noted in the discussion of these signs in Chap. 3. One can detect by palpation that agonist and antagonist muscles are contracting simultaneously, thereby holding the limb in place rather than opposing the examiner, and when the resistance is suddenly withdrawn, there is no follow-through or rebound, as is normally the case. Many other signs have been devised to demonstrate inconsistencies with normal physiologic principles and a purposive lack of cooperation. These are elaborated on in the literature (Stone and associates 2002b and 2013a, b). Discrepancies are usually found by testing an agonist, antagonist, or fixator movement while the patient is focused on making an effort with another group of muscles (e.g., the Hoover sign; see Chap 3). Muscular tone in the affected limbs is usually normal but slight resistance may sometimes be found. A seeming lack of effort and the absence of full compliance with the examiner's requests during the testing of muscle strength, while common in hysterical patients, are not confined to them; one encounters such findings not infrequently during the examination of suggestible but nonhysterical patients who harbor a neurologic disease and in those with a painful condition in an adjacent joint.

Walking and standing may be impossible (astasia-abasia) or the gait may be bizarre with collapsing legs that bring the patient to a squat, or a "skating" gait in which one foot is pushed ahead of the body. Other forms—some quite absurd such as the ability to walk only backwards, as noted in Chap. 6—are easily recognized as inconsistent with the makings of the nervous system in disease. Weakness and poor balance are combined elements in both the quadriparetic and hemiparetic forms. In an informative series of 60 cases of functional gait disorders, the hemiparetic and monocrural forms were twice as frequent as the quadriparetic (Keane). The gait disorder is sometimes difficult to describe because of its variability but is usually mistakenly called "ataxic" by inexperienced examiners. Sudden falls without voluntary protective movements and inconsistencies of balance are helpful features. Difficulty in walking and moving the legs that disappears when the patient is seated is, of course, not unique to hysteria; it also occurs in so-called frontal lobe gait apraxia and in ataxia from midline cerebellar lesions and in hydrocephalus.

In a most remarkable and recalcitrant form of psychogenic movement disorder, maintenance of the limbs in a rigid or dystonic posture for a long time may result in a bed-bound, crippled state with severe flexion pseudocontractures of the limbs. We have seen one such case of 18 years' duration. The tendon reflexes are usually normal if they can be tested, but with hysterical rigidity and muscular contractures, the abdominal and plantar reflexes may be suppressed.

Anesthesia or hypesthesia is almost always inadvertently suggested by the physician's examination. Seldom is sensory loss a spontaneous complaint, although "numbness" and paresthesias are not uncommon in hysterics. The sensory loss may involve one or more limbs below a sharp line (stocking and glove distribution), or may involve precisely one-half of the body, or vibratory sense may be lost over precisely one-half of the skull (a test favored to demonstrate hysterical hemianesthesia). Touch, pain, taste, smell, vision, and hearing may all be affected on that side, which is an anatomic impossibility from a single lesion. Other aspects of psychogenic sensory disturbance are discussed in Chap. 8. The closest syndrome is that produced by a thalamic infarction but this, too, is easily distinguishable from psychogenic hemianesthesia. The sometimes-stated notion that hysterical paralysis and sensory deficits are more common on the left side is apparently untrue (Stone and colleagues, 2002a).

The features of functional tremor and other movement disorders are described in Chap. 4. Emphasized here is the cessation of tremor with distracting tasks—for example, complex finger movement patterns on the side opposite the tremor (such as touching the fourth, second, and fifth fingers in sequence rapidly), or refixation of the eyes on a target, or walking on the outside of the heels. The ability of the examiner to "chase" the tremor to proximal or distal parts of the limb by holding and immobilizing one part is highly characteristic. Another fairly dependable but not invariable sign is worsening of a tremor with loading that is accomplished by placing a heavy object in the patient's hand (most basal ganglionic and cerebellar tremors are muted by this maneuver).

Some general characteristics of psychogenic movement disorders include a typically acute onset and rapid progression of the movements, distractibility, variability and the simultaneous occurrence of various abnormal movements and of unexplainable paralysis, sensory loss, or pain (Hinson and Haren). The movements are not explainable by characteristics of organic brain diseases, but as with all forms of functional disorder, it is not on this feature alone that the diagnosis can rest.

Functional Blindness (See Also Chap. 12)

This dramatic event may affect one or both eyes and may be coupled with hemiparesis or appear in isolation. The symptoms usually develop suddenly, often after an altercation or other emotionally charged event. The patient stares straight ahead blandly when undisturbed but may squint or move the head as if straining to see when asked to view an object. Some such individuals can reduce reflexive blinking in response to a visual threat. The psychic nature of the problem may be recognized by a nurse or assistant who observes the patient reaching for a cup or phone. The preservation of vision is confirmed by the presence of normal

pupillary reflexes and of optokinetic nystagmus, although one occasionally encounters a patient who has learned to suppress the latter response. A mirror passed slowly in the patient's central vision often engages eye movements. Other similar maneuvers are favored by different examiners. The presence of visual evoked responses also confirms the intactness of retinooccipital connections. The condition is usually short-lived. To be distinguished from these disorders are cortical blindness and variants of the Balint syndrome are the main diagnostic considerations (see Chap. 21).

Convergence spasm, occurring as an isolated phenomenon, is practically always of hysterical nature. A related phenomenon involves the *self-administration of mydriatic eyedrops* by healthcare personnel. The patient arrives on the emergency ward complaining of reduced vision (expected) or with headache and claiming to have an intracranial mass. This behavior is perhaps more sociopathic (or malingering) than hysterical.

Functional Amnesia

Despite being a Hollywood trope, patients brought to a hospital not knowing their own identity, in a state of amnesia, are usually hysterical or sociopathic individuals involved in a crime or having experienced an embarrassing event that they wish to obscure (e.g., marital infidelity). Epileptic patients or victims of a concussion, transient global amnesia, or acute confusional psychosis do not arrive asking for help in establishing their identity. Moreover, the complete loss of memory for all previous life experiences by patients who are otherwise able to comport themselves normally is not observed in any other condition.

In the *Ganser syndrome* patients essentially pretend to have become insane or demented. They may act in an absurd manner, simulating the way they believe that a deranged or demented person would act, and give senseless or approximate answers to every question asked of them (calling the color red, *blue* or answering *5* for 2 + 2).

Etiology and Pathogenesis

Psychoanalytic theory, which held that both conversion and dissociative symptoms were based on particular psychodynamic mechanisms, is impossible to affirm or refute. Although subject to some questions of fabricated recall, the high rate of childhood sexual abuse in severe monosymptomatic cases of hysteria or fugue states has been commented on in literature and seems unassailable. An acknowledged history of childhood abuse related by the patient alerts the physician to the possibility of hysteria. Sociologic and educational factors may be important. A genetic causation must also be considered since family studies have disclosed that approximately 20 percent of first-degree relatives of female sufferers of functional disorders have the same illness, an incidence 10 times that in the general population. This supports, in some views, the idea that ongoing functional disorder is a disease and not merely a surfacing of a personality trait (Goodwin and Guze).

Pathophysiology of Hysteria

Whether conversion symptoms are consciously produced by the patient or arise unconsciously, without the patient's awareness, is a question that has been debated endlessly without resolution. Babinski attributed the symptoms to *hypersuggestibility*. In fact, he defined hysteria as an illness whose symptoms could be induced (and removed) by suggestion. The present authors place credence on the notion of hypersuggestibility, in keeping with older ideas and studies that emphasized susceptibility to hypnosis and suggestion. Fascinating in this regard were the observations of Charcot's students that on their wards, the patients' symptoms disappeared when he died. There is some evidence to support this idea, as many patients can be readily hypnotized and their symptoms temporarily eliminated by this procedure or by an interview and examination under the influence of midazolam (formerly drugs such as pentothal were used). The potentially condescending or deceptive aspects of undertaking these tests has evinced modern comment and has limited their use without assent of the patient.

Some insights can be obtained from studies of functional imaging in functional paralysis (see also Chap. 3). In general, activity in the contralateral prefrontal cortex is suppressed when the patient with hysteria attempts to move a limb, suggesting a "choice" of an active attempt not to move the limb (Spence and colleagues, Carson and colleagues). The pattern of activation is different from volunteers who purposefully feign paralysis and do not demonstrate such reduced prefrontal activity. When the hysteric with unilateral sensory loss is stimulated on the affected limb, there is no activation of the contralateral sensory cortex but bilateral stimulation results in activation of the appropriate regions in both hemispheres (Ghaffar et al).

Functional disorder and sociopathy may be related (Carothers). This relationship is also supported by family studies. First-degree male relatives of women with functional disorders have an increased incidence of sociopathy and alcoholism; among first-degree female relatives of convicted male felons, there is an increased prevalence of hysteria.

Diagnosis

It should be emphasized that single bouts of isolated functional paresis, blindness, and anesthesia are common in neurologic practice and do not presage a chronic illness. The same is true for transient neurologic signs exhibited during the course of the examination, mainly pertaining to unusual or drifting sensory loss or asthenic weakness of a limb.

With respect to the diagnosis of a life-long functional disorder (Briquet disease), the characteristic age of onset; the longitudinal history of recurrent multiple complaints as outlined earlier; the attitude of the patient and the manner of presenting symptoms; the incongruity of affect and clinical state; the discrepancy between the report of neurologic deficit and the signs; the impossibility of explaining the patient's signs on an anatomic or physiologic basis; and the absence of symptoms and signs of other medical and surgical disease will permit diagnosis in the majority of cases. Certain tests designed to reveal normal functioning of a limb, of vision, and of gait already have been mentioned.

As to the frequency of incorrect diagnosis in these disorders, an assessment of over 1,000 patients who were given the diagnosis of a functional disorder, only

0.4 percent were later found to have an organic explanation for their symptoms but surveys in specialty clinics for functional disorders have acquisition bias that inflates incidence figures (Stone and colleagues, 2009). In contrast, on record are studies in which patients with an initial diagnosis of hysteria by general physicians were followed for many years and in which up to one-third (far less in most series) turned out eventually to have an "organic condition" that, in retrospect, explained the symptoms (Couprie et al). The physician can be reassured that in most follow up studies of patients with so-called conversion disorder (exclusive of pseudoseizures), virtually none develops a neurologic lesion that in retrospect was related to the initial episode (Stone and colleagues, 2003). It is of interest that in the series cited, most patients had persistent functional disability from their conversion symptoms, even a decade later. When the diagnostic criteria in these cases are closely analyzed, it becomes apparent that the diagnosis was made solely by the "discrepancy method"—that is, the patient's symptoms or signs were not deemed to be credible manifestations of disease, based mainly on the clinical experience of the examiner. Of course, this assumes that the examiner has a wide experience; unfortunately for the novice, many syndromes are difficult to identify and comprehend. However, when diagnosis is based on the totality of the clinical picture and not on the "discrepancy method," it can be quite accurate.

Projective tests (the Rorschach and Thematic Apperception Tests), which for a time were popular with dynamic psychiatrists, are apparently not helpful in diagnosis and are now used very little. The presence of extreme suggestibility and the tendency to dramatize symptoms as measured by one part of the Minnesota Multiphasic Personality Inventory and other psychometric tests is helpful in diagnosis but not pathognomonic; these traits appear under certain conditions in individuals who never develop hysteria.

Treatment of Functional Symptoms

Here, opinions differ but modern approaches that are nonjudgmental, straightforward, and aimed at returning the patient to good function have great appeal. Treatment may be considered from two aspects: the recognition of childhood trauma and amelioration of any maladaptive long-standing traits and relieving recently acquired physical symptoms. Psychotherapists have attempted to modify traumatically induced personality traits through long-term reeducation, but their results are uninterpretable and there are no control studies for the few reports of therapeutic success. In less severe cases and especially in those in whom hysterical symptoms have appeared under the pressure of a major crisis, explanatory and supportive psychotherapy appears to be helpful, and the patients have been able to resume their roles in life and work.

Acute symptoms can often be mitigated by persuasion and demonstration. One approach is to explain the nature of the illness and point out how common it is and offer support to reverse the main features. Reassurance that recovery is possible and that the patient seems to be in the process of recovering may be useful. It has been suggested that showing the patient objective evidence of the functional nature of weakness, such as Hoover sign, is useful demonstrating the correctness of the diagnosis and demonstrating its potential reversibility (Stone and Edwards). The earlier this is done after the development of symptoms, the more likely they are to be relieved. Sometimes a single symptom such as hemiparesis or tremor can be halted by a particular maneuver and this demonstration suffices to begin recovery. In chronically bedridden patients, pressure to get out of bed and resume function can be applied.

Several approaches to discussing the symptomatology with the patient have been suggested. At one extreme is a confrontative approach in which the patient is told the symptoms are psychologic, or "in your head." We have found this to be counterproductive and almost always provokes an angry response that does not aid clinical improvement. At the other extreme is complete avoidance on the part of the physician, an approach that is almost as unproductive. We prefer to ask the patient if the symptoms can in some way be the result of "stress" or an upsetting recent experience. On occasion, in private, we will inquire about childhood sexual abuse and often get an affirmative response from the patient, with later confirmation by a spouse or sibling. Very powerful is nonjudgmental but firm reassurance that there is no serious disease. We have found it useful to list the diseases that have been excluded by examination and testing: brain tumor, stroke, amyotrophic lateral sclerosis, multiple sclerosis, etc. This often evokes an acknowledgment by the patient that one of the diseases had been a preoccupying concern. We then indicate, without using psychologic terms, that the brain may at times adopt certain patterns of behavior that do not reflect structural damage, and, furthermore, that these patterns can be unlearned with physical therapy and time, as described in the following text.

That the patient's response to these conversations varies widely is not surprising. One group seems not to mind and to be relieved by the expression of concern and reassurance that there is no dangerous disease at the root of the problem. They can be sent for physical therapy and may do well in the short run. Another group is indignant and unlikely to consult the physician again; several in the past have refused to pay the doctor's bill (before the era of insurance coverage) or written critical letters to hospital representatives. Many have objected to the explanation based on their own view, often derived from research on the Internet and with similarly afflicted persons, that Lyme disease, chronic viral infection, environmental toxins, allergies, etc., are to blame. A few of these cases have the flavor of a delusion. All that the physician can offer here is an openness to see and reexamine the patient in several months as "cure" has limited meaning in these instances and there is a high likelihood that such individuals will see a long list of doctors.

The success of any of these programs over a long period is unknown. The eradication of recently acquired hysterical symptom is relatively common. The real test is whether it enables the patient to adjust satisfactorily to family and society and to perform daily activities effectively, and whether it prevents addiction, unnecessary medical treatments, and operations. Estimates of the recurrence rate of hysterical symptoms vary widely from 12 to 80 percent. In various series (Gatfield and Guze; Merskey), the recurrence of somatic symptoms of similar or of other types was

as high as in sociopathies. We have seen a few patients with monosymptomatic hysteria (paraparesis, bizarre gait, crippling dystonia) that persisted for years on end regardless of treatment. The use of a wheelchair for more than several days has been a bad prognostic sign.

Hypochondriasis

This is the preoccupation with bodily functions or physical signs and sensations, leading to the fear or belief of having serious disease. Hallmarks of this condition are the failure of repeated examinations to disclose any physical basis for the patient's symptoms and the failure of reassurance to affect either the patient's symptoms or his conviction of being sick. It is estimated that 85 percent of hypochondriasis is secondary to other mental disorders, chiefly depression, but also schizophrenia and anxiety neuroses. In approximately 15 percent of cases, however, there appears to be no associated illness (*primary hypochondriasis*). Most patients in this latter category are habitués of medical outpatient clinics, who are passed from specialist to specialist, perplexing and angering doctors along the way, because their symptoms defy both satisfactory diagnosis and cure.

Related to hypochondriasis, but probably delusional are young adults who present with a fixed somatic belief regarding a peculiar symptom such as that the tongue is swollen, the jaw is not properly aligned, or the penis is ulcerated, when in fact no such abnormalities are present. The troubling aspect to the family and physician of such an illness is the persistence of the symptom and disability that extends for years, all tests having been negative. Probably these patients should be treated like schizophrenics, which many of them probably are. What to do with patients who are less severely affected but who have an unshakable belief that they have Lyme disease or environmental "allergies" as mentioned above depends on the context, but the likelihood of dissuasion is almost as poor as for the worst hypochondriac patients.

The treatment of primary hypochondriasis is difficult unless the physician keeps in mind the personality of the patient and the therapeutic goals. A psychodynamic outlook would suggest that these patients need to retain their symptoms, so that the usual concept of "curing" is inapplicable. The presence of symptoms provides the context for a relationship with a physician, and it is the continuation of this relationship, which is often the only dependable contact in the patient's life, which is the motivation for some hypochondriac patients. Such patients are best managed by general physicians who realize that these are patients who do not necessarily want or expect a cure, and who are content with small gains and the avoidance of unnecessary surgery.

SOCIOPATHY

Of the abnormal personality types listed in Table 47-1, the antisocial type is the best defined and the one most likely to cause trouble in the family and community. It had been defined (in DSM) as a state in which the individual "is always in trouble, profiting not from experience or punishment, unable to empathize with family or friends or to maintain loyalties to any person, group, or code. He is likely to be shallow, callous, and hedonistic, showing marked emotional immaturity with lack of sense of responsibility, lack of judgment, and an ability to rationalize his behavior so that it appears warranted, reasonable and justified."

Since Prichard, in 1835, first described this condition under the term *immoral insanity*, there have been many attempts to give it a more precise definition and to avoid using it as a psychiatric wastebasket. At the turn of the century, Koch introduced the term *psychopathic inferiority*, implying that it was a constitutionally determined deviation in personality. Later the term *psychopathic personality* came into common use. In the past, many authors used this last term indiscriminately to embrace all forms of deviant personality. Subsequently, the term came to be used in a more restricted sense to define a subgroup of antisocial or aggressive psychopaths (*antisocial personality disorder*). Aubrey Lewis has given a lucid account of the history of the concept of sociopathy. A study of sociopathy based on a 30-year follow-up study of 524 cases from a child guidance clinic and 100 controls concluded that the behavior is intransigent over time (Robins). Investigations of psychiatric illness in large numbers of felons and their first-degree relatives are also instructive and emphasize the complexity of the problem (Cleckley; McCord and McCord; Guze and coworkers). Common to these individuals is unemotional and remorseless behavior. The following material and the preceding quotation are taken largely from these writings and from those of Reid.

Clinical Description

This condition, unlike the majority of psychiatric disorders, is manifest by the age of 12 to 15 years, and frequently earlier. The manifestations of sociopathic behavior in children and adults are 5 to 10 times more frequent in males than they are in females. It consists essentially of deviant behavior in which individuals seem driven to cause difficulty in everything they do or behave in a way that most societies identify as grossly criminal. Norms imposed by family, school, religion, and society are broken. Seemingly, the sociopath acts on impulse, but after committing the unsocial act, he shows no remorse. The most frequent antisocial activities are theft, truancy, running away, associating with undesirable characters, indiscriminate sexual relations, repeated fighting, recklessness and impulsivity, lying without cause, vandalism, abuse of drugs and alcohol, and, later, inability to work steadily or keep a job. Criminality is intimately associated. Fire setting and cruelty to animals are particularly associated with future sociopathy according to several authors (the "callous youth" alluded to above). Of children or adolescents who exhibited 10 or more antisocial symptoms, 43 percent were categorized as sociopaths in adulthood (Robins et al). If only 8 or 9 of these traits were present, 29 percent were so grouped; if 6 or 7, 25 percent; and 3 to 5, 15 percent. Conversely, not a single adult sociopath was observed who did not manifest antisocial symptoms in earlier life. Interestingly, a number of other problems of childhood and adolescence—such

as enuresis, dirty appearance, sleepwalking, irritability, nail biting, oversensitivity, poor eating habits, nervousness, being withdrawn or seclusive, unhappiness, tics, and fears—were not predictive of adult sociopathy.

At the same time, it should be noted that more than half the disturbed children in large studies (Robins) had lost most of their sociopathic traits by adulthood. This does not mean that they remained societally normal. Of those who did not become adult sociopaths, the most developed other adult psychiatric illnesses, particularly addiction to alcohol. Only in the group of children with fewer than three antisocial symptoms did a reasonable number (one-third) remain entirely well from a psychiatric point of view in adult life. Because sociopathic behavior in children may terminate spontaneously or evolve into other disorders, it is advised that the diagnosis of antisocial personality disorder be reserved for adults; the same behavior pattern in children is designated as *conduct disorder*.

In most series, a search for evidence of encephalitis, often postulated in the past as the basis of sociopathy, was not revealing, nor was there any proof of other brain damage. In the current era, head trauma is often imputed as the cause of troublesome behavior in adolescents and young adults, but there is no basis for this view. EEG abnormalities, taking the form of mild to moderate bilateral slowing, are more frequent in criminals and sociopaths than they are in the normal population in some series, but the validity of this finding is uncertain.

Some findings suggest a genetic predisposition to antisocial personality. In a Danish study of criminals, "inappropriate nonpsychotic impulse-ridden behavior" was found five times more frequently in first-degree biologic relatives than it was in the general population (Christiansen). Criminality was two times more frequent in monozygotic twins than it was in dizygotic twins. Further evidence of a genetic factor was provided in a study of adoptees who were separated at birth from antisocial biologic parents (Cadoret). A higher incidence of antisocial behavior was present in the adoptees than were in controls.

Treatment There is limited information as to the best approaches to treatment and the role of the medical profession has never been clear. Most psychiatrists have been discouraged by the results of psychotherapy, but whether behavioral therapy, psychoanalysis, or drugs have more to offer cannot be determined from available data. Medical efforts should be directed to evaluating the patient's neurologic status, assessing his intelligence, and explaining the nature of the disorder to parents and social agencies, tasks best performed by a psychiatrist. It seems reasonable to approach minor criminal behavior early in life and to use peer counselling and guidance by organized groups to engage in juvenile delinquency. However, some of the substrate for these behaviors in disadvantaged socioeconomic circumstances is a larger societal problem.

Malingering

This problem arises frequently in connection with both functional illness and sociopathy, and the physician should know how to deal with it. The term *malingering* refers to the conscious and deliberate feigning of illness or disability to attain a desired goal. It does not appear as an isolated phenomenon, and its occurrence must be interpreted as a sign of a serious personality disturbance, often one that prevents effective work or military service, as a means of obtaining recompense for an alleged injury, or avoiding the penal system, although noteworthy exceptions to this statement can be found.

In the malingerer one may observe pain, hyperesthesia, anesthesia, limping gait, tremor, contracture, paralysis, amaurosis, deafness, stuttering, mutism, amnesia, pseudoconvulsions and fugues, jumping of limbs with touch, and unexplained skin lesions—in short, the same array of symptoms and signs, singly or in combination, as in the patients with functional disorders. Probably the medical profession has placed too great a reliance on degree of conscious awareness of deception. In such unstable and immature individuals, the terms *conscious*, *unconscious*, and *deception* are too uncertain to be useful.

A particular form of sociopathy or malingering, which consists essentially of systematically and specifically deceiving the medical profession, has been called *Munchausen's syndrome*—named (not altogether aptly) after a 17th-century German soldier, Baron von Munchausen, who invented incredible tales of adventure and daring. In an analysis of 59 cases (45 men, 14 women), the following characteristic features are common, which will be recognized by experienced neurologists: feigned severe illness of a dramatic and emergency nature; factitious evidence of disease, surreptitious interference with diagnostic procedures, or self-mutilation; a history of many hospitalizations (sometimes more than 100); extensive travel or visits to innumerable physicians; and, finally, regular departure from the hospital against medical advice (Ireland and colleagues).

Intermittent Explosive Disorder

Designated by this title is an uncommon disorder, the characteristic feature of which is the occurrence of repetitive, unpredictable outbursts of violent, aggressive behavior disproportionate to the provoking situation. This condition needs to be set apart from the uncontrollable outbursts that sometimes are associated with dementia, developmental delay, autism, schizophrenia, drug addiction, alcoholism, or those that follow serious head injuries or other brain diseases. Neurologic opinions have been solicited on our services for patients afflicted with this condition, the question usually being one of seizures as a cause of the aberrant behavior. Some persons with intermittent explosive disorder have, from early childhood, reacted to frustration with a loss of self-control, striking out in blind rage at anyone who crossed them (*episodic dyscontrol syndrome*); as adults, they may inflict serious injury or kill. Lesser degrees are recognized as expressions of "hot temper." Sometimes such behavior appears to be a continuation of the temper tantrums of earlier childhood. What is surprising in some of our patients has been a discrepancy between this episodic behavior and a pleasant and concerned, even contrite, demeanor at other times. Such patients are aware of the inappropriate nature of their behavior and its impact on others; they express remorse and may seek medical

assistance to mute the outbursts. Others, of course, have no such insight and their anger episodes are simply an extension of their sociopathy.

The causes of aggressive violence are poorly understood. There appears to be a heritable tendency (Cadoret et al, 1997); males predominate and a sex-linked form extending over several generations has been described. Polymorphisms of the androgen receptor have been implicated in several preliminary studies. In only a very small number of patients, a seizure disorder can be identified, particularly temporal lobe epilepsy, but the majority still appear to be constitutional in nature. A state of adrenergic hyperactivity has been suggested and supported to some extent by these patients' response to propranolol, but this is not explanatory of the behavior (Elliott; Jenkins and Maruta; also see Chap. 25 discussion of the limbic system). Intense outbursts of anger and physical violence are also infrequent features of the diagnostic category of *borderline personality disorder*, the other manifestations of which include "a pervasive pattern of instability of mood, interpersonal relationships, and self-image." Besides propranolol, lithium, carbamazepine, and phenytoin have been found to be helpful in controlling and preventing the explosive attacks in uncontrolled studies. We have noted the recent increased use by psychiatrists of serotonergic antidepressants in these patients but have no way to judge their effect.

ANOREXIA NERVOSA AND BULIMIA

Anorexia nervosa is a behavioral disorder of previously healthy girls and young women living in affluent societies, mainly from upper and middle social classes, who become emaciated as a result of voluntary starvation. It is rare in Asian and African American women, and very uncommon in males. Richard Morton first described the condition in 1649, under the title of "nervous phthisis," a "nervous consumption" resulting from "sadness and anxious cares"—a title that embodied enigmatic roots in psychologic derangements (Herzog and Becker). Bulimia (literally ox-hunger), to which it is closely related, was not identified as an eating disorder until the latter part of the 19th century.

As a rule, anorexia nervosa begins shortly after puberty—sometimes later, but seldom after 30 years of age. Some of the patients were overweight in childhood, especially in the prepubertal period. Dieting is much talked about and may have been encouraged. In times when dieting and female thinness are considered normative or desirable, the disorder seems to be more common and lesser but transient forms of the disorder are frequent in high school- and college-age young women. Sometimes there appears to be a precipitating event, such as leaving home, disruption of family life, or other stress. Whatever the provocation, it leads to an obsessive refusal to eat. What is more important, the abnormal eating habits persist even when the patient has become painfully thin, and when counseled to eat normally she will use every artifice to starve herself. Food is hidden instead of being eaten, vomiting may be provoked after a meal, or the bowel may be emptied by laxatives. The patient shows no concern about her obvious emaciation and remains active, if not overactive in exercise. If left untreated, these patients may waste away, and approximately 5 percent have succumbed to some intercurrent infection or other medical complication, placing it among the lethal psychiatric conditions.

One is struck with the degree of emaciation; it exceeds that of most of the known wasting diseases. Often 30 percent or more of the body weight may have been lost by the time the patient's family insists on medical consultation. Bradycardia and hypotension are indicators for hospitalization. A fine lanugo covers the face, body, and limbs. The skin is thin and dry, without its normal elasticity, and the nails are brittle. The dental enamel is eroded. Pubic hair and breast tissue (except for loss of fat) are normal, and, in this respect, anorexia nervosa is unlike hypopituitary cachexia (Simmonds disease). Surprisingly, however, there are infrequently neurologic signs of nutritional deficiency. The patient is alert and cheerfully indifferent to her condition. Any suggestion that she is unattractively thin or seriously depleted is rejected.

Amenorrhea is practically always present and may precede the extreme weight loss. Luteinizing hormone (LH) concentrations are reduced to pubertal or prepubertal levels. Clomiphene citrate fails to stimulate a rise in LH, as it does normally. Administration of gonadotropic-releasing factor raises the LH and follicle-stimulating hormone (FSH) levels, suggesting a hypothalamic disorder. The basal metabolic rate is low; triiodothyronine (T_3) and thyroxine (T_4) are low, while levels of physiologically inactive 3,3,5-triiodothyronine (reverse T_3) are normal or increased. Plasma thyrotropin (thyroid-stimulating hormone [TSH]) and growth hormone levels are normal. Serum cortisol levels are usually normal; excretion of 17-hydroxysteroids is slightly reduced. In sum, there is evidence of hypothalamic–pituitary dysfunction, but this is probably secondary to starvation (and there are no definite changes in the pituitary gland in fatal cases (Scheithauer and colleagues). These endocrine abnormalities, most of which are probably secondary effects of weight loss have been summarized in various reviews (Becker and colleagues). Brain imaging shows slight to moderate enlargement of the lateral and third ventricles, which return to normal size when the disorder subsides.

The etiology of anorexia nervosa is unknown, although there is no lack of hypotheses. A high concordance in monozygotic twins as compared with dizygotic twins has been noted (Holland and coworkers). Earlier signs of hysterical tendencies, obsessional personality traits, and depression are mentioned as being frequent in some series, but not in others. Certain polymorphisms in the serotonin transporter gene, of types different from those that have been tentatively attached to anxiety and to obsessive traits, have also been reported. These findings are difficult to interpret. A functional imaging study has shown activation of the left insula, amygdala, and cingulate when high-calorie drinks were imbibed by anorectic women (Ellison et al), but this conceivably may have reflected anxiety termed *calorie fear* rather than a specific biologic feature of the disease.

Reports concerning the percentage of first-degree relatives of anorectic patients with bipolar disease are

also inconsistent. An increased prevalence of neurosis or alcoholism has been noted in other members of the family. However, psychiatrists seem to agree that the patient does not have symptoms that conform to any of the major neuroses or psychoses. Certainly, loss of appetite, lack of self-esteem and interest in personal appearance, and self-destructive behavior—common features of anorexia nervosa—are also symptoms of depressive illness, yet most of the patients do not look or admit to being dejected. Moreover, endogenous depression affects both sexes. The pathologic fear of becoming fat and the obsession with weight might be interpreted as a phobic or obsessional neurosis.

That anorexia nervosa is practically confined to females must figure in any acceptable explanation of the syndrome. Probably important is that anorexia nervosa has its onset in relation to menarche, at a time when the female exhibits rather large fluctuations in appetite and weight. This has suggested to some an imbalance between the satiety center, believed to lie in the ventromedial hypothalamus, and the feeding center, in the lateral hypothalamus.

An association of *anorexia* with structural disease involving the appetite centers has not been established, although rare cases of acquired anorexia have been attributed to lesions of the lateral hypothalamus (Lewin and colleagues; White and Hain; Martin and Reichlin). A disorder of infants described under "diencephalic syndrome" causes progressive and ultimately fatal emaciation despite normal food intake in an otherwise alert and cheerful infant. The causative lesion has usually proved to be a low-grade astrocytoma of the anterior hypothalamus or optic nerve region (Burr et al). Also interesting is a case in which profound and long-standing anorexia nervosa resolved after a left thalamic stroke (Dusoir et al). See Chap. 26 for further discussion and references.

Treatment Treatment at the moment consists of winning the patient's confidence, supportive psychotherapy, assignment of one individual to sit with the patient as each meal is eaten, and a gradual increase of a balanced diet (Anderson). Extreme cases require hospitalization. If the patient refuses to eat, tube feeding may be lifesaving. As weight is gained over several weeks, the patient usually becomes more normal in attitude toward eating and will continue to recover on this regimen at home. Menses do not return until considerable weight has been gained (approximately 10 percent above the weight at the time of the menarche). Some of our colleagues report better success with such a regimen when imipramine or fluoxetine has been added; others have found these drugs to be ineffective except in patients with prominent symptoms of depression.

The potentially devastating medical complications to which severely anorectic patients are prone and the need to evaluate and treat these problems at the same time that nutritional therapy is undertaken has been emphasized (Becker and colleagues). In particular, an electrocardiogram may disclose a prolonged QT interval—the presence of which contraindicates the use of tricyclic antidepressants and increases the risk of ventricular tachycardia.

On average, about half of patients recover completely or almost completely (Steinhausen and Seidel). In the remainder, the outcome is generally unfavorable. They either relapse after an initial period of improvement or remain chronically anorectic. Many patients are said to lapse into a chronic dysfunctional state characterized by a persistent preoccupation with food, weight, dieting, and exercise. It is not generally appreciated that chronic anorexia nervosa significantly shortens life; after a mean follow-up period of 12 years, 11 percent of a group of 84 patients had died (Deter and Herzog), and 15 percent after 20 years (Ratnasuriya et al). Suicide is a contributor to this high mortality rate (Sullivan). The few adolescent boys with this syndrome recovered on antidepressant medication.

In general, the therapeutic benefit of medications is considerably greater in cases of bulimia than in anorexia nervosa (Mehler).

Depression and Bipolar Disorder

These disorders are ubiquitous in all societies and cause considerable suffering. These disorders, while manifesting themselves as changes in mental life, are nevertheless clearly mediated by brain function. They assume importance for psychiatrists and neurologists but are embedded in the practices of virtually all branches of medicine.

DEPRESSION

Depression is perhaps the cause of more grief and misery than any other single disease to which humankind is subject. This view, expressed by Kline more than 50 years ago, is still shared by almost everyone in the field of mental health and the several forms of depression taken together are the most frequent of all psychiatric illnesses. The term "depression" denotes both a state of being and a more formally defined psychiatric disorder. The Global Burden of Disease Study 2019 affirms this view and estimates that depression is the fourth leading serious illness cause of disability in adolescents and young adults and a major contributor to self-harm and suicide deaths (GBD 2019). In a general hospital, as indicated in the previous chapter, depression accounted for an estimated 50 percent of psychiatric consultations and 12 percent of all admissions.

Although depression has been known to physicians for more than 2,000 years (melancholia is described in the writings of Hippocrates), it has been difficult to separate the medical aspects (Kraepelinian concept) from the psychologic reaction (Meyerian concept). In other words, is it basically a biologic derangement or a response to psychosocial stress? A balanced position is that both are correct—that is, there are two basic substrates for depression: exogenous (an apparent cause) and endogenous (with no overt external cause), and that there is an interplay between them and biologic susceptibility to either one. The boundaries between a biological disease and the medicalization of everyday life are therefore blurred. However, clinical and physiological states of depression that do not accord with external circumstances, when prolonged or severe, constitute an illness and recurrent bouts can probably be said to constitute a disease.

In respect to endogenous depression and the related condition of bipolar disease, genetic and neurochemical data cited further support the Kraepelinian view of a disease state. Nevertheless, a lay concept persists, perpetuated by process-oriented psychiatrists, that events in one's life, either distant or current, underlie all types of depressive illnesses. A potential consequence of this view is the assumption that an inability to deal with these stresses represents a personal failure of sorts, and this, in turn, may inhibit the acceptance of psychiatric help. It is in this subject of depression that the interplay between our ongoing internal conversation and brain states meets. As noted further on, the difficulties of daily life can entrain the circuits that correspond to depressive feeling and affect. Seeking causality in either direction is complicated and self-referential; for example, functional imaging that purports to show patterns of depression may be the brain representation of that activity and not its genesis.

Of considerable consequence for clinical work, depressive states are often associated with obscure physical symptoms. For this reason, these manifestations of depression are likely to come first to the attention of general physicians. All fields of medical specialty, however, have depressive equivalents; the physical symptoms of depression may be mistakenly attributed to conditions such as anemia, low or high blood pressure, hypothyroidism, migraine, tension headaches, chronic pain syndrome, or chronic infection. Neurologists are most likely to encounter depressed patients who complain of fatigue and weakness, chronic headache, pain, and difficulty in thinking or remembering. In 249 "manic-depressive" patients, who were mainly depressed, compared to 50 hospitalized patients who had systemic medical diseases, the depressed patients had higher rates of headache, tinnitus, blurred vision, chest pain, palpitations, and a long list of other physical symptoms than the medically sick patients (Cassidy et al). Depression masquerading as chronic pain, fatigue, or some other medical condition had been called *masked depression* or *depressive equivalent*, terms we still find useful in explaining certain symptoms to patients.

There are numerous reasons for separating the problem of endogenous depression from bipolar disease, defined as a life history of both mania and depressive episodes, but the distinction clinically may be difficult because the bipolar disease may be dominated by depressions, with manic or hypomanic episodes appearing as only a minor or infrequent problem. Foremost among the reasons to consider them separately are differences that

have been highlighted in response to treatment. In keeping with modern notions, endogenous depression and bipolar disorder are presented separately in this chapter, but an understanding of either one is incomplete without knowledge of the other.

Another important reason why physicians should be aware of depressive illness in all its forms is the danger of suicide, which may be attempted and successfully accomplished before the depression is recognized. Timely diagnosis may prevent such a tragedy—one that is all the more regrettable as some depressive illnesses can be successfully treated.

As remarked in Chap. 23, the term *depression* embraces more than a feeling of sadness and unhappiness. It stands for a complex of disturbed feelings (*mood* or *affective disorder*)—which may include despair, hopelessness, sense of worthlessness, and thoughts of self-harm—associated with decreased energy and libido, loss of interest in personal affairs, impaired concentration, various abnormalities of behavior and appearance, and sometimes, prominent physical complaints. The most important of these include anxiety, insomnia, anorexia or overeating, headache, and various types of regional pain. At one extreme are depressive symptoms of psychotic proportions that incorporate paranoid or somatic delusions, which create chaos in the lives of patients and those close to them. At the other extreme are the common feelings of unhappiness, anhedonia (loss of pleasurable responses), discouragement, and resentment that may occur in almost everyone as a reaction to the disappointments of everyday life, such as loss of employment, failure to gain recognition, or unsuccessful social adjustment.

The place in this nosology of the special case of *postpartum depression* has not been clear, and it is discussed in this chapter as well in the next one, as it is sometimes difficult to differentiate it from postpartum psychosis, a more dramatic and well-defined disorder. Some authors question the primacy of a primary biologic entity that is tied to the postpartum period (Brockington), but this diverges markedly from the general experience, in which varying degrees of depression are quite common in the weeks after delivery and cannot simply be attributed to psychosocial factors or sleep deprivation.

As a purely phenomenological observation, an abnormally elevated mood, or *mania*, is about one-third as frequent as depression. It may develop as a relatively pure, recurrent clinical state, or, more often, may alternate or be intertwined with depression, in which case it was referred to as *manic-depressive disease* (now, *bipolar disorder* in the classification of the *Diagnostic and Statistical Manual of Mental Disorders* (American Psychiatric Association). *Hypomania* and *cyclothymic disorder* have been the names given to milder forms of mania and bipolar disorder, respectively. The DSM classifications acknowledge the existence of a mixed *schizoaffective state* in which attributes of depression and schizophrenia are combined. Distinguishing these various types of depressive illnesses is of therapeutic as well as theoretical importance insofar as a particular type may respond better to one form of treatment than to another. Finally, the neurologist should bear in mind the possibility of an incipient dementia presenting as a depression, although the reverse, a masked depression causing difficulty with thinking and memory (pseudodementia) is more common in general practice.

Reactive Depressions and Depressions With Medical and Neurologic Diseases

Patients reacting to a medical or neurologic illness seldom express feelings of sadness or despair without mentioning physical accompaniments such as easy fatigability, anxiety, headaches, dizziness, loss of appetite, reduced interest in life and love, trouble in falling asleep, or premature awakening. It follows that whenever these symptoms become manifest in the course of medical disease, they should arouse suspicion of a depressive reaction (Table 48-1).

Chronic pain is a frequent somatic manifestation of depression. The pain may be based on an attendant disease but is prolonged, disabling, sometimes vague in nature, and recalcitrant to straightforward medical and surgical approaches. Furthermore, a depressed mood exacerbates and prolongs the pain of any type. All patients with chronic pain syndromes should be evaluated psychiatrically, as pointed out in Chap. 7.

Table 48-1

DEPRESSION SECONDARY TO NEUROLOGIC, MEDICAL, AND SURGICAL DISEASES AND DRUGS

1. Neurologic diseases
   a. Neuronal degenerations—Alzheimer, Huntington, frontotemporal dementia, Lewy-body disease, Parkinson disease, and multiple system atrophy
   b. Focal CNS disease—strokes, brain tumors, trauma, multiple sclerosis
2. Metabolic and endocrine diseases
   a. Corticosteroids, excess or withdrawal
   b. Hypothyroidism, rarely thyrotoxicosis
   c. Cushing syndrome
   d. Addison disease
   e. Pernicious anemia (vitamin B_{12} deficiency)
3. Myocardial infarction, open heart surgery, and other operations
4. Infectious diseases
   a. Brucellosis
   b. Viral hepatitis, influenza, pneumonia
   c. Infectious mononucleosis
   d. Whipple disease
   e. Creutzfeldt-Jakob disease
5. Cancer, particularly pancreatic and metastatic
6. Parturition
7. Medications
   a. Corticosteroids and ACTH
   b. Interferons
   c. Analgesics and anti-inflammatory agents (other than steroids)—indomethacin, phenacetin
   d. Certain antiseizure drugs
   e. Antibiotics, particularly cycloserine, ethionamide, griseofulvin, isoniazid, nalidixic acid, and sulfonamide
   f. Antihypertensive drugs—clonidine, propranolol (and certain other beta-adrenergic blockers)
   g. Cardiac drugs—digitalis, procainamide
   h. Disulfiram
   i. L-Dopa
   j. Methysergide
   k. Oral contraceptives
8. Alcoholism

ACTH, adrenocorticotropic hormone; CNS, central nervous system.

In several major medical illnesses, depressive symptoms occur with such frequency as to become almost part of the disease. Contrariwise, in certain chronic and occult diseases, symptoms econdary such as lassitude and fatigue may resemble and be mistaken for a depressive reaction. Hypothyroidism, infectious mononucleosis, hepatitis, lymphoma, myeloma, metastatic carcinoma, malnutrition, polymyalgia rheumatica, and frontal lobe tumors, especially frontal meningiomas, may simulate depression for weeks or months before the medical diagnosis becomes evident. A special relationship to occult pancreatic or other abdominal cancers has been suggested over the years, but it is difficult to understand. Sedative drugs, beta-adrenergic blocking agents, beta-interferons for the treatment of multiple sclerosis and hepatitis, and phenothiazines may also evoke a depressive reaction; corticosteroids can induce a peculiar psychiatric state in which confusion, insomnia, and either an elevation of mood or depression are combined, even to the point of psychosis. A depressed mood may also emerge during the tapering-off period of corticosteroid medication (a hypomanic state is more common in our experience during active use). In neurologic practice, there has been increased awareness of depression associated with the use of antiseizure medications, for example, levetiracetam.

Of particular significance is the reactive depression that occurs on learning of a serious medical or neurologic disease. Often such an emotional reaction, which the physician may tend to ignore, is the dominant manifestation of a disease that threatens the life pattern and independence of the patient. Recognition by the patient that he has suffered a stroke or that he has cancer, multiple sclerosis, amyotrophic lateral sclerosis, or Parkinson disease is almost always followed by some degree of reactive depression, often with an element of anxiety. A prime example is depression that follows myocardial infarction (Wishnie et al). Usually, it begins toward the end of the patient's stay in the hospital and attracts little attention. Once the patient is home, fatigability that approaches exhaustion may be the main complaint and interfere with accustomed activities and rehabilitation. It may be described as weakness and falsely attributed to heart failure. Symptoms of irritability, anxiety, and despondency are next in order of frequency, followed by insomnia and feelings of aimlessness and boredom. Although most of these patients ultimately recover without medical assistance, depression exacts a high toll in terms of mental suffering and some surveys suggest a relation of depression to poorer cardiovascular outcomes.

Depression Following Stroke and With Degenerative Neurologic Disease

An analogous depressive reaction occurs in some patients after stroke. Some, but not all, studies have indicated that patients with left anterior cerebral lesions, involving predominantly the lateral frontal cortex or basal ganglia, have a greater frequency and severity of depression than do patients with lesions in other locations (Starkstein et al, 1987; Robinson). Lesions of the right hemisphere have not shown this correlation with depression but have a higher association with pathologic cheerfulness or mania, although these phenomena are rare. However, a British community-based study of stroke survivors failed to confirm these findings, perhaps because the infarcts were small in size (more than half the patients had never been admitted to hospital) and many patients were examined for the first time only at 6 and 12 months after their strokes (House and colleagues). The occurrence of psychotic depression with hallucinations and delusions has been reported in patients with right temporoparietal infarcts (Levine and Finkelstein). Our experience suggests an unsurprising relationship between the degree of motor and language disability and the severity of poststroke depression but a less predictable relationship to the location of the lesion. The possible predisposing effects of minor previous episodes of depression, family history of depressive illness, and medications have not been studied systematically. These issues are also incorporated into Chap. 33 on Cerebrovascular Disease.

With regard to emotional reactions in degenerative brain diseases, Parkinson disease is complicated by a depressive reaction in approximately one-quarter of cases. Weakness and fatigability, already aspects of the motor syndrome, are added to the principal psychologic manifestations and the resulting therapeutic problem becomes formidable. Another hazard in Parkinson's and in Lewy-body disease is the tendency for L-dopa itself to provoke a depression in a limited number of patients, sometimes with suicidal tendencies, paranoid ideation, and psychotic episodes. (The state of acute anxiety, sometimes extreme, that accompanies off periods in Parkinson's disease is a well-known but separate phenomenon.) Huntington chorea is quite often associated with depression, even before the movement disorder and dementia become conspicuous. In one series, 10 of 101 patients with Huntington disease either committed suicide or attempted it, and this outcome is commented on in almost all large series of that disease. Alzheimer disease may be accompanied by depressive symptoms, in which instance, it is difficult or impossible early in the illness to evaluate the relative contributions of the mood disorder and dementia. In later stages, the overt signs of depression usually abate, even though various behaviors in the late stages of the disease are often imputed to depression.

Depression During and after Pregnancy

The main risk for depression during pregnancy is a history of previous depressions. Certain epidemiologic factors also come into play, including a family history of depression, single motherhood, cigarette smoking, low income, youth, and domestic violence. The implications, however, of depression during pregnancy are great in that the fetus and neonate are at risk of suffering due to inadequate prenatal and postnatal care and there is an increased rate of miscarriage. Several pieces of controversial evidence suggest that maternal depression may affect fetal growth and infant temperament. Furthermore, postpartum depression is also more common in women with prenatal depression and may lead to similar difficulties with infant care.

Postpartum depression is formally defined as a major depressive episode within 4 weeks of delivery, but this interval seems arbitrary. A distinction has been made between postpartum depression and mild depressive symptoms, which are common after delivery, but this also seems somewhat arbitrary. Estimates of this disorder are in the range of 10 percent of women after pregnancy, perhaps higher in low-income areas. The symptoms are generally

as expected for depression, including anxiety, irritability, and insomnia, and may blend into various preoccupations or suicidal ideation or worry about causing harm to the baby. Risk factors for postpartum depression include a history of mood disorders and depression during previous pregnancies. The theories for causation are not satisfactory and revolve around rapid declines in hormones. Most authorities recognize environmental factors as contributors in some cases as well. Most cases resolve, with or without treatment, but up to one-fifth of women may remain depressed for a year or longer (Stewart).

Because of the potential seriousness of this disorder, screening by obstetricians and general practitioners has been emphasized and formal sales have been developed. As of the mid to earlier, there may be some crossover with postpartum psychosis, in which women become delusional, confused, and have disorganized thinking that may accompany either depressed or elevated mood.

The treatment of depression during pregnancy has attracted considerable attention because of the potential risks to the fetus of the class of serotonin reuptake inhibitors (SSRIs). This is discussed in a later section. Treatment of postpartum depression includes psychological interventions for milder cases and serotonin reuptake inhibitor antidepressant medications in more severe cases if the disorder does not resolve. Newer steroid-like agents are being explored for treatment.

Clinical Presentation of Depression

Fully developed endogenous depression may evolve within a few days, or more often, it emerges gradually, on a background of vague prodromal symptoms that had been present for months. Chapter 23 provides a detailed description of the symptoms and signs of depression. Here it need only be repeated that the patient expresses feelings of sadness, unhappiness, discouragement, hopelessness, and despondency, with a loss of self-esteem. Reduced energy and activity, typically expressed as mental and physical exhaustion, is almost always present to the point of catatonia in the most severe cases. As emphasized in Chap. 23, the most common cause in general practice of symptoms relating to reduced psychic and physical energy and drive (conation) is depression. There is usually heightened irritability, most often reported by a spouse or friends, as well as a lack of interest in activities that formerly were pleasurable.

According to DSM, an abstract of the essential diagnostic criteria of endogenous depression ("major depressive syndrome") consists of a (1) depressed-dysphoric mood nearly every day, (2) loss of interest or pleasure in all usual activities (including sexual activity) in combination with (3) disturbance of appetite and loss of weight; (4) insomnia or hypersomnia; (5) psychomotor retardation or agitation; (6) decreased energy and fatigue; (7) self-reproach, feelings of worthlessness or guilt; (8) indecisiveness, complaints of memory loss and difficulty in concentrating; and (9) thoughts of death or suicide or actual suicide attempts. In recent versions of DSM criteria (5th edition), five or more features are required, in contrast to the previous version, which required four items, and that the state should represent a departure from the previous functioning. This is a useful listing but simply recapitulates the well-described emotional, conative, and physical aspects of endogenous depression. Several formalized diagnostic criteria have been devised for both screening and diagnosis of major depression (Table 48-2). These codify the clinical features discussed in previous paragraphs but separate major depression from bipolar disorder by requiring the absence of elements that suggest a manic or hypomanic episode and further exclude depression that is plausibly connected to personal distress or grieving due to a loss or the effects of a drug or toxic substance. The U.S. Preventive Services Taskforce Joint has recommended depression screening for all adult patients in primary care settings, and the Joint Commission has recommended screening for suicidal ideation.

Table 48-2

DIAGNOSTIC CRITERIA FOR MAJOR DEPRESSIVE EPISODE ADAPTED FROM DSM[a]

Five more of the following symptoms are required during the same 2-week period with at least 1 of the first 2 included:
Depressed mood most of the day, nearly everyday
Markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly everyday
Significant weight loss without diet, or weight gain of more than 5% of body weight in a month, or decrease or increase in appetite nearly everyday
Insomnia or hypersomnia nearly everyday
Psychomotor agitation or retardation nearly everyday
Fatigue or loss of energy nearly everyday
Feelings of worthlessness or excessive or inappropriate guilt nearly everyday
Diminished ability to think or concentrate or indecisiveness nearly everyday
Recurrent thoughts of death, recurrent suicidal ideas without a specific plan, or suicide attempt or specific plan for committing suicide

[a]Appropriate exclusions are made for manic episodes that would mark the illness as bipolar, and special forms of depression due to grief, significant personal or social distress, and drugs or toxic substances are discussed in the text.

Source: From the American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*, 5th ed (DSM-5). Washington, DC, APA, 2013.

The depressed patient tends to move slowly; sighing is frequent, and speech is reduced. The mental life of such an individual may narrow to a single-minded concern about physical or mental health. In dialogue, the patient's responses become so stereotyped that the listener can soon predict exactly what is going to be said. There is a poverty of ideation and sometimes a notable absence of insight. Consciousness is clear, and although there is no evidence of a schizophrenic type of thought disorder, delusional ideas, and less often hallucinations, may be prominent in some patients, justifying the term *depressive psychosis*. The delusions are generally congruent with the patient's mood and are not as fixed or bizarre as those of schizophrenia or paranoia. In our experience, delusions are more common in older patients and tend to appear only after weeks or months of more typical symptoms of depression. Common ones in experience with our patients have been gas poisoning in the house, unaccustomed suspiciousness, alleged home break-ins, having inadequate money, or being stolen from or cheated. (Some of these arise in early dementia as well.) Hallucinations, when they occur, are usually transitory,

vocal, and only vaguely accusatory; their presence should raise the possibility of an associated structural brain disease, drug intoxication, or alcoholic auditory hallucinosis.

Frequently, agitation or irritability rather than physical inactivity and mental slowness are the principal behavioral abnormalities. The source of the agitation appears usually to be related to an underlying anxiety state. Pacing the floor and wringing the hands, particularly in the early morning hours, are characteristic. Such patients tend to be overly talkative and vexed in their manner of expression, irritable, short-tempered, impatient, and intolerant of minor problems—changes noted mainly by family members. Attempts at reassurance may meet with initial success, only to be dispelled in the next rush of doubts. These patients remain impervious to reason and logic with respect to their symptoms, even though they are reasonable and logical in other areas of their lives. At its worst, the illness takes the form of a depressive stupor; the patient becomes mute, indifferent to nutritional needs, and neglectful even of bowel and bladder functions (anergic depression). The condition in this extreme form is *catatonic depression*. Such patients must be fed and their other needs attended to until therapy (usually electroconvulsive therapy [ECT]) brings about improvement.

The immediate concern in patients with mid- and late-life major depression is the potential for suicide, a topic addressed again further on. Because many of these individuals have reputations for being sound, dependable, and stable and may deny being depressed, one's inclination is to doubt the possibility of self-destruction. Such patients should nonetheless be questioned forthrightly on this subject: Have there been thoughts of suicide? Do they feel that life is not worthwhile? Do they think themselves capable of committing suicide? Have they made such plans or made suicide attempts before? Is there a family history of suicide? Do they own a firearm? Are they fearful of dying? Do they have a strongly held religious view that proscribes suicide? These questions relate to features that have been shown to put depressed individuals at risk (or less risk) of suicide, but none are infallible guides to the risk of suicide. If, from their answers, they are judged to carry an imminent risk of suicide, they should be directed to a psychiatrist and generally admitted to a hospital. In recent years, it has come to be appreciated that the elderly are increasingly prone to suicide and that older white men have the highest rates of completed suicides (mainly with firearms).

In some depressions, hypochondriacal preoccupation with bowel and digestive functions accounts for repeated visits to the physician. Persistent insomnia may be the major complaint of depressed patients. Early awakening is typical, and the morning hours are then the worst period of the day for the low emotional state. Other patients have difficulty falling asleep, especially if there is an associated anxiety state. A complaint in the male of loss of libido and erectile dysfunction is another monosymptomatic presentation; only with probing inquiry about other disturbances common to depression will the diagnosis become evident.

Adherence to the aforementioned or similar diagnostic criteria (see Table 48-1) undoubtedly facilitates diagnosis, but not infrequently, a single one of these symptoms so dominates the clinical picture as to suggest the diagnosis of another disease state and obscure the presence of an underlying depression. As mentioned earlier, depressed patients who are referred to the neurologist tend to complain inordinately of physical and cognitive symptoms and to minimize or deny the emotional ones. Complaints of fatigue, weakness, malaise, or widespread aches and pains, for example, suggest a variety of medical diseases, such as anemia, Addison disease, hypothyroidism, chronic infection, polymyositis, or early rheumatoid arthritis. Quite often, the fatigue state is misinterpreted as muscular weakness, and this directs a medical search for neuromuscular disease. Similarly, complaints of persistent headache may suggest the presence of intracranial disease. Complaints of poor memory, inability to concentrate, and other cognitive impairments raise the question of dementia until it is found, by careful examination, that mental competence belies the patient's appraisal of his own defects.

Several psychologic scales are used to score the severity of depression, mainly for the purposes of clinical trials. They can also be helpful in clinical work as they are sensitive to one or another aspect of depression, but they do not supplant the clinical examination in determining if an individual is depressed or suicidal. They may be helpful in differentiating depression from dementia and in detecting depression in cases where physical complaints are more prominent than psychic ones. The tests most familiar to neurologists are the Hamilton and the Beck scales, but others have been validated and widely used.

BIPOLAR DISEASE AND MANIA

Bipolar disease is a disorder of mood consisting of prolonged episodes of depression interrupted by or coexistent with episodes of mania. It was given the name manic-depressive disease by Kraepelin in 1896, and it was with him that our current clinical concept of this disorder originated. He viewed the manic and depressive attacks as opposite poles of the same underlying process and pointed out that, unlike dementia praecox (the prevalent name at the time, given by Pick, for schizophrenia), bipolar psychosis entails no intellectual deterioration. A traditional view of bipolar disease was that of a periodic or cyclic condition in which one major mood swing was followed by an equal but opposite excursion. This is seldom the case, however. Episodes of depression are more than twice as frequent as manic ones, and according to current experts, the most common form of the illness is characterized by episodic depression alone with many patients having several episodes of depression before their first period of mania.

Recurrence of episodes of pure mania without interspersed episodes of depression is known to occur but is relatively less common. As a consequence, bipolar psychosis has currently been divided into two subtypes, one characterized predominantly by manic episodes, often with delusions or hallucinations (bipolar I), and another in the form of mainly episodes of depression interspersed with hypomania rather than overt mania (bipolar II). The bipolar I variety occurs in approximately 10 percent of patients with affective disorder. The biologic accuracy of

this classification has not been critically determined and the older classification of unipolar versus bipolar (encompassing both types of cycling depression with mania) is, at times, easier to understand.

In addition, there are *mixed affective states*, in which symptoms of both depression and mania occur within a single episode of the illness. A so-called rapid-cycling form of bipolar disease has also been recognized in which four or more circumscribed cycles of manias and depression occur in a year. Like other variants of the disease, it tends to have an aberrant or unpredictable response to medication. Still, other patients with affective elements of depression present with atypical features; for example, instead of anorexia, weight loss, and insomnia, they sleep and eat excessively.

The prevalence of bipolar disease cannot be stated with precision, mainly because of varying criteria used for diagnosis. Certainly, depression and depressive episodes are ubiquitous and mania is less common. The apparent increase of the disease in the past 50 years probably reflects a growing awareness of the condition among both physicians and the laity. Studies of large groups of patients from relatively isolated areas of Iceland and the Danish islands of Bornholm and Samsø indicated that 5 percent of men and 9 percent of women developed symptoms of major depression, mania, or both at some time during their lives (Goodwin and Guze). Other studies, such as the one conducted by the National Comorbidity Survey, report lifetime prevalence for bipolar disorder in the United States as 4.5 percent (Merikangas et al). According to the Global Burden of Disease Study, the incidence of bipolar disease increased by about 50 percent between 1990 and 2013, but it is still considered rare by comparison to depression and to other medical diseases (Ferrari).

Bipolar disease begins most frequently in early and middle adult years, with a peak age of onset stated to be around the age of 20 for both sexes. However, a significant proportion of patients experience the first attack in childhood, adolescence, or late adult life. A study of 997 persons older than age 65 years in North Carolina found symptoms of a major depressive illness in 3.7 percent (Blazer and Williams). The disease was two or three times more frequent among women. There is no known explanation for this sex difference, but some have speculated that just as many men are depressed, only they deny it or turn to alcohol. Patients in the bipolar group have an earlier age of onset, more frequent and shorter cycles of illness, and a greater prevalence of affective disorder among their relatives than do patients with unipolar depression (Winokur).

Clinical Presentation

The *manic state* is in many ways the opposite of the depressed state, being characterized by a euphoric flight of ideas, motor and speech hyperactivity, and an increased appetite and sex urge. When such a state is fully developed, it qualifies as a psychosis. After a minimum of sleep, the patient awakes with enthusiasm and expectation. The manic individual appears to possess great drive and confidence yet lacks the ability to carry out plans. Often headstrong, impulsive, socially intrusive behavior is characteristic. Judgment may be so impaired that reckless investments are made; fortunes are spent in gambling or on extravagant shopping sprees. Setbacks do not perturb the patient but rather act as goads to new activities. Euphoria and expansiveness sometimes bubble over into delusions of power and grandeur, which, in turn, may make the patient offensively aggressive. Up to a point, the patient's mirth and good spirits may be contagious, and others may join in; however, if the patient is thwarted, the warmth and good humor can suddenly change to anger. Irritability rather than elation may become the prevailing mood. The threshold for paranoid thinking is low, which makes the patient sensitive and suspicious.

Personal neglect may reach the point of dishevelment and poor hygiene. In its most advanced form, a condition formerly described as "delirious mania," the patient becomes totally incoherent and altogether disorganized in behavior. Such were the descriptions in some of the great literature of the 19th and early 20th centuries depicting the mania of neurosyphilis. At this stage, visual and auditory hallucinations and paranoid delusions may be rampant.

Hypomania describes a milder degree of the disorder, but this term is also used loosely to depict behavior in a normally functioning individual who is unusually energetic and active. In this latter sense, hypomania is a personality trait found in some talented and productive persons and need not arouse concern unless it is excessive and out of character for the individual. A number of highly creative individuals have had bipolar disorders (Belmaker), but full-blown mania is uniformly destructive of careers and personal relationships. Such individuals are actually more creative when treated with appropriate medications. Even though many authors, such as Thomas Mann in his character of Adrian Leverkühn in *Doctor Faustus*, romanticized a link between madness and creativity, the linkage, in reality, goes only so far.

First attacks of either depression or mania last an average of 6 months if untreated, although the duration varies greatly. With treatment, this can be reduced, according to some trials, by more than half in many patients. Although most episodes of bipolar disease subside in a matter of months, a significant number, remain chronic for longer periods. According to Winokur and colleagues, 14 percent of their bipolar patients had not recovered after 2 years, and 5 percent had not recovered after 5 years. Comparative figures for primary unipolar patients were 19 and 12 percent, respectively. Most depressed patients have one or more recurrences. Variables that are predictive of an unfavorable outcome are high degrees of anxiety, strongly positive family history of a similar psychiatric illness, and the presence of depression-provoking circumstances (Hirschfeld et al). Perhaps most important is the duration of illness before treatment, that is, earlier treatment is generally associated with a more favorable prognosis.

Mania presenting as an encephalopathy The manic patient may be disoriented and slightly agitated, with a clouded sensorium. This extreme is not frequently encountered, but we have several times admitted patients to the neurology service with mania that presented in a manner suggesting an encephalopathy and global confusional state. The patient conducted himself pleasantly, without

psychosis, pressured speech, or overactive motor behavior but with an inattentive, confusion as the dominant feature. Conditions such as herpes encephalitis, alcohol or drug withdrawal, stroke, and paraneoplastic encephalitis were considered until the patient began filling notebooks with writing, manifesting insomnia, and making connections between ideas and events that were individually valid but just outside the realm of likelihood. One patient insisted that one of us was also his wife's cardiologist and another that one of the authors had scored a winning touchdown at a college football game at which he was present. Stories about public figures were factually correct but attached to the wrong person. The patient sat near the door to his hospital room and incessantly but pleasantly attracted our attention to speak to him every time one of us was in sight. At the same time, performance on orientation, arithmetic, and language tasks was normal.

ETIOLOGY OF DEPRESSION AND BIPOLAR DISEASE

The following are the main theories, not mutually exclusive, that have been proposed to explain the origin of depression; for a detailed review of the subject, the reader is referred to the review by Belmaker and Agam.

Genetic Factors

The capacity to experience sadness and depression is common to all people, but there is no question that some individuals are more liable to depression than others who are subjected to similar psychosocial forces. It has been estimated, using various genetic techniques, that as much as 40 percent of the risk of depression is heritable (lower than for schizophrenia and bipolar disease; in the latter, it has been estimated to be from 70 to 90 percent). Adopted children whose biologic parents had affective disorder are at greater risk of developing this disease than adoptees whose biologic parents were not affected (Mendlewicz and Rainer; Cadoret). The frequency of these illnesses is greatly increased in the relatives of affected patients (prevalence rate of 14 to 25 percent in first-degree relatives). Similarly, the risk of depression among first-degree relatives is increased (15 percent, in comparison to 1 to 2 percent risk in the general population). If several twin studies are taken together, 72 percent of monozygotic twins are concordant for bipolar disease, compared with 14 percent of same-sex dizygotic twins; comparative figures for unipolar disease are 40 percent and 11 percent, respectively (see Goodwin and Guze). All of these findings indicate a strong genetic factor. Genome-wide association studies have identified about three dozen loci that are seemingly associated with bipolar disease, but together they probably account for less than one-quarter of the overall heritability. One indication that specific genes may alter the susceptibility to depression has been allelic variations in the serotonin transporter gene (the main target of the selective serotonin antidepressants) that have been associated with a sevenfold increased risk of major depression (Ogilvie and colleagues). Not all studies agree on these points, and the complexity of interaction with genetic factors and the environment is demonstrated by a variant in the serotonin transporter that correlates with an increase in depression in response to stress (Caspi et al). Other hypotheses have postulated various susceptibility loci, but again, a single gene locus seems unlikely (see Sanders et al).

Anatomic Correlates

Several lines of study, including those employing functional and network imaging, indicate that a few regions of the brain are implicated in the pathogenesis of the complex symptomatology of depression (Drevets). Hypometabolism in the left frontal cortex is among the most consistent findings. Also prominent in many studies are metabolic changes in the cingulate and orbitofrontal cortices, related parts of the medial limbic system, and the hippocampus. As with all functional imaging studies, it is difficult to know if the observed changes are the cause or simply the representation of activity that corresponds to the depressive state.

An intriguing observation, and one that does not entirely accord with the above, has been observed during deep brain stimulation for the treatment of Parkinson disease (Bejjani and colleagues). A patient displayed transient but dramatic manifestations of depression only when high-frequency stimulation was delivered to the left substantia nigra. Positron emission tomography imaging during stimulation showed activation in the left orbitofrontal cortex and, less consistently, in the left amygdala, globus pallidus, thalamus, and right parietal lobe. In two other cases with no prior psychiatric symptoms, deep brain stimulation of the subthalamic nucleus induced a reversible manic state (Herzog et al; Kulisevsky et al). A hypomanic episode has been noted in the early stages of herpes encephalitis (Fisher), and numerous cases of temporary secondary mania have been reported after stroke and after brain trauma, the latter most often affecting the right temporal lobe. It is likely that the structures implicated in these cases are part of a larger and widely distributed network that is activated during depression.

The results of network and connectome studies in depression have given interesting but broadly ambiguous results. One such study of focal brain lesions associated with depression found no consistent location but converged on a circuit that involved the dorsolateral prefrontal cortex (Padmanabhan et al).

On the histologic level, several studies have shown depletion of, and changes in, the pyramidal neurons of the CA3 region of the hippocampus in both depression and stress, but the meaning of these findings is unclear (Sapolsky). They are referred to later in relation to neurogenesis (the appearance in adults of new neurons) in the temporal lobe and recovery from depression and these ideas which are speculative, are also mentioned in Chaps. 17 and 28. Based in part on observations in this field, a relationship has been suggested between depressive illness and the later development of dementia. Evolving work on alterations in the brain connectome in mania has given varied results but focuses on decreased activity between various brain hubs that are considered "rich" in connectivity and between the hemispheres

(Collin et al), but these are not easily applicable concepts and will probably change as more investigation is performed.

Biochemical Theories

It has been evident for decades that the biogenic monoamines (norepinephrine, serotonin, and dopamine) are in some way involved in the biology of depression. However, most of the neurochemical theories of depression suffer from the weakness that they have been the result of backward reasoning from the effects of antidepressants on various neurotransmitters to putative mechanisms. Following the observations that the tricyclic antidepressants and the monoamine oxidase (MAO) inhibitors exerted their effect by increasing norepinephrine and serotonin at central adrenergic receptor sites in the limbic system and hypothalamus and that depression-provoking drugs (such as reserpine) deplete biogenic amines at these sites, it was proposed that naturally occurring depressions might be associated with a deficiency of these substances. Furthermore, depressed patients and their first-degree relatives, as well as healthy individuals, develop a depressed mood after dietary depletion of the monoamine precursor tryptophan, and concentrations of 3-methoxy-4-hydroxyphenylglycol (MHPG), a metabolite of norepinephrine, are reduced in the cerebrospinal fluid during endogenous depression and the levels are elevated in manic states. Some neurochemical imaging studies corroborate these findings and others do not. Along similar lines, 5-hydroxyindoleacetic acid (5-HIAA), a deaminated metabolite of serotonin, is reduced in the cerebrospinal fluid of depressed patients (Carroll et al).

Certain of the newer antidepressants act as selective SSRIs and ostensibly produce their salutary effects by increasing the amount of serotonin that is functionally active in the synapse (they also raise the concentrations of norepinephrine). For these reasons, serotonin and its neuronal pathways have also been implicated in the genesis of depression. However, the reader should be reminded that even recently, it was widely held that depletion of norepinephrine fulfilled this role. It is also not yet clear which neurochemical alterations are primary and which modulate other systems. For example, reports suggest that substance P plays an important role in the causation of depression (Kramer et al) and that blockade of substance P receptors has antidepressant effects. Why there is a delay of several weeks in the improvement of depression related to the taking of the various antidepressants is unexplained by any of the neurochemical models.

Another set of observations that had captured interest implicates a disorder of hypothalamic–pituitary–adrenal axis function (Schlesser et al). It had been found several decades ago that the parenteral administration of 1 to 2 mg of dexamethasone failed to suppress serum cortisol secretion while the patient was ill with endogenous depression but suppressed this activity after recovery. In reactive depressions, there was a normal suppression of cortisol secretion. At one time, the dexamethasone suppression test was believed to separate the two large groups of depressed patients and to predict the response to drug therapy. However, subsequent studies have shown that the specificity of this test was far less than earlier reports had indicated (Amsterdam et al; Insel et al). Accumulated evidence indicates that 50 percent of severely depressed patients do not show suppression of cortisol secretion, and a positive test can be obtained in a significant number of patients with other psychiatric disorders.

The failure of dexamethasone suppression had been attributed to hyperactivity in the hypothalamic-pituitary axis and a corresponding increase in secretion of corticotropin-releasing hormone, adrenocorticotropic hormone (ACTH), and glucocorticoids. Elevated levels of glucocorticoids had been theorized to impede neurogenesis in the medial temporal lobe and perhaps to explain or exaggerate the loss of hippocampal neurons demonstrated in some studies of the brains of deceased depressed patients. A proposal that ECT acts by elevating levels of neurotrophic factors is at least consistent with this view and with the hypothesis that one component of recovery from depression is in some way associated with restoration of normal neuronal architecture in regions of the hippocampus and the hypothalamus (Chen et al). Although highly speculative, perhaps some of these changes explain the delay in improvement after the administration of antidepression drugs.

At the present time, it must be conceded that there is no reliable biologic test or biomarker, chemical or imaging, for depression. One must resort to clinical analysis not only for diagnosis but also for the differentiation of special types of depressive reactions.

Psychosocial Theories

Many experienced psychiatrists emphasize the importance of psychosocial factors in the genesis of depressive illness. Among patients with primary depressive disorders, life events of a stressful nature were found to have occurred more frequently in the months preceding the onset of depression than in matched control groups. This has been equally true of patients with a family history of depression and of those without such a history. Nor do patients with endogenous depression differ in this respect from those with reactive depression. Left unanswered is the question of if and why some individuals are subject to a reactive depression; are they predisposed by psychologic, personality, or genetically transmitted factors of heightened vulnerability to the effects of psychosocial stress? One is tempted to conclude that many depressions attributed to psychosocial stress are contaminating a group of endogenous depressions. Psychiatrists have also failed to find a consistent correlation between depressive illness and personality type or a particular psychodynamic mechanism. The biopsychosocial theories of mental illness have the most appeal in explaining depression, but which elements are operative in any individual are difficult to discern.

TREATMENT

Here, a distinction is made between the treatment approaches to depression and to bipolar disorder, including depressive disorders as a component of the latter. The use of medications for depression is now so widespread that all physicians should be familiar with them. It must be

acknowledged, however, that reports on the magnitude of the effect on depression of these medications have been dominated by a few clinical trials conducted by pharmaceutical companies. Meta-analyses of several large studies on the therapeutic effects of antidepressants suggest that clinical improvement attributable to the drugs themselves occurs in approximately 50 percent of patients; an additional improvement in up to 25 percent is attributable to a placebo effect or, more likely, to the natural course of the disease. The remainder fails to improve in a timely manner or relapse while on medication. The incremental value of certain forms of psychotherapies in tandem with medications is discussed further on.

Those untrained in psychiatry would be unwise to undertake the management of bipolar disease or a serious endogenous depression without the advice or assistance of a psychiatrist. On the other hand, if the symptoms are primarily neurologic (e.g., chronic headache, generalized weakness, and fatigability) and if there is a low risk of suicide, it may be appropriate for the experienced neurologist to institute treatment with antidepressant medication.

Antidepressant Medication

In the management of bipolar and depressive disease, the main categories of drugs in general use are—the tricyclic antidepressants, the "atypical" or nontricyclic group of compounds, the MAO inhibitors, serotonin agonists (reuptake inhibitors), antipsychotic drugs, antiepileptic drugs, and lithium. The pharmacologic properties and modes of action of these drugs were considered in the context of their side effects in Chap. 41. Additional points of interest are mentioned here.

Most psychiatrists currently prefer to begin treatment of patients with depression (not bipolar disease) with one of the functional serotonin agonists (reuptake inhibitors-SSRIs, or others, of a related group of serotonin-norepinephrine reuptake inhibitors. New drugs of similar type are appearing regularly. These drugs have less sedating and anticholinergic effects than the tricyclic antidepressants discussed below and may have a slightly faster onset of effect against depression. Certain side effects, such as loss of libido and erectile dysfunction, occur in a proportion of patients and are difficult to differentiate from the signs of depression. Other side effects occur in a proportion of patients, including insomnia or hypersomnia, weight gain or loss, gastrointestinal upset, increased anxiety as discussed in Chap. 47, blurred vision, and dizziness, among many others (see Chap. 41). The very consequential "serotonin syndrome" that occurs with overdose includes delirium, hypertension, tachycardia, diaphoresis, muscular rigidity, myoclonus, and clonus. The pupils may be dilated. This disorder and its treatment are discussed in Chap. 41.

The contentious issues of these drugs inducing mania in undiscovered bipolar disease, precipitating suicide soon after the institution of these medications, and the use of these drugs in children are important ones that can only be addressed here cursorily. The overall rates of suicide among adolescents with depression were decreasing at the time of increasing use of SSRI agents (Ryan). The precipitation of a manic episode by serotonergic antidepressants in some patients with bipolar disorder seems a regular enough occurrence that this risk is no longer a point in question. Also emphasized is an increased risk of pulmonary hypertension in the babies of mothers exposed to SSRI during the pregnancy.

The tricyclic antidepressants, in general, are equally effective, although an individual patient may have a better response or tolerance to one than to another. These drugs, taken at bedtime, may also be helpful in alleviating insomnia that accompanies depression. The therapeutic effect of tricyclic medication is generally not evident for 2 to 4 weeks after treatment has been initiated, and it is important that this be explained to the patient and family. Common side effects are orthostatic hypotension, dry mouth, constipation, tachycardia, urinary hesitancy or retention (especially in patients with prostatic hypertrophy), tremor, and drowsiness. Closed-angle glaucoma may decompensate. Caution should be exercised in elderly patients with cardiac disorders of all types because of the possibility of causing heart block or arrhythmia. The nontricyclic drugs appear to be as effective as the tricyclic agents in the treatment of depression without the adverse anticholinergic and cardiotoxic effects.

If one of the SSRI or tricyclic and related drugs given in full doses for 4 to 6 weeks does not produce the desired effect, or as often happens, the patient is intolerant of the given drug, an alternative group, for example, an MAO inhibitor may be tried. In one of the many new "effectiveness" trials sponsored by the National Institutes of Mental Health, as distinguished from "efficacy" in randomized trials, failure of citalopram to accomplish remission of depression by changing to bupropion, sertraline, or venlafaxine was successful in 25 percent of cases (Rush et al). After discontinuing SSRIs, there a drug-free interval is advised of 1 to 2 weeks before instituting an MAO inhibitor in order not to provoke a serotonin syndrome. Some studies suggest that MAO inhibitors are superior in depression with atypical features such as increased appetite. The most serious risk of MAO inhibitors is hypertensive crisis; consequently, these drugs should be dispensed with caution in patients with hypertension and with cardiovascular or cerebrovascular disease. Patients taking these drugs are advised to avoid foods with a high tyramine content (aged cheese, many pickled foods, chicken liver, beer, wines, yeast extract) as well as medications containing sympathomimetic agents or L-dopa (decongestants, amphetamines, caffeine) and the aforementioned serotonin agonists. The use of the monoamine oxidase inhibitor (MAOI)-B drugs for the treatment of Parkinson disease (see Chap. 38) is also interdicted.

Supplementation of antidepressants with antiepileptic medications as a "mood stabilizer" in depression is a popular approach with many psychiatrists. Valproate or gabapentin are often used, but also used are carbamazepine or phenytoin. There are few credible studies by which to judge the value of this strategy, and one randomized trial showed no benefit with respect to recovery of depression in bipolar disease (Sachs et al), but these drugs may provide some additional benefit if only as antianxiety agents. More persuasive are the data suggesting that antiepileptic drugs are useful in treatment of the manic state.

Because many depressed patients are responsive to one class of drugs but not to another, the clinician is aided by information regarding which of these drugs has been helpful in past episodes. As mentioned, clinical response to antidepressant drugs is not expected for several weeks. Treatment,

if successful, is usually continued for 6 to 9 months and combined with psychotherapy. The premature discontinuation of medications is a source of relapse, as demonstrated in a trial that compared maintenance to gradual discontinuation of antidepressants in primary care practices showed that relapse occurred in a higher proportion of patients who stopped medication (Lewis et al). However, the symptoms of antidepressant withdrawal, particularly anxiety, may mimic the symptoms of depression. If nothing else, this points out that discontinuation of antidepressants is best accomplished over many weeks or months.

After all these drug manipulations fail, a common approach is to add aripiprazole or bupropion to existing antidepressants ("augmentation"). Approximately 25% of patients will have remission of depression. The side effects of antidepressants are given in tabular form and adapted for Table 48-3.

Trials of lithium monotherapy or in combination with a mood stabilizer (often valproate) in bipolar disorder (Carvalho et al), but many of the trials are flawed or have limited generalizability. Also to be kept in mind are the side effects of the drugs used for bipolar disorder and the risks of some of the mood stabilizers in pregnancy.

There has been renewed interest in the guided use of psychedelic drugs, particularly psilocybin preparations, for depression. Randomized trials in very selected groups of patients, including with treatment resistant depression (failure of two to four antidepressants) (Goodwin et al) and a comparison to escitalopram (Carhart-Harris et al) both over only weeks of observation, suggest some benefit. The psychotherapeutic resources required and the inability to account for anticipation bias and unblinding of participants makes the practical application of these provocative observations with psychedelic compounds for depression difficult to gauge. There have also been explorations in major depressive disorder of modulators of GABA-A receptors that have given promising but preliminary results in the short-term (Gunduz-Bruce et al).

Electroconvulsive Therapy and Transcranial Magnetic Stimulation

What used to be called infelicitously "electroshock" therapy continues to be a highly effective treatment for severe endogenous depression or catatonic depression that has been unresponsive to other measures and can be used

Table 48-3

CLASSIFICATION AND SIDE EFFECTS OF ANTIDEPRESSANTS

	SIDE EFFECTS						
FUNCTIONAL CLASSIFICATION	INSOMNIA AND AGITATION	SEDATION	HYPOTENSION	ANTICHOLINERGIC EFFECTS	NAUSEA OR GASTROINTESTINAL EFFECTS	SEXUAL DYSFUNCTION	WEIGHT GAIN
Reuptake Inhibitors							
Selective serotonin reuptake inhibitors (SSRIs)							
Fluoxetine	++	−/+	−/+	−/+	++	++	+
Paroxetine	++	−/+	−/+	+	++	++	+
Sertraline	++	−/+	−/+	−/+	++	++	+
Fluvoxamine	++	+	−/+	−/+	++	++	+
Citalopram	++	−/+	−/+	−/+	++	++	+
Escitalopram	++	−/+	−/+	−/+	++	++	+
Nonselective norepinephrine reuptake inhibitors							
Desipramine	+	−/+	++	+	−/+	+	+
Nortriptyline	+	+	+	+	−/+	+	+
Maprotiline	+	−/+	+	+	−/+	+	++
Mixed or dual-action reuptake inhibitors

to interrupt manic episodes. One of its advantages is the rapidity of onset of effect, making it useful in acute or critical situations of psychiatric disease, but there is little doubt that the treatment has been stigmatized as a result of popular conceptions. In major depressive disorder, rates of response have been estimated to be 60 to 80 percent, and rates of remission, 5 to 60 percent (Tor et al).

The technique, if properly supervised, is considered to be safe and a comprehensive informed consent process is used. The risk of death with ECT has been estimated to be 2 per 100,000 treatments and the risk of medical events is extremely low (Kaster et al). The patient is anesthetized by an intravenous injection of a short-acting barbiturate, benzodiazepine, or propofol and is also medicated with a muscle relaxant. In the conventional method, an electrode is placed over each temple (or placed in the right unilateral or bifrontal regions), and a current of about 400 mA and 70 to 120 V is passed between them for 0.1 to 0.5 s. The machine itself has as the essential element a large capacitor that is discharged to produce an electrographic seizure. The paralytic agent prevents injurious muscle spasms. The patient is awake within 5 to 10 min and is up and about in 30 min. The mechanism by which ECT produces its effects is unknown, but it appears that an electrographic seizure is necessary for clinical effect in depression. Treatments are usually given every other day for 6 to 12 sessions. If there has been a therapeutic response, maintenance ECT at increasing intervals and concurrent administration of an antidepressant is usually employed with the goal of sustaining an antidepressant response with the fewest treatments necessary.

One contraindication to the use of ECT is the presence of increased intracranial pressure, as may occur with a neoplasm or intracranial hematoma. Whether epilepsy is precipitated or worsened by ECT is debated, but the presence of epilepsy is generally considered a contraindication. This treatment should also be used cautiously in the presence of uncontrolled systemic hypertension or with a known sensitivity to the anesthetic agents that are used as premedication.

The drawback of ECT is the production of impairment of recent memory for the period of treatment and for the days that follow, the degree of impairment related to the number of treatments given. Placing both electrodes on the nondominant side (unilateral ECT) or using lower amounts of current and a briefer pulse rather than a sine wave produces less memory disturbance and has been adopted in some situations because it is almost as effective. Cognitive and memory effects vary with electrode placement and duration of the electrical discharge that is used. Anterograde amnesia occurs immediately after treatment but resolves over weeks, whereas retrograde amnesia develops more gradually over the course of treatment and may take months to dissipate. There are rare cases of delirium following a treatment. Despite the short-term sequelae, neuropathological and imaging studies after ECT have not found damage, and cohort studies have not shown that dementia occurs later in life (Osler et al).

With the recognition that transcranial magnetic motor stimulation sometimes produces an elevation of mood, it has been introduced as a potential substitute for ECT. The magnetic technique has the advantage of being free of any but minor physical effects, and because it produces no loss of consciousness, anesthesia and neuromuscular paralysis are not needed. Brief pulses of high-frequency stimuli are used. Few controlled studies have been performed and it is not as effective against severe or prolonged depressions and probably not at all for catatonia. Related methods, such as direct current stimulation of the cortex, have met with mixed but generally negative results (Brunoni et al).

Until the advent of antidepressant drugs, ECT was the treatment of choice for the agitated depression of middle and late life and for catatonia. Following a course of 6 to 14 treatments, close to 90 percent of patients recovered within 2 months or less. Prior to the use of ECT, this type of depression might last for 2 years or longer before remission or suicide. Deep brain stimulation is under study for refractory depression.

Treatment of Bipolar Disease

Lithium Carbonate

After the extraordinary discovery by Cade in 1949, lithium has, for decades, until very recently, been the drug of choice in treating the manic phase of bipolar disease, and it is continued to be used in preventing relapses of bipolar disease and depression in some patients. The newer antipsychotic drugs discussed in the next chapter have overtaken lithium for the acute treatment of bipolar disease, with only limited evidence that they are superior. During an acute manic attack, hospitalization may be required to protect the manic patient from impulsive and aggressive behavior that might cause personal and interpersonal difficulty or jeopardize a career. Haloperidol or one of the newer antipsychotic agents (discussed in Chap. 49) or ECT (see earlier) can be used to control mania until lithium carbonate becomes effective, usually a matter of 4 or 5 days. The usual dosage of lithium is 1,200 to 2,400 mg daily in divided oral doses, which produces the desired serum level of 0.9 to 1.4 mEq/L. The serum level of lithium is checked regularly, both to ensure that a therapeutic dose is being taken and to limit toxicity (see later).

The side effects of lithium are nausea and vomiting, diarrhea (especially if the dose is increased too rapidly), a feeling of mental dullness, action tremor, weakness, ataxia, slurred speech, blurred vision, dizziness, nystagmus (especially vertical or down beating), stupor, and coma. A confusional psychosis with polymyoclonus and ataxia that together simulate Creutzfeldt-Jakob disease (including periodic sharp waves in the electroencephalogram) may occur at toxic levels. In patients who do not tolerate lithium, carbamazepine, valproate, or another antiepileptic is sometimes substituted. A combination of lithium and a tricyclic or SSRI medication at the lowest effective level has been used as long-term preventive therapies for bipolar disease, and the same combination is useful for patients with mixed bipolar disorder in which depressive and manic manifestations occur within a single episode of illness. Concern that the use of lithium during pregnancy might lead to fetal cardiac malformations, particularly right ventricular outflow obstruction, was affirmed in one study but the rates were low (Paterno et al).

Antipsychotic Drugs

Perhaps the most marked change in the treatment of acute episodes of bipolar disease is to initiate one of the

approved antipsychotic medications (quetiapine, fluoxetine) rather than lithium to bring both the depression and episodic cycling into mania under control. Failing this, a "mood stabilizing" drug such as lamotrigine or divalproex has been used. As mentioned earlier, there is scant evidence that these approaches are superior to lithium. The point to be made is that the use of conventional antidepressants is currently less popular in bipolar disease because of the risk of worsening depression to the point of a suicidal state or of inducing mania. Other combinations have been used such as olanzapine with a serotonergic antidepressant. These are summarized in the review by Frye. Taken together, the effectiveness of these new approaches serves to emphasize the importance of proper diagnosis of bipolar disease. Haloperidol may be necessary to control a dangerous manic episode while one of these medications becomes effective.

Psychotherapy

In patients with depression or bipolar disease, careful explanations of the patient's illness, reassurance that the illness is usually self-limited, and encouragement and instruction to the family are of value in helping both the patient and family to understand the illness and cope with it. At the same time, there should be vigilance for suicidality, admittedly a difficult task given its unpredictability. As a general rule, bipolar illness is best managed by a physician who is willing to follow the patient over a long period of time and is available to reevaluate the patient on suspicion of relapse. Although the prognosis for any individual attack is relatively good, it is wise to arrange for a plan of action that will be set in operation at the first hint of a recurrence.

Tomes have been written about various psychodynamic approaches to psychotherapy and the authors are unable to comment authoritatively on them. A structured and problem-oriented approach to psychotherapy using "cognitive-behavioral" and "interpersonal" strategies has gained considerable popularity since its introduction in the 1970s by Beck. It draws to only a limited extent on psychoanalytic and other psychodynamic theories and has been used in patients with depression and in those with anxiety, chronic pain, and other disorders. Cognitive-behavioral therapy has been stated to be most effective in patients with mild to moderate (not chronic) depression, generalized anxiety and panic disorder, and obsessive-compulsive and phobic disorders (Blenkiron). Essentially, in the short term, the therapist provides the patient with information on the nature of the illness, its common symptoms, and the active interventions that are to be undertaken by the patient with the aid of the therapist to alter the specific misperceptions and the dysfunctional behaviors that spring from them. In one study of difficult-to-treat chronic forms of depression, an antidepression drug (nefazodone), cognitive-behavioral therapy, or the combination, led remissions in approximately 50 percent of each of the first two groups and in 85 percent of the combined treatment cohort at 12 weeks (Keller and colleagues). This stands as one demonstration of the value of result-oriented psychotherapy. One derivative approach is "Acceptance and Commitment Therapy" (ACT), which aids in accepting the difficulties of life. The interested reader can find discussion of this subject in the current edition of *Kaplan and Sadock's Comprehensive Textbook of Psychiatry* (Sadock and Sadock). Noteworthy is the opinion that behavioral-cognitive psychotherapy may be no better or worse than other forms of psychotherapy (Gabbard), but it has the virtues of relative brevity, uniformity of application, and straightforwardness that avoids blaming the patient, family, environment, or other external forces.

SUICIDE

Some 30,000 suicides are recorded annually in the United States and attempted suicides exceed this number by approximately 10 times. Psychiatrists agree that these are conservative figures. Suicide is the eighth leading cause of death among adults in the United States and the second leading cause among persons between the ages of 15 and 24 years, rates that emphasize the importance of recognizing depression that has a high potential for self-destruction. Recent worldwide surveys show a wide variety of rates across ages and sex. With the exception of the Americas, suicide rates have seemingly declined over two decades but remain high in older people. Physicians are well advised to be familiar with the few imperfect clues to identify patients who intend to end their lives. Some of the questions that may be broached in an interview regarding depression were listed earlier, but particularly, "Do you think of hurting yourself or taking your own life?" and the follow-through query, "Do you have a plan?" Physicians should also be aware that many suicides are accomplished by taking an overdose of prescribed medications, for which reason caution needs to be exercised in their distribution and administration in depressed patients. Successful suicide is 3 times more common in men than in women and particularly common among men older than 40 years of age, and patients with a history of suicide in either mother or father carry a higher risk than those without such a history. A previous suicide attempt adds to the risk.

Some workers view suicidal intent as a special form of depression or an important variant of it (Mann, 1998), and that certain individuals are by nature susceptible to attempt suicide as a result of biologic factors. In other words, suicide is not viewed as simply a cognitive response to extreme stress or despondency. Certainly, impulsivity, a frontal lobe phenomenon, seems to be an element of the suicidal act in many cases, but this also is difficult to anticipate and prevent. There is no way for the authors to judge these views, but proponents have pointed to indices of serotonin function that differ between depressed individuals who attempt suicide and those who do not all tentative observations. It has also been observed that the inception of modern antidepressant medications has not greatly altered the rates of suicide among depressed patients. Bipolar illness, endogenous depression, depression resulting from a debilitating disease (e.g., Huntington disease, cancer, and HIV), pathologic grief, and depression in an alcoholic or schizophrenic all carry the risk of suicide. In bipolar disease and endogenous depression, the risk of suicide over the lifetime of the patient is approximately 15 percent (Guze and Robins). In Robins' series of 134 patients who committed suicide, 47 percent had a known depressive illness, and 25 percent were alcoholic. Other

series have recorded even higher rates of depression, alcoholism, and drug abuse (Andreasen and Black).

Despite the above comments regarding impulsivity, many suicides are planned. Furthermore, the intention of committing suicide is sometimes communicated to someone significant in the patient's life. The message may be in the form of a direct verbal statement of intent, or it may be indirect, such as giving away a treasured possession or revising a will. As alluded to earlier, important deterrents to suicide are devout Catholicism or comparable religious belief against suicide, concern about the suffering it would cause the family, and fear of death sincerely expressed by the patient. However, no single one of these attributes stands out as entirely predictive of suicide. Tests and scales alluded to earlier have been devised to gauge suicide risk, but they seem to be as imperfect as clinical judgment. As a consequence, one is left with clinical judgment and an index of suspicion as the main guides. The only rule of thumb is that all suicidal threats are to be taken seriously, and patients who threaten to kill themselves should be evaluated quickly by a psychiatrist.

SPECIAL PROBLEMS IN PATIENTS WITH DEPRESSIVE ILLNESS

In our experience, the following are some of the common and troublesome clinical situations in which it may prove difficult to recognize an underlying depression:

1. *Patients with chronic pain*. The association between chronic pain and depression has long been appreciated. This is far from a homogeneous group of affected individuals. The special case of chronic headache, confronted often by neurologists, is discussed below and in Chap. 9. In some patients with chronic pain, the symptoms and signs of depression are quite apparent, and it is certainly not unreasonable to attribute depression to chronic discomfort. If the pain has been present for less than 1 year and had its onset at the same time as other depressive symptoms, response to antidepressant treatment is likely to be favorable. Far more difficult to understand, and to manage, are patients with persistent pain as the only complaint; the head, face, and lower back are the most common loci. Weeks or months of unremitting daily tension-type headaches in the context of a normal examination are highly suggestive of depression at any age. If an exhaustive search for the source of the pain proves unsuccessful, the conclusion is finally reached that the pain is "psychogenic," but this attribution of pain to some obscure psychologic mechanism is hardly helpful. Nevertheless, in a fair proportion of such patients, that pain will be alleviated to some extent by antidepressant drugs is suggestive of a linkage of pain and depression, although determining a connection in any particular case is difficult and one cannot exclude an independent biological effect of these medications on pain. The problem may have been made even more difficult by repeated surgical operations as well as dependency on analgesic drugs, which in themselves deplete energy and have other adverse effects. Such patients are to be found among those disabled after multiple operations for ruptured intervertebral disc or arthritic hips or those with atypical facial pain.
2. *Depression and alcoholism*. These are commonly associated, and it is important to determine which is primary and which is secondary. In a series of patients with alcohol dependence reported many years ago, secondary depression occurred in 30 of 61 females and in 41 of 112 males; moreover, once the alcoholism was established, depression became evident much earlier in the women than in the men (Cadoret and Winokur). The opposite occurrence (the development of alcoholism on the background of a primary depression) is considered to be less common. Some early family studies suggest that the same genetic predisposition leads to depression in females and alcoholism and sociopathy in men (Winokur 1991). Whether there is a similar linkage between depression and drug addiction, for example, to opiates, is not clear, but it seems not in our experience.
3. *Depression in childhood and adolescence*. We have observed depressive states in children and they have often been misdiagnosed by both pediatricians and psychiatrists. The common manifestations have been chronic headache, refusal to go to school, withdrawal from social activities, anorexia, vomiting and weight loss, and scholastic failure. Puberty is a time of onset in many cases, and the disorder is frequent in late childhood and in high school and college students. It is worthwhile appreciating this fact and to avoid treating the child for some presumed nonaffective nervous symptoms, only to have the patient attempt suicide, but admittedly the diagnosis is difficult in this age group.
4. *Anxiety, hypochondriasis, and pseudodementia*. These are clinical circumstances in which an underlying depressive illness may not be immediately apparent but can be suspected, as discussed in Chap. 47. The complaint of severe chronic fatigue without medical explanation should raise the same suspicion (see Chap. 23). An elderly person with seemingly early signs of dementia may, on closer examination, turn out to have a severe depressive illness.

Psychosis, Schizophrenia, Delusional, and Paranoid States

This chapter discusses disorders characterized by psychosis. The definition of this state has been difficult to attain with certainty. At its simplest, it reflects a continuous disconnection of thought processes from reality. At times, it has been defined largely by the presence of hallucinations or delusions. In DSM-5, psychosis is characterized by hallucinations, delusions, disorganized thinking, grossly disorganized motor behavior, or negative symptoms, which are defined in the following discussion. None of these captures the sometimes subtle but often bizarre ideas and behaviors of individuals with psychosis or the experience of communicating with them being in the presence of a person with psychosis. While psychosis is a core feature of schizophrenia, it can be fully expressed in a number of acute states such as drug intoxications. Some of these aspects are discussed in Chap. 19 on "Delirium and Other Acute Confusional States."

SCHIZOPHRENIA

Schizophrenia is among the most serious of all unsolved diseases. This was the opinion expressed 60 years ago in *Medical Research: A Mid-Century Survey*, sponsored by the American Foundation. Because of a worldwide lifetime prevalence of approximately 0.85 percent and particularly because of its onset early in life, its chronicity, and the associated social, vocational, and personal disabilities, the same conclusion is justified today (Carpenter and Buchanan). Schizophrenia has been found in every ethnic and social group so far studied. On average, 35 new cases per 100,000 population appear annually (Jablensky). The Global Burden of Disease Study derived from multiple sources (Charlson et al) gives estimates in 2016 of 0.28 percent of the world's population, which do not vary greatly cross populations or regions. Estimates of the prevalence of schizophrenia and related psychotic disorders in the United States have been 0.25 to 0.64 percent. Despite the low incidence, the resultant number of years of life with disability are enormous.

The incidence of schizophrenia has remained more or less the same over the past several decades. Males and females are affected with equal frequency. For unknown reasons, the incidence is higher in social classes showing high mobility and disorganization. It has been suggested that this is a by-product of "downward drift"—a result of deteriorating function in those with the disease that forces them into the lowest socioeconomic stratum where one finds poverty, crowding, limited education, and associated disadvantages—and the same data have been used to support the idea that schizophrenia can be caused by such social factors.

Schizophrenic patients occupy about half the beds in psychiatric hospitals—more hospital beds than are allocated to any other single disease—and they constitute 20 to 30 percent of all new admissions to psychiatric institutions (100,000 to 200,000 new cases per year in the United States). The age of admission generally is between 20 and 40 years, with a peak between 28 and 34 years. The economic burden created by this disease is enormous—the direct and indirect costs in the United States have been estimated to be over $50 billion.

Neurologists and psychiatrists currently accept the idea that schizophrenia comprises a group of related disorders characterized by a particular type of disordered thinking, affect, and behavior. The syndrome by which these disorders manifest themselves differs from those of delirium, confusional states, dementia, and depression in ways that will become clear in the following pages. The diagnosis of schizophrenia depends on the recognition of characteristic psychologic disturbances largely unsupported by abnormal physical findings and laboratory data. This inevitably results in a degree of diagnostic imprecision. In other words, any group classified as schizophrenic will include patients with diseases that only resemble schizophrenia, whereas variant or incomplete cases of schizophrenia may not have been included. Moreover, there is not full agreement as to whether all the conditions that are called schizophrenia are the expression of a single disease process. In the United States, for example, *paranoid schizophrenia* had been considered a subtype of the common syndrome, whereas in some parts of Europe it is thought to be a separate disease.

Historical Background

Present views of the disease now called schizophrenia originated with Emil Kraepelin, a Munich psychiatrist, who first clearly separated it from bipolar psychosis. He called it *dementia praecox* (adopting the term introduced earlier by Morel) to refer to a deterioration of mental function at

an early age, from a previous level of normalcy. At first, Kraepelin believed that "catatonia" and "hebephrenia," which had previously been described by Kahlbaum and by Hecker, respectively, as well as the paranoid form of schizophrenia, were separate diseases, but later he concluded that several subtypes were a single disease. He emphasized the characteristics of an onset in adolescence or early adult life and a chronic course, often ending in marked deterioration of personality as the defining attributes of all forms of the disease. Early in the twentieth century, the Swiss psychiatrist Eugen Bleuler substituted the term *schizophrenia* for dementia praecox. This was an improvement insofar as the term *dementia* was already being used to specify the clinical effects of another category of disease; unfortunately, however, the new name implied a "split personality" or "split mind." By the "splitting" of psychic functions, Bleuler meant the lack of correspondence between ideation and emotional display—the inappropriateness of the patient's affect in relation to his thoughts and behavior. In contrast, in bipolar disease, the patient's mood and affect accurately express his morbid thoughts. Bleuler also introduced the term *autism* ("thinking divorced from reality") as an aspect of the thought disorder.

Bleuler believed that all the schizophrenic syndromes were composed of primary or basic symptoms, summarized by subsequent authors as the "four A's" (loose *a*ssociations, flat *a*ffect, *a*mbivalence, and *a*utism) and of secondary or "partial phenomena" such as delusions, hallucinations, negativism, and stupor. However interesting this formulation proved to be, the psychologic abnormalities are so difficult to define precisely that these divisions have come to be of only mnemonic value.

Meyer, who introduced the "psychobiologic approach" to psychiatry, sought the origins of schizophrenia, as well as other psychiatric syndromes, in the personal and medical history of patients, emphasizing particularly their habitual reactions to life events. Freud viewed schizophrenia as a manifestation of a "weak ego" and an inability to control anxiety and instinctual forces—the result of a fixation of libido at an early ("narcissistic") stage of psychosexual development. None of these theories has been corroborated, and none ever gained wide acceptance, particularly as the biological disease model of schizophrenia, propelled by successful pharmacologic treatment, defined a disease and not a psychologic disorder.

A contemporary approach to schizophrenia, summarized below, has involved the isolation of its many pervasive mental and behavioral features into three clusters: (1) *negative symptoms* of diminished psychomotor activity (poverty of speech and spontaneous movement, flatness of affect); (2) a "disorganization" syndrome, or *thought disorder* (fragmentation of ideas, loosening of associations, tangentiality, and inappropriate emotional expression); and (3) *reality distortion*, comprising hallucinations and delusions, or positive symptoms (Liddle). The separation of behaviors into "positive" and "negative" symptoms was believed to be useful in distinguishing among the types of schizophrenias and perhaps to align the mental status with conventional physiologic analysis, but this view is an oversimplification (Andreasen). Although there is disagreement as to whether each of these features is primary or secondary, positive or negative, they have the value of lending themselves to objective study and scales have been devised to measure them.

Clinical Syndrome of Schizophrenia

The central abnormalities in schizophrenia are hallucinations, mainly auditory, and a special disorder in the perception of one's self in relation to the external world. Some patients with chronic schizophrenia, before the onset of a flagrant psychosis or when in remission, show none of the usual symptoms and—during brief testing of mental status—appear normal. But on longer observation, they are vague and preoccupied with their own thoughts. They seem unable to think in the abstract, to understand fully figurative statements, or are unable to separate relevant from irrelevant data. There is what has been called a circumstantiality and tangentiality about their thinking and remarks. They fail to communicate their ideas clearly. Their thinking no longer respects the logical limits of time and space so that parts of ideas are confused with the whole or are clustered together or condensed in an illogical way. In an analysis of a problem or a situation, there is a tendency to be overinclusive rather than underinclusive (as happens in dementia). In conversation and in writing, the trend of an argument or thought sequence is often interrupted abruptly, with a resulting disorder of verbal communication. Such disorders of thinking are reflected in the patient's behavior. Over time there is a general deterioration in functioning, social withdrawal and bizarre actions, self-absorption, and aimlessness.

In more severely affected patients with schizophrenia, thinking is even more disintegrated. They appear to be totally preoccupied with their inner psychic life (thus the early use of the term *autism*) and may do no more than utter a series of meaningless phrases or neologisms, or their speech may be reduced to a nonsensical "word salad." They are unable to attend to any task or to concentrate, and their performance is interrupted by sudden "blocking" or by insertion of some extraneous idea or inexplicable act, somewhat like that observed in a severely confused or delirious patient. At times these patients are talkative and exhibit odd behavior; at other times they are quiet and idle. In the extreme, the patients are mute or assume and maintain imposed postures or remain immobile (catalepsy). With remission, they may remember much of what has happened or may have only fragmentary memories of events that occurred.

Typical of schizophrenia is the patient's expression of remarkably unusual experiences and ideas. The patient may express the thought that his body is somehow separated from his mind, that he does not feel like himself, that his body belongs to someone else, or that he is unsure of his own identity or even sex, experiences called *depersonalization*. *Thought insertion*, wherein it seems to the patient that an idea has been implanted into his mind, or *thought withdrawal*, wherein an idea has been extracted from his mind by an outside agency, may be other parts of this problem. Closely related, and characteristic of schizophrenia, are ideas of being under the control of some external agency or being made to speak or act in ways that are

dictated by others, often through the medium of radar, telepathy, television, or the Internet (*passivity feelings*). Thought projection, the notion that external elements in the environment are being controlled by the patient's mind, is similar. Frequently, there are *ideas of reference*—that the remarks or actions of others are subtly or overtly directed to the patient. Finally, the patient may feel that the world about him is changed or unnatural, or his perception of time may be altered, not in a brief episode like the *jamais vu* of a temporal lobe seizure, but continuously; this is the phenomenon of *derealization*. However, the bizarreness of these delusions, once considered a characteristic feature, has been removed from the diagnostic criteria for schizophrenia in the DSM (American Psychiatric Association) because of its nonspecificity and the difficulty determining exactly what constitutes bizarre.

Auditory hallucinations are frequent and a core feature of the typical illness. They consist of voices that comment on the patient's character and activities and are usually accusatory, threatening, or claiming control of the patient's actions. The voices may or may not be recognized; they may belong to one person or two or more persons who converse with the patient or with one another. Seldom can the voices be localized to a point outside the patient. Instead, they seem to come from within, so that they cannot be distinguished from his own feelings and thoughts. Certain somatic hallucinations and delusions may predominate in any one individual. Visual, olfactory, and other types of hallucinations also occur but are much less frequent. The patient believes in the reality of these hallucinations and often weaves them into a delusional system.

It should be reiterated here that hallucinations are a feature of several disparate neurologic processes, but in most people visual hallucinations predominate, whereas auditory hallucinations are more the hallmark of schizophrenia. Of interest in this regard is "The Report on the Census of Hallucinations" by Sidgwick in 1894 who suggested (cited by Frith) that almost 1 in 10 ostensibly normal respondents has experienced hallucinations, mostly visual. The main illnesses in which hallucinations and delusions are prominent are hallucinogenic drug ingestion and the Charles Bonnet syndrome (see Chap. 12).

With respect to negative symptoms in schizophrenia, they have been divided into four groups (Liddle and Barnes): (1) flat affect, diminution in expressive gestures, latency of response, reduced spontaneous movements, apathy, restricted recreational activities, inability to feel intimate or close, and motor retardation; these negative symptoms, which have resemblances to frontal lobe behavioral syndromes, correlate with reduced blood flow in the frontal lobes and a poor prognosis; (2) disorganization of thought, incoherence, inappropriate affect, illogicality, bizarre behavior, aggression, agitation, and tangentiality; these abnormalities are nonfrontal; (3) hallucinations and delusions that the patient's mind is being read and that thoughts are being extracted from his mind or being controlled or broadcasted, probably related to temporal lobe function; and (4) suspicion, hostility, and delusions of reference. These features can coexist in various combinations. However valid or invalid such subdivisions prove to be, they direct attention to the functional anatomy and physiology of particular neuronal systems in the brain (see further on; Friston et al).

The behavior of the individual with schizophrenia who experiences these ideas and feelings is correspondingly altered. Early in the course of the illness, normal activities may be slowed or interrupted. No longer does the patient function properly in school or at work. Associates and relatives are likely to find the patient's complaints and ideas disturbing. The patient may be idle for long periods—preoccupied with inner ruminations—and may withdraw socially. A panic or frenzy of excitement may lead to an emergency ward visit (a high degree of anxiety occurring for the first time in a young person should raise the suspicion of a developing schizophrenia), or the patient may become mute and immobile, that is, *catatonic*. Attacks of catatonia are infrequent, but lack of will, drive, assertiveness, and motor activity are characteristic of the disease. Over time, a deteriorated and dilapidated state occurs, which in the extreme results in an unkempt and malnourished state with which the public unfortunately associates schizophrenia. Individuals of this type may roam the streets and live in appalling conditions on the fringes of society where they are subject to the criminal behavior of others.

That schizophrenia of all types carries a significant risk of suicide is not widely appreciated. In a follow up study of schizophrenic and bipolar patients, in each group the proportion of patients who had committed suicide was the same (approximately 10 percent) (Winokur and Tsuang) but this is not a uniformly held view. Suicide occurs most often among young patients with schizophrenia living apart from their families who may be frightened and overwhelmed by their symptoms and who experience the difficulties of independent existence. Sometimes suicide is a response to terrifying and commanding vocal hallucinations. The schizophrenic patient may also be homicidal, usually acting on a delusion that he has been wronged or is threatened by the victim. Incidents of this type are unpredictable and infrequent, but the presence of escalating paranoia should be a warning.

Finally, whether a genuine dementia results from chronic schizophrenia has been much debated over the years but the mental deterioration differs somewhat from the neurologist's conception of dementia. The notion of this type of "dementia praecox" has been discarded, but clinicians continue to encounter cases of progressive generalized, and sometimes severe, intellectual impairment in both acute and long-standing cases of schizophrenia; this has been true before and after the modern era of therapeutics. The problem was highlighted by a series that analyzed a frontotemporal type of dementia in eight patients after 9 to 30 years of schizophrenia with frontal or temporal hypoperfusion on functional imaging (de Vries and colleagues).

Diagnostic Criteria

Included in the early definitions of the disease, both of Kraepelin and of Bleuler, were a characteristic premorbid personality, an insidious onset of the more flagrant symptoms in adolescence or early adult life, and a chronic but fluctuating course with a tendency to progressive

deterioration. Both of these early investigators regarded hallucinations and delusions as secondary symptoms that could be absent, as in their category of "simple schizophrenia." Embodied in both their definitions was the concept of disease characterized by a poor prognosis and, as stated earlier, a unique constellation of symptoms different from those of delirium, confusion, depression, mania, and dementia—which are manifestations of brain diseases. Many of their seminal ideas, and others discussed below, have been retained but most have been discarded in modern diagnostic criteria. Nevertheless, they established a lexicon for the clinical description and grading of schizophrenic disorders and all subsequent progress has been essentially to refine these ideas. For that reason, they are summarized here so that the student may appreciate the evolutionary nature of diagnostic criteria, as expressed through the *Diagnostic and Statistical Manual of Mental Disorders* (DSM).

Attempts to apply the early criteria initially met with difficulty, especially when hallucinations and delusions were absent. To overcome this, Schneider proposed that the distinction between primary and accessory manifestations be abandoned. He attached more importance and reliability to the occurrence of auditory hallucinations, perceptual delusions (misinterpretation of what the patient hears and feels), and disturbances of thinking (experiences of alienation and influence). This constellation of symptoms, which was more precise and easy to recognize, came to be known as *Schneider's first-rank symptoms* of active schizophrenia. The Schneider diagnostic criteria, when applied to a group of patients admitted to the hospital with a diagnosis of schizophrenia, served to distinguish those with better and worse prognosis (Taylor). Those without hallucinations, delusions, and thought control or projection responded more poorly to treatment and required a more prolonged period in the hospital and higher doses of neuroleptic drugs than did those with these features. The two groups correspond closely to two categories of schizophrenic disorders later separated based on prognosis (Robins and Guze). The Schneider-positive, poor-prognosis schizophrenia (also referred to in older literature as *nuclear* or *process schizophrenia*) corresponded closely to kraepelinian schizophrenia, while many of the Schneider-negative patients with good prognosis were probably suffering from some other nonschizophrenic illness such as bipolar disease (see Chap. 48). Having made these comments, it must be acknowledged that newer classifications of schizophrenia give these distinctions less credibility and point to marginal differences in outcome and responses to treatment.

Feighner and colleagues, who drew up a set of diagnostic criteria for research in the major psychiatric syndromes (which were subsequently incorporated, until recently, into successive editions of the DSM) stated that the diagnosis of schizophrenia is tenable only in the presence of (1) a chronic illness of at least 6 months' duration and a failure (after an acute episode) to return to the premorbid level of psychosocial adjustment, (2) delusions or hallucinations without significant confusion or disorientation (i.e., without clouding of consciousness), (3) verbal productions that are so illogical and confusing as to make communication difficult (if the patient is mute, diagnosis should be deferred), and (4) at least three of the following manifestations: (a) among adults, the lack of a partner or spouse; (b) poor premorbid social adjustment or work history; (c) family history of schizophrenia; or (d) onset of illness prior to age of 40 years. Important exclusions from certainty in the diagnosis of schizophrenia include the absence of a family history of bipolar disease, absence of an earlier illness with depressive or manic symptoms, and absence of alcoholism, drug abuse, or other organic disease.

While the Feighner criteria are so strict as to exclude certain patients with a schizophrenic illness, those patients who are included will be found to constitute a fairly homogeneous group. After a 10-year period in one study that used these criteria (Morrison and colleagues) there was practically no need to change the diagnosis to another category of mental disease; in other words, they had reliably separated schizophrenia from schizophreniform psychosis (in which only the acute delusional-hallucinatory syndrome was present), and from bipolar psychosis.

Newer diagnostic criteria are no less refined but achieve clarity by stating that a patient must have at least one of the symptoms of delusions, hallucinations, and disorganized speech (not thinking). Also in updated versions is the removal of the necessity for delusions to be "bizarre", as already mentioned, and for there to be some elements of Schneiderian first-rank symptoms, namely an auditory experience of two or more voices conversing.

Subtypes of Schizophrenia

Psychiatrists had in the past separated a number of subtypes of schizophrenia, although the usefulness of these distinctions has been questioned and most modern criteria eliminate them entirely because they have proved to have limited clinical and therapeutic importance. They are briefly reviewed here for their historical interest and because they allow an explication of some of the more interesting symptoms and signs of schizophrenia that are entirely descriptive but are still instructive and retain clinical interest.

In what was called *simple schizophrenia*, the least florid form, the patient exhibits thought disorder, bland affect, social withdrawal, and reduction in speech and movement, all of which impair work performance. Poverty of psychomotor activity is the dominant feature and hallucinations and delusions are absent. These patients may attract notice in middle and high school because they behave in an odd manner, tending to remain by themselves ("loners"), making no effort to adjust to a social group at school or to find work, have dates, or later, to establish a family.

Catatonic schizophrenia is still the most readily identifiable type because of the striking syndrome of catatonia, and while still distinctive, it is now, for unclear reasons, found to be infrequent. In most cases the onset is relatively acute. In others, after a long prodrome of slackening interest, apathy, and dreamy preoccupation, a state of dull stupor supervenes, with mutism, inactivity, refusal of food, and a tendency to maintain one

position "like a mummy" (*catalepsy*). Like other forms of catatonia, this type of schizophrenia was the one most characterized by the retention of a posture: if a limb is lifted by the examiner, it will be held in that position for hours (*flexibilitas cerea*). Pinprick or pinch induces no reaction. Yet these patients may be fully aware of what is said to them or happening around them and will reproduce much of this information during a later spontaneous remission, a feature vividly recalled in the autobiographical novel "The Snake Pit" by Mary Jane Ward (although she would certainly by current standards have been diagnosed as bipolar instead of schizophrenic). Catatonia is recognized to be a feature of other mental disorders and is more frequent in severe involutional depression than in schizophrenia (the catatonic state is further discussed in Chap. 16 on Coma and Related Disorders of Consciousness).

Disorganized, or *hebephrenic, schizophrenia* was believed by Kraepelin to be a particularly malignant form. It tended to occur at an earlier age than the other varieties, hence the prefix *hebe* ("youth"). The thought disorder is pronounced—there is a striking incoherence of ideas and a grossly inappropriate affect; the frequent occurrence of hallucinations and delusions leaves little doubt that the patient is psychotic. *Paranoid schizophrenia* was one of the most frequent and well-circumscribed types, even if now unattached from schizophrenia in the DSM-5 diagnostic criteria. The mean age of onset is in the early forties, later than that of the preceding types (Winokur). The central feature is the preoccupation with one or more delusions related to a single or to a limited ensemble of themes, accompanied by auditory hallucinations. More often than not, the delusional hallucinatory content is persecutory, but it may also be religious, depressive, grandiose, or bizarrely hypochondriacal in nature. It is mentioned again that these distinctions are interesting and have some heuristic value but not often mentioned in modern work,

Course of Schizophrenia

Some patients with schizophrenia are subject to periodic exacerbations of their illness, sometimes at regular intervals. Remissions that allow functioning in society are more frequent and lasting when medication is given and prolonged institutionalization is avoided. A small proportion (approximately 10 percent), after an acute schizophrenic episode, have a long-lasting and fairly complete remission before lapsing into a chronic form of the illness. Unfortunately, these latter patients, at the time of their acute psychosis, cannot be distinguished from those few who will have a permanent remission.

Modern therapeutic programs have vastly reduced the number of patients in mental hospitals. However, readmission rates have also risen (revolving-door phenomenon) and the total number of very young and very old patients in hospitals has even increased slightly. The life expectancy of schizophrenic patients is reduced, possibly because of the malnutrition, neglect, and exposure to infections that occur in some public institutions and from living on the streets or in marginal circumstances.

Neurologic and Neuropsychologic Abnormalities in Schizophrenia

The early findings of Kraepelin and of Bleuler, that many schizophrenic patients will, on detailed examination, show subtle and inconsistent neurologic changes, have been substantiated by many studies but these refer mainly to "soft neurologic signs" that are present in schizophrenia more often than in healthy populations. These include impersistence in motor and mental tasks, astereognosis and graphesthesia, sensory extinction, hyperreflexia and hyporeflexia, slight tendency to grasping, mild impairment of coordination and disturbances of balance, abnormal (choreiform) movements, abnormalities of motor activity, adventitious and overflow movements, anisocoria, slight esotropia, and faults in visual auditory integration. Features of this type have been present in up to half of patients and are vaguely correlated with the degree of cognitive disorder. Some of them are certainly the result of inattention. Also evident in about half of schizophrenic patients are subtle defects in ocular tracking movements (Levin et al) in the form of slowed smooth pursuit and intrusions of saccades during pursuit; some relatives of schizophrenic patients also show these eye signs when carefully tested. In contrast, "hard neurologic signs" (such as unilateral motor or sensory defects) are not seen unless they are the result of an additional neurologic disorder.

Electroencephalographic (EEG) abnormalities have been detected in about one-third of patients, but are generally minor and their meaning is uncertain, especially if they have occurred after long-standing treatment. When EEG patterns were in the past a focus of research, they were found to be more frequent in schizophrenic patients who had a positive family history and in those with enlarged ventricles.

Sophisticated psychometric testing has disclosed abnormalities, not so much in intelligence and memory (which are slightly reduced in 20 to 30 percent of cases), as in other psychologic functions. Alertness is not generally impaired, but the ability to maintain attention, as measured by continuous performance tasks, is reduced (Seidman). In tests of verbal and visual pattern learning, problem-solving, and memorizing, there is a surprising degree of impairment in both acute and chronic schizophrenic patients that is not easily attributable to previous treatment. In the acute schizophrenic patient, verbal memory was more affected than visual pattern memory and left-hemispheric functions were more reduced than right-hemispheric ones. Yet, in chronic schizophrenia, there is usually subtle evidence implicating bihemispheric impairment in respect to several cortical functions (Cutting and Flor-Henry).

Theories of Causation and Mechanism

Although there is no agreement as to the fundamental cause of the disease, increasing evidence favors broad interactions between a genetic predisposition, neurotransmitter derangements, and early developmental events. One widely held hypothesis is that this disease reflects an underlying developmental disorder, determined either

genetically or because of an environmental insult, leading to abnormalities of synaptic connectivity, prominently affecting the hippocampus and prefrontal cortex. With detailed analysis, many potential causes have been suggested, as summarized in reviews (Marder and Cannon).

Genetic Factors

Several studies have estimated that genetic factors may account for upward of 80 percent of the risk of developing schizophrenia, more than for any other mental illness. Early studies showed that the frequency of disease in 5,000 siblings of schizophrenic patients was 11 percent, in contrast to slightly less than the approximately 1 percent in the general population noted above (Kallmann). In 90 sets of fraternal twins of whom one had schizophrenia, the incidence of disease in the other twin was also 11 percent, the same as in nontwin siblings; however, in 62 sets of monozygotic twins, the incidence in the second twin was 68 percent. The risk that a child of a schizophrenic parent will develop schizophrenia is the same as that for the sibling of a schizophrenic patient (i.e., 11 percent); if 1 sibling and 1 parent have schizophrenia, the risk is 17 percent. If both parents are schizophrenic the chances are 46 percent that the child will have the disease. Subsequent family and twin studies have confirmed these findings (Goodwin and Guze for a more complete tabulation). It is noteworthy, however, that the penetrance of this trait appears to be less than it is for bipolar disease but that genetic factors seem to play a larger role in patients whose schizophrenia manifests in their teenage years.

Although the importance of genetic factors in the etiology of schizophrenia is undeniable, a mendelian pattern of inheritance has not been determined. Polymorphisms in several genes have been implicated as risk factors but only 1 percent of risk can be attributed collectively to single nucleotide variants. Such genes include those expressing neuregulin, dysbindin, catechol *O*-methyltransferase (COMT), proline dehydrogenase, and "disrupted in schizophrenia 1" (DISC1). Some provocative sites are rare alleles in genes that also are overrepresented in autism—*NRXN1*, *SHANK3*, *CNTNAP2*, and *PRODH* (McClellan and King). There are also a copy number variations at genetic "hotspots" that occur in schizophrenia, autism, and other developmental disorders. What has merged from large population studies using genomewide array screening, is that there are not likely to be common risk variants for schizophrenia (Lieberman and First). Many of the polymorphisms seem to be of recent evolutionary origin or have a substantial rate of arising de novo. Some of the more provocative findings have been of connections to loci in the major histocompatibility (MHC) gene loci, putatively creating an immune link to schizophrenia, one that is often cited but has no proof. The studies implicating these genes must be interpreted cautiously because the functional significance of the allelic variants is not defined. Nevertheless, considered together, they point to disorders both of neuronal development and neurotransmission.

Environmental and Developmental Factors

There continues to be debate concerning the relative importance of genetic versus environmental factors in the causation of the disease. The lack of complete concordance between monozygotic twins and the fact that approximately 80 percent of schizophrenic patients have no other family members with the disease, indicate that factors other than genetic ones probably play a role. Some of these appear to be early events that occur *in utero* or infancy and alter normal developmental programs of brain structure.

The neuropsychiatric literature contains tentative and only circumstantial evidence that schizophrenia is associated with overt brain injury during the intrauterine or neonatal period, but there is reportedly an increased incidence of obstetric complications during the gestational period and birth of schizophrenic patients. Also consistent with an early adverse environmental factor is the observation by several groups that in the northern latitudes, more schizophrenic persons are born in the winter months and to women who were exposed to influenza during midpregnancy—inviting speculation that a viral infection may have damaged the fetal brain. In one study being born in an urban region, particularly in February or March, carried with it a higher risk for developing the disease than having an affected parent or sibling (Mortensen and colleagues). Among 5,362 infants who were followed prospectively since their birth in 1946 by Jones and colleagues, the 30 individuals who later developed schizophrenia had been delayed in the attainment of motor milestones and speech and exhibited greater social withdrawal and schoolroom anxiety as well as lower scholastic achievement. Thus, it is possible that schizophrenic individuals are not entirely normal in early childhood, but whether their abnormalities are already early manifestations of schizophrenia or risk factors for the disease has not been determined.

Neuropathologic, Brain Imaging, and Neurophysiologic Findings

Notably lacking in reports of developmental changes in schizophrenia, are accurate and modern neuropathologic data. Dunlap, in 1928, in a critical analysis, repudiated all earlier interpretations of cellular alterations that had been reported in the brains of schizophrenic patients. He pointed out that many of them, such as dark "sclerotic" nerve cells, were artifacts and that the presence of lipofuscin was a nonspecific age change. He also asserted that the neuronal loss described by Alzheimer was based on impression and could not be corroborated by quantitative methods. Similarly, the claim of Oscar Vogt of neuronal loss in the cortex was rejected by his contemporaries, Spielmeyer and Scholz, who were unable to find any consistent cellular abnormality in schizophrenia. Spielmeyer, in a critical study of the problem in 1930, concluded that such changes as had been described up to that time could not be clearly distinguished from the normal, and that the more marked changes in some cases were due to coincidental causes. Corsellis, based on yet another review of the neuropathologic data in 1976, found no reason to deviate from Spielmeyer's view. The uncertain neuropathologic findings were responsible for the enigmatic categorization of schizophrenia as a "functional" disorder, that is, a disorder with no structural basis.

Nevertheless, there has been a general sense that, while the number of neurons in the gray matter is normal, the pyramidal cells are smaller and more densely

packed, resulting in a thinning of laminae II and III. These cytoarchitectonic changes have been the most difficult to interpret and to confirm. Capricious methods such as the rapid Golgi stain indicate that density of dendritic spines is decreased in the frontal and temporal cortex of chronic schizophrenic patients. Also, several studies with other labeling methods converge on the observation that affected individuals have fewer dendritic spines than age-matched controls.

More contemporary reports using special cell-labeling studies have found subtle cytoarchitectonic abnormalities in the brains of schizophrenic patients. For example, aberrant distribution of interstitial neurons in the frontal lobe white matter has been described (Akbarian and colleagues). These cells have their origin in the embryologic subplate that guides neuronal migration, and the inference is that the abnormally migrating cells have formed aberrant neuronal connections. The number of small neurons in one study was reduced in layers I and II of the anterior cingulate cortex (Benes and colleagues). These are gamma-aminobutyric acid (GABA)–releasing (inhibitory) neurons. Other studies describe a paucity of gabanergic, inhibitory interneurons (so-called chandelier cells) in the prefrontal cortex (Woo et al). These observations suggest a developmental rather than an acquired lesion. The absence of gliosis supports but does not prove that the developmental disorder occurs prenatally

Imaging by CT and subsequently MRI of the brain provided a new stimulus to the anatomic study of schizophrenia. Johnstone and coworkers were the first to describe ventricular enlargement and sulcal widening in 18 patients and correlate these findings with dulling of intellect and affect. In a study of 58 individuals with chronic schizophrenia younger than age 50 years, there was enlargement of the lateral ventricles in 40 percent (Weinberger and colleagues, 1979). In 15 pairs of monozygotic twins, one of whom had schizophrenia, the anterior hippocampi were found to be smaller and the lateral and third ventricles larger in the affected twin (Suddath et al). Others have demonstrated a reduction in the volume of gray matter in the posterior part of the left superior temporal gyrus, which includes Heschl gyri and the planum temporale (Shenton and colleagues). The degree of volumetric reduction correlated roughly with the severity of the thought disorder. Other MRI studies have shown a volumetric change in the gray matter of the left hippocampus, parahippocampal gyrus, and amygdala (in right-handed patients). Equally compelling is the finding that young individuals having two or more relatives with the disease, and therefore being at risk for developing schizophrenia, have volumetric brain changes detected by imaging studies (Lawrie et al); the left hippocampal–amygdaloid region is smaller than in healthy people, but slightly larger than in affected relatives.

Neuropsychologic testing has disclosed deficits in attention and abnormalities of the P300 waves (cortical "event-related" potentials). These deficits are probably concordant with reduced cognitive activation activity in functional MRI, for example, decreased blood flow in the prefrontal areas during cognitive tasks (Weinberger et al, 1986). It is unclear, however, if these changes represent primary defects or are secondary to an inherent lack of motivation.

Studies of regional glucose metabolism and postmortem norepinephrine measurements have yielded ambiguous data, although most show a reduction in glucose metabolism in the thalamus and frontal cortex. Several lines of investigation point to the medial part of the left temporal lobe and related limbic and frontal systems as being the focus of a developmental abnormality (see Tsuang et al and Friston et al for pertinent references). The inconsistent findings on functional imaging may be accounted for by correlations between certain blood flow patterns and specific symptoms (Sabri and colleagues). For example, the formal thought disorder corresponded to increased flow in the frontal and temporal regions, whereas delusions and hallucinations were associated with reduced flow in the cingulate, left frontal, and temporal areas. PET studies in schizophrenic patients while they were experiencing auditory hallucinations have found increased blood flow mainly in both thalami, left hippocampus, and right striatum, but also in the parahippocampal, orbitofrontal, and cingulate areas (Silbersweig and coworkers).

Alterations in Neurotransmitters

When certain hallucinogens, such as mescaline and lysergic acid diethylamide (LSD), were first observed to induce hallucinations and abnormalities of thinking, it was hoped that they might provide experimental models of schizophrenia. This hope was never realized but there are instances, difficult to interpret, in which these drugs have induced a prolonged relapse in a schizophrenic patient. The psychosis caused by these drugs implicates serotonin ($5\text{-}HT_{2A}$) systems, an idea now resurrected as noted below. Similarly, when methionine, a potent source of methyl groups, was observed to exacerbate the symptoms of some schizophrenic patients, it was thought that a primary metabolic fault had been discovered. More recently, a glutamine hypothesis has been offered and is being investigated.

The dopamine hypothesis that held sway for decades and still has credibility was based on the response of psychotic symptoms to phenothiazine and related medications, which implicates the dopaminergic system of the temporal lobe (Carlsson). The evidence for this has been circumstantial but is supported by observations that antipsychotic drugs reduce the electrical activity of mesolimbic dopaminergic neurons in experimental models. Furthermore, there have been several demonstrations of increased concentrations of dopamine or its metabolite, homovanillic acid, in schizophrenic brains obtained at autopsy. The finding that dopamine receptors are organized in two systems, one limbic and the other cortical, has led to an expanded but speculative hypothesis that an excess of dopaminergic activity in the mesolimbic system gives rise to the positive symptoms of schizophrenia—that is, psychosis—whereas a diminished activity in the mesocortical system accounts for the negative symptoms. The involvement of the mesolimbic system, which plays a role in attention, has prompted further speculation that the thought disorder of schizophrenia is attributable to a breakdown of the normal "filtering" of stimuli reaching cognition. As mentioned earlier, it has been found that a variant in the gene for COMT that enhances metabolism of dopamine is overrepresented in schizophrenia, further

incriminating a disorder of dopaminergic neurotransmission in the pathophysiology of this disease (Egan et al).

However, the dopamine hypothesis has weaknesses, the most prominent of which is the relative ineffectiveness of dopamine-blocking drugs in alleviating many aspects of the disease that have been pointed out by several authors (e.g., Freedman). The complexity of dopamine systems and their interaction with other neurotransmitter circuits make a simplistic mechanism unlikely. Modifications of the dopamine hypothesis of psychosis have included deficiency of GABA or NMDA receptors (see below), both of which balance the dopamine (and glutamate) systems.

A hypothesis based on changes in the serotoninergic system has been again proposed. As with the dopaminergic model, attention was drawn to mechanisms relating to a newer class of antipsychotics (clozapine, risperidone), which have major effects on the serotonin system and were found to ameliorate the psychosis. Several groups have reported alterations in serotonin receptors in the brains of schizophrenic patients (see later). A further connection is of an allelic variation in the gene on chromosome 13 encoding for a serotonin receptor (5-HT_{2A}) that confers a susceptibility to schizophrenia (Williams and colleagues). The variation in this gene is insufficient to explain the disease in any one individual, if for no other reason than that many patients who are homozygous for the suspect allele do not develop schizophrenia. Perhaps a nearby region relating to the receptor may be at fault through linkage disequilibrium (see commentary by Harrison and Geddes).

A third biochemical hypothesis derives from observations that a psychosis syndrome is produced by chronic ingestion of phencyclidine (PCP), an *N*-methyl-D-aspartate (NMDA) antagonist and from the NMDA autoantibody syndrome. These implicate the glutaminergic system, but it must be pointed out that the dopaminergic and glutaminergic systems converge on certain cortical neurons and that glutaminergic release is modulated in several places in the brain by dopamine (Lieberman and First).

A variety of physiologic and endocrine differences between schizophrenic and healthy subjects have been claimed. None has proved to be significant. Because psychoses may complicate corticosteroid administration and certain endocrine disorders (Cushing syndrome, thyrotoxicosis, see later), there have been many attempts to uncover such abnormalities in the schizophrenic patient; all have failed.

Psychosocial Hypotheses

The notion that psychosocial factors play an important role in the genesis of schizophrenia was a recurrent theme in older psychiatric writings but is now given less credence. Prominent in these early writings was Freud's view that the schizophrenic process represents a fixation at an early autoerotic stage of sexual development. There is no way of affirming or refuting this proposition, even if one adopts a Freudian view of psychodynamics. The same can be said for the many suggestions that disturbed intrafamily relationships engender schizophrenic traits or possibly provoke psychosis in genetically vulnerable persons. Behind all these suggestions is disturbance of interpersonal relations in the family that interfered with the normal maturation of personality. The extent to which these aberrations of family relationships are primary or secondary cannot be ascertained.

The often-cited observations of Harlow on the deleterious effects of maternal and peer deprivation in primates opened the possibility that similar deprivations in humans may be responsible for the development of schizophrenia. However, such severe degrees of familial deprivation have rarely been documented in humans and when they were, as in some orphans, the effects were only transitory.

Nevertheless, stressful life events coincide with the first onset of a psychosis syndrome in some patients destined to manifest schizophrenia. One of these events is entry to college but this happens to coincide with the typical time of onset of schizophrenic symptoms. Also, cannabis use has been noted to be common among individuals with schizophrenia or at a minimum, with an earlier onset of the disorder but a causal link cannot be established (Large et al). Similar considerations may pertain to the earlier mentioned use of psychedelic drugs.

Differential Diagnosis

From a neurologic standpoint, the main initial distinction to be made is between an acute schizophrenia-like psychosis and the chronic disease, schizophrenia. A delusional-hallucinatory syndrome in which there is little if any disturbance of consciousness is characteristic of schizophrenia, but it may occur in the manic phase of bipolar disease, encephalitis, temporal lobe epilepsy, chronic amphetamine intoxication, withdrawal from alcohol, glucocorticoids, anti-NMDA encephalitis, and most often in the emergency department, from PCP, angel dust, LSD, and other drug intoxications. On rare occasions it is seen with postpartum psychosis (see further on) and with certain endocrine and metabolic disorders in which consciousness is not impaired. These distinctions are made by the premorbid history and the course of the illness. If the patient had been reclusive, withdrawn, and socially maladapted and does not seem to recover fully from the acute psychosis, then the diagnosis of schizophrenia is likely. Lacking these features, and in particular with a full remission, one assumes the occurrence of hypomania or of a toxic-metabolic psychosis, which can be detected by laboratory screening for drugs and endocrine diseases. Furthermore, it has been estimated that only 10 percent of patients with typical schizophrenia will have such an acute episode. Adherence to the criteria enumerated earlier, particularly to those devised by Feighner and colleagues will avoid most errors in diagnosis.

Further complicating matters, is the status of acute schizophrenia and of the so-called schizothymic and schizoaffective states, which bring to light a nosologic problem. How biologically sound is the traditional separation of depressive disease, bipolar disease, and schizophrenia? The suggestion has been made that they are linked in some way by these transitional forms. Neurologists should keep an open mind about these and other theoretical problems that lack a firm genetic and neuropathologic basis.

In addition to the acute schizophreniform psychosis, the authors have encountered difficulties in the diagnosis of neurological disorders simulating schizophrenia:

1. A patient with a healthy family and premorbid history with an acute illness having many of the typical features of schizophrenia but associated with confusion, forgetfulness, and/or clouding of consciousness. This type of illness combines the features of schizophrenia and a confusional state. This syndrome is characteristic of autoimmune encephalitis, particularly a form caused by anti-NMDA antibody (Chap. 35), of hallucinogenic drug use, particularly phencyclidine intoxication, glucocorticoid-induced psychosis, and thyrotoxic psychosis. Usually, recovery is complete with appropriate treatment, and schizophrenia is excluded by the fact that the patient remains well.
2. Adolescents and young adults whose social relationships are disorganized and who are unusually sensitive, resentful, rebellious, fearful, discouraged, in trouble with school authorities and the law, and using drugs. Such patients may be classified as having a borderline personality or sociopathy that appears to go back several years. These types of personality disorders and social maladjustments turn out not to be schizophrenia.
3. There is another related type of diagnostic problem, arising in an individual who has been only marginally competent because of personality problems and many vague neurotic and hypochondriacal symptoms, often requiring prolonged psychotherapy. Only a few such individuals will indeed later be found to have schizophrenia.
4. In a chronic delusional-hallucinatory state in a patient *with* chronic alcohol use disorder (chronic alcoholic hallucinosis); it will usually be disclosed that the illness began when alcohol was withdrawn, after a period of sustained drinking, and at first took the form of an acute auditory hallucinosis characterized by threatening, exteriorized auditory hallucinations to which the patient's emotional reaction was appropriate. Only later do a few of these patients drift into a quiet hallucinatory, mildly paranoid state, with rather bland affect. Cases of this type with which we are familiar had their onset between 45 and 50 years of age, that is, much later than the usual age of onset of schizophrenia.
5. A patient who is confused or stuporous and seemingly catatonic-negativistic, refusing or unable to speak, to execute commands, or to be activated in any way. If signs of focal cerebral or brainstem disease are absent, one is tempted to make a diagnosis of catatonic schizophrenia, not appreciating that *catatonia* as a phenomenon may be indistinguishable from akinetic mutism (Chap. 16). It may also appear with widespread disease of the associational cortices and as mentioned earlier, with severe depression, certain confusional states, and hysteria. The authors have seen cases of hypoxic and other metabolic encephalopathies, Schilder disease, certain storage diseases, and Creutzfeldt-Jakob disease that were initially mistaken for schizophrenia because of failure to adhere to this principle.
6. A patient with temporal lobe epilepsy who, apart from intermittent psychomotor seizures, has long periods (weeks or months) of hallucinations, delusions, bizarre behavior, and disorganization of thinking. Such a disturbance may reflect a persistent state of temporal lobe seizures (temporal lobe status epilepticus), which in some cases has been demonstrated by depth electrodes to originate in the amygdaloid or other medial temporal areas. The nature of the disturbances of emotionality and mentation in such patients, a somewhat controversial subject, is discussed in Chaps. 15 and 24.
7. Patients with prominent depressive symptoms who have made repeated suicide attempts pose an exceptionally difficult problem. They were referred to in the past as *schizothymic* and to this day it is not certain whether they have schizophrenia, a chronic depressive illness (dysthymia), or both ("schizoaffective"). When in remission, patients with affective disorders are usually normal, whereas those with schizophrenia are not.
8. One should be hesitant to make the diagnosis of schizophrenia during childhood, although such a diagnosis has been entertained in children who have a variety of developmental and adjustment problems and who at some time become psychotic, that is, they become excited, depressed, or hallucinatory and express bizarre ideas. There is no evidence that such children go on to have schizophrenia later in life. And although what are thought to be "schizoid" traits may be recognized in childhood, a frank psychosis is hardly ever recorded at this age. Of particular importance in such children is to exclude the presence of metabolic errors, mental retardation, or an early onset depressive illness. Similarly, childhood autism and particularly its milder forms, such as Asperger syndrome discussed in Chap. 37, should not be confused with schizophrenia. That the incidence of schizophrenia is not increased in the families of autistic children supports the idea that the two are separate diseases.
9. The special problem of mania that manifests for the first time as a confusional-encephalopathic state was discussed in Chap. 48.

Treatment

Treatment aims to suppress psychotic symptoms, ameliorate the disorder of thinking and the apathetic state, prevent relapse, and optimize social adjustment. The physician soon becomes accustomed to the pattern of the patient's psychotic behavior and can help support the patient and his family during difficult periods. Relapse with psychosis may require hospitalization and drug therapy, especially if there is a possible hazard of injury or suicide or difficulty in management at home. Hospitalization aims to protect the patient, relieve the family of the need for constant vigilance and supervision, and ensure the administration of drugs until the exacerbation spends itself. If medication is successful in preventing progressive decompensation, the patient can many times return to the family and community but as often will need a supervised environment. It is invaluable to have a competent social worker or nurse maintain frequent contact with the patient and his family and ensure continuity of medication.

In recent years a trend of early intervention with a first psychotic episode has gained favor. This includes a more thorough medical evaluation than had been typically conducted in the past and a team approach to reorienting the patient by providing straightforward cognitive behavioral or psychotherapy and family counseling. In some health systems, this has reduced the incidence of relapse.

The modern era of treatment of schizophrenia began in 1952, with the incidental demonstration by the French surgeon Henri Laborit of the antipsychosis properties of chlorpromazine (while working as a military physician in Tunisia). Subsequently, many other phenothiazines have been used to treat chronic and acute psychosis but their use is limited by extrapyramidal side effects. Treatment currently consists essentially of the administration of one of several newer antipsychotic medications. The various classes of antipsychotic drugs, their mode of action, and neurologic ("neuroleptic") side effects are discussed in Chap. 41.

The second generation of "atypical" nonphenothiazine antipsychosis drugs that have complex effects on the dopamine and serotonin systems are now used in preference to the standard dopamine antagonists, the phenothiazines and the butyrophenones. They are "atypical" in that their extrapyramidal side effects are far less than that for the phenothiazines. They all serve to calm the patient, blunt emotional responses, and reduce hallucinosis and aggressive and impulsive behavior, leaving cognitive functions relatively intact. The main side effects, pertaining mostly to the phenothiazine group, are summarized in Table 49-1 and Chap. 41. The antipsychotic action of these drugs is more impressive in the short and intermediate term than over the long term, although some data suggest that they are also of value in preventing relapses. Negative symptoms (apathy and withdrawal) respond less well than positive ones, and it is generally acknowledged that 10 to 20 percent of patients respond little or not at all to medication. Approximately one-quarter of patients will have a relapse while being treated with an effective drug and three-quarters of patients with non-adherence to a previously effective regimen will relapse.

Clozapine, *olanzapine, risperidone*, *quetiapine*, and others listed in Table 49-2 are common atypical antipsychosis drugs with incompletely defined pharmacologic properties but with narrower affinities for certain receptors. In addition to their reduced extrapyramidal side effects, they produce clinical improvement in about half of patients who have proved to be unresponsive to other antipsychotic medications. These drugs bind to and inhibit serotonin receptors and, to some extent, dopamine receptors (Meltzer and Nash), but have a much lower affinity for striatal dopamine receptors, thus providing an advantage—the absence of immediate or tardive (delayed) extrapyramidal side effects. This has led most psychiatrists to use one of the newer drugs, rather than the phenothiazines, as a first choice. The addition of a second drug, specifically combining clozapine with risperidone, was not found to be useful in a trial (Honer and colleagues). Moreover, in another effectiveness trial sponsored by the National Institutes of Mental Health, ("CATIE" Investigators) found that most chronic patients with schizophrenia discontinued their antipsychosis drugs within 18 months. Among the medications they compared, olanzapine was slightly more effective than quetiapine, risperidone, and ziprasidone; of equal interest, the phenothiazine perphenazine was equivalent in efficacy and tolerability to the last 3 second-generation (atypical) drugs.

Table 49-1

EXTRAPYRAMIDAL SYNDROMES ASSOCIATED WITH TYPICAL NEUROLEPTIC-ANTIPSYCHOTIC AGENTS

REACTION	FEATURES	MAXIMUM RISK	PROPOSED MECHANISMS	TREATMENTS
Acute dystonias	Muscle spasms; tongue, face, neck, back; terrifying; rarely fatal from asphyxia	1–5 d or with each injection of decanoates	Dopamine excess	Anticholinergic agents
Parkinsonism	Bradykinesia, rigidity, variable tremor, mask facies, shuffling gait	Evolves slowly in 1–4 wk, often persists	Dopaminergic deficiency	Oral anticholinergics, amantadine; dopaminergics are too risky
Malignant syndrome	Catatonia, stupor, fever, unstable pulse, blood pressure and respirations, elevated serum creatine kinase and myoglobin; can be fatal	Days to weeks	Hypothalamic and extrapyramidal dysfunction likely; not muscle calcium influx problem as in hyperthermia of anesthesia	Stop neuroleptic; expert intensive care; dantrolene or bromocriptine may help
"Rabbit" syndrome	Rare perioral tremor; usually reversible	Months to years	Parkinsonism variant	Oral anticholinergics
Akathisia	Motor restlessness with anxiety and agitation	Can start immediately and usually persists	Unknown; adrenergic component	Reduce dose or change drug propranolol; antiparkinson agents and benzodiazepines
Tardive dyskinesias	Oral-facial dyskinesia choreoathetosis, variable dystonia; often slowly reversible; rarely progressive	6–120 mo; worse when drug stopped	Dopaminergic excess likely	Prevention best; Tetrabenazine and similar drugs, reintroduction of offending drug and slow tapering, slow spontaneous remission

Note: Akathisia and early tardive dyskinesias are often overlooked unless specifically considered at examination. The risk of most reactions is greater with high potency, typical neuroleptics, and all but acute dystonia (young males at greatest risk for both acute and tardive dystonias) and akathisia (any age) are more likely in the elderly. Children may also be at elevated risk for parkinsonism as well as reversible neuroleptic withdrawal-associated dyskinesias. Table 49-2

"ATYPICAL" ANTIPSYCHOTIC DRUGS WITH LIMITED EXTRAPYRAMIDAL SIDE EFFECTS

MEDICATION	BRAND NAME	INITIAL DOSE	TARGET OR MAXIMAL DOSE	POTENTIAL SIDE EFFECTS[a]
Olanzapine	Zyprexa	5 mg	10 mg	Orthostatic hypotension, transaminase elevation, hyperprolactinemia
Quetiapine	Seroquel	25 mg bid	300 mg	Orthostatic hypotension, cataracts, transaminase elevation
Clozapine	Clozaril	12.5 mg bid	300 mg	Agranulocytosis, transient fever, anticholinergic activity, hyperglycemia
Risperidone	Risperidol	1 mg bid	3 mg bid	Orthostatic hypotension
Ziprasidone	Geodon	20 mg	160 mg	Less weight gain than others in this class. Prolongation of QT interval
Aripiprazole	Abilify	5 mg	30 mg	Less weight gain than others in this class. Prolongation of QT interval
Amisolpride	Solian	100 mg	1,000 mg	

[a]All have the potential to cause tardive dyskinesias and neuroleptic malignant syndrome (see Table 49-1), but these complications are less frequent than with phenothiazines and haloperidol. Weight gain is common with this class of drugs.

Approximately 1 percent of patients treated with one of the most effective drugs, clozapine, develop leukopenia in the first 18 months of treatment, which may be fatal due to overwhelming infections, for which reason monitoring of white blood cell count is incorporated into the treatment plan; there is less risk with the related agent, olanzapine, but leukopenia and agranulocytosis have been reported in rare instances with it as well. Orthostatic hypotension, tachycardia, fever, and hypersalivation may be troublesome in the first days and weeks of therapy with any agent in this class. *Risperidone* is a potent serotonin and dopamine-receptor antagonist. Low doses reportedly attenuate the negative symptoms of schizophrenia (apathy, emotional withdrawal, lack of social interaction) and the incidence of extrapyramidal side effects is low provided that the dosage is kept below 6 mg daily. Newer classes of agents that are being investigated include agonists 5-HT and trace amine-associated receptors that do not have D-2 activity (Koblan et al) and muscarinic cholinergic receptor agonists combined with peripheral muscarinic blockers to mitigate side effects (Brannan et al). These have only been tested in short-term trials and compared only to placebo.

Table 49-2 summarizes typical dosages of some antipsychotic drugs. In the higher dose ranges, parkinsonian features may nevertheless appear. Tardive dyskinesias, however, are infrequent. Common to most of the drugs is weight gain and other aspects of the "metabolic syndrome" including hyperlipidemia and hyperglycemia. With long-term treatment this may accumulate to 20 percent of the patient's original weight. In a few cases, the newer generation antipsychotics have induced some obsessive-compulsive symptoms. In one meta-analysis of extrapyramidal symptoms and various drugs, low-potency first-generation antipsychotics (excluding haloperidol) may have had similar complications to the new generation of drugs when dose-equivalent amounts are given (Leucht and colleagues). Many clinicians do not agree with this perspective. Several series have also suggested that the atypical antipsychosis drugs have a risk of ventricular arrhythmias and sudden death compared to conventional medications. However, other series indicate that the frequency of these complications, while increased approximately twofold compared to nonusers, are the same for older and newer drugs when adjusted for medication dose (Ray and colleagues). These comparisons are matters of ongoing debate; however, a "black-box" warning appears with these drugs in relation to increased mortality risk from cardiovascular events in the elderly. The precise cause(s) of this increase are not clear.

Attempts are made to individualize and eventually lower the dosage until the patient's behavior suggests that a relapse is imminent. Antidepressants and lithium have also been used in those schizophrenic patients with prominent affective symptoms. Electroconvulsive therapy (ECT), which may be effective, is now seldom used except in patients who are catatonic or severely agitated or who have prominent affective symptoms.

To some extent, the acute extrapyramidal side effects of haloperidol and the phenothiazines can be mitigated by the simultaneous parenteral administration of antihistaminic drugs—for example, diphenhydramine, 25 mg tid—and the anticholinergic drugs used in the treatment of Parkinson disease—for example, benztropine, 0.5 to 1 mg bid. However, the latter drugs must be given cautiously for they may interfere with the action of the antipsychotic drugs and, if given in large doses, themselves induce a toxic confusional state. If it becomes necessary to treat the extrapyramidal side effects, it is usually possible to eliminate the anticholinergic drugs after 2 to 3 months without a return of motor symptoms. In chronically medicated patients, 20 to 40 percent of whom develop tardive dyskinesias, an increased dose of the antipsychotic drug may suppress the dyskinesia, but only temporarily. The most dreaded complication of pharmacotherapy is the neuroleptic malignant syndrome. The nature and management of this complication and of the more common problem of tardive dyskinesias are discussed in Chaps. 4 and 41.

Outcome of Schizophrenia

This is a complex matter as a result of uncertain diagnosis early in a psychotic disorder, variation in socioeconomic and support systems across studies, duration of study, and differences in treatment patterns. Various studies estimate that between 4 and 30 percent of patients who recover from an acute psychotic episode will remain relatively well, even without treatment (Correll et al). So far, no dependable method of predicting outcome has been devised. As an approximation, with modern drug therapy and supportive psychiatric management, approximately 60 percent of schizophrenic patients will recover sufficiently to return

to their homes and become socially adjusted to varying degrees (about half of this group can engage in some occupation). Approximately 30 percent remain severely disabled and 10 percent remain hospitalized.

DELUSIONAL DISORDER AND PARANOID DISORDER

The term *paranoid* (*para* = beside, *nous* = mind) literally means a mind beside itself. It designates patients who show "fixed suspicions, persecutory delusions, dominant ideas or grandiose trends logically elaborated and with due regard for reality once the false interpretation or premise has been accepted. Further characteristics that differentiate pure paranoia from typical schizophrenia are formally correct conduct, adequate emotional reactions, and coherence of the train of thought" (Rosanoff). In other words, in pure paranoia (*delusional disorder* in DSM), there is supposed to be no mental defect other than the delusional system—no dementia, hallucinations, or emotional disturbance. In past years, a large group of the mentally ill was classified as paranoid. But with advancing knowledge of mental illness, a decreasing number has been left in this category.

The trouble that psychiatrists have taken to couch this definition in negatives implies that paranoia is frequently a feature of other forms of mental illnesses, notably schizophrenia, bipolar disease, Alzheimer disease, Lewy-body disease, toxic or alcoholic psychosis, and general paresis. This fact about paranoia was known from the beginning, when Heinroth originally described it in 1818 and classified it as a limited disorder of the intellect. Kraepelin, in agreement with the ideas of Kahlbaum, distinguished between paranoia and dementia praecox, but remarked that approximately 40 percent of patients who developed paranoia early in life went on to become schizophrenic. In DSM-IV, this disorder is classified as "delusional (paranoid) disorder" and defined it as a *persistent* delusion that is not part of any other mental disorder. Furthermore, the delusions are nonbizarre, that is, while improbable, they involve situations that could occur in real life, such as being followed, poisoned, infected, loved at a distance, deceived by a spouse, or having a disease.

Figures on the frequency of isolated paranoia are probably not reliable because they are of necessity based on hospital records. Doubtless there are many individuals with mild forms of the disorder who have never crossed the threshold of a mental hospital. These individuals are relatively harmless and in their communities are judged to be "off," eccentric, or simply odd. Males and females are equally affected. Among psychiatric hospital patients, true isolated paranoia has been rare, accounting for approximately 0.1 percent of admissions (Winokur).

Clinical Manifestations

It would be difficult to give an account of all the ways in which patients with paranoia behave. A simple amalgam will suffice—that of a middle-aged man of uneasy, brooding, asocial, eccentric nature who gradually develops a dominating idea or belief of his own importance, of having in his possession special powers that make him the envy of others who become bent on persecuting him. As the delusion grows, he becomes more preoccupied, less efficient, and increasingly suspicious of others, with a tendency to interpret every one of their words, gestures, or actions as having some reference to himself. On examining such a person, one is impressed with his capacity for careful reasoning, even betraying good intelligence. Whatever the delusional theme—erotomania (a delusion that another person, usually of higher status, is in love with the patient), grandiose, jealous, persecutory, or somatic, the last being the most common—the patient's arguments are logical and buttressed cogently by evidence. The patients express their false beliefs with certainty and conviction and are totally unaccepting of all arguments that impugn their rationality. Also, the views of such patients about matters other than their delusions can be quite sensible.

The querulous patients with paranoia are the most problematic. They remain in the community, flooding the mails and emails with documents accusing people falsely of various misdeeds, incessantly writing to newspapers and websites, and expressing their opinions about anything and everything. As the years pass, the patient changes little, although a few such patients may later break down and begin to hallucinate and finally end in a deteriorated state much like that of schizophrenia. This trend supports Bleuler's opinion that the illness is a variant of schizophrenia.

Regarding causation, there have been several completely unverifiable ideas. The Freudian school attributed paranoia to repressed homosexuality and fixation at the narcissistic level. Meyer invoked a long-standing personality disorder, the *paranoid constitution*, using the term to refer to a lifelong tendency to hold biased views, to be overly concerned about what others think of the individual, and to attribute deliberate intentions to indifferent actions. There have been many discussions of proposed psychologic mechanisms of paranoia (Manschreck).

The authors' experience with pure paranoia in a general hospital has been limited. One sees deluded patients, to be sure, but usually their abnormal ideas have centered on self-persecution, health and bodily functions, infidelity of a spouse, theft of possessions, and the like. The claim that poisoning by carbon monoxide has left the person with ill-defined defects in concentration and other mental functions or the belief that there exists an unobservable parasitic skin infestation have been the most common delusions in our experience. Whether unshakable beliefs about Lyme disease or environmental toxins or multiple imagined allergies fit in this category is unclear. One of our patients, functioning normally in every other way, carried the unshakable idea that people were sneaking into her house at night when she was away and rearranging the furniture. She functioned extremely well through her eighties but had a schizophrenic sister. Also, several physicians under our care have woven extensive delusional ideas around tenuous scientific theories; these ideas have applied to personal life events as well as physical and psychologic symptoms and in some cases have resulted

in bizarre regimens of self-medication. Rarely, a patient comes to the hospital for some other medical reason, and it is found that they have been living quietly in the community, preoccupied with a strange and outlandish delusional system, yet appearing neither depressed nor schizophrenic. Certainly, one often sees delusions in depressed patients who decompensate as their depression deepens.

Sharply separated from the more or less pure delusional disorders are the ones that occur as part of a confusional state or delirium. Delusions occurring in the latter setting are characteristically bizarre, changeable, poorly systematized, and, with rare exceptions, transitory and are associated with many other aberrations of mental function. The same can be said for delusions that occur in the early stages of a dementing disease. Such events are common, of course, in elderly persons with an incipient or well-compensated dementia (called by Raymond Adams, "beclouded dementia"; see Chap. 19). Occasionally, one of the degenerative dementing diseases of middle and late life (Alzheimer, Huntington, and especially Lewy-body) presents first with a delusional disorder. Otherwise healthy persons without known mental illness may experience a brief delusional episode, notably after surgical procedure or the administration of sedative drugs or at times of extreme personal stress. In most, there are no subsequent mental problems, but a proportion of these older patients will be found to later develop dementia. There is also the frequent problem of varied delusions with manic states that are part of the bipolar disorder discussed in Chap. 48 in which the ideas tend not to be always so clearly persecutory, are usually multiple and disconnected to each other, and often reflect misidentification or distortion of memories.

Certain drugs have a tendency to produce paranoia in otherwise nonpsychotic individuals; corticosteroids, phencyclidine, amphetamine, psychedelics, and cocaine are the main offenders seen in patients arriving in emergency departments, and anticholinergic drugs are often responsible in hospitalized patients. A few patients became depressed, sometimes profoundly, after use of interferon for multiple sclerosis and display delusional thinking. Some antiseizure drugs, among them levetiracetam, may have delusions or psychotic-like syndromes as part of an induced depression. These have all been called "organic delusions" (Cummings).

Management

We have no way of determining whether psychotherapy has influenced these states of paranoia and delusion; our impression is not. In a general hospital, where most of our paranoid patients have been depressed, manic, or demented, we have several times been gratified by the effects of antidepressant or antipsychotic medication, with full knowledge of the potential risks discussed earlier. In the treatment of patients with pathologic jealousy, at least one report in an earlier era found phenothiazine drugs to be useful (Mooney) but this is anecdotal.

From what has been said, the clinical analysis of patients with delusions requires a careful study of mood and cognitive function to rule out bipolar disease and dementia. If either of these two states exists, the treatment proceeds along the lines discussed in Chaps. 20 and 48. A matter of practical importance is for the physician to evaluate the nature of the delusional ideas and try to judge whether the patient is homicidal or suicidal. Occasionally, physicians and others have been killed or maimed by patients with paranoia who thought they were being mistreated.

POSTPARTUM PSYCHOSES (SEE ALSO POSTPARTUM DEPRESSION IN CHAP. 48)

Parturition, associated as it is with many biologic disturbances such as the effects, drugs, eclampsia, hemorrhage, infection, and perhaps most prominently, an abrupt hormonal adjustment, is frequently associated with a disturbance of mood. Obstetricians have observed that a woman may feel extraordinarily well immediately postpartum, only to lapse in the following days into a weepy, depressed state in which she may be distressed by lack of feeling for her newborn infant. Usually this lasts for only a few days ("postpartum blues"), being quelled by the return home, responsibility for the infant, and nursing. In some patients, however, the depressive symptoms persist for months (see later). A few affected women have psychosis appended to a severe depression but there is apparently an independent entity of postpartum psychosis with no overt depression. As mentioned in the previous chapter, some authors have questioned the existence of a special depressive illness that is linked to the postpartum period, an opinion that is not supported by our clinical experience (see Brockington). Depression *during* pregnancy may be a separate entity and is noted in Chap. 48.

The period after childbirth is therefore also one in which there is a potential disposition to psychosis. Opinion varies as to whether there is a special *puerperal, or postpartum psychosis*. Some psychiatrists believe that the psychotic break that may occur at this time is either a confusional-delirious state or a schizophreniform or depressive psychosis, and that these illnesses do not differ from those occurring at other times in life.

Postpartum psychosis is therefore not easily categorized. It has its onset between 48 and 72 h or longer after a delivery that may have been complicated by excessive bleeding or infection but as often, is not. The patient alternates between periods of noisy hyperactivity and of mutism and inactivity. She is disoriented and incapable of thinking clearly. The baby is sometimes rejected as not belonging to her (instances of infanticide are not unknown). Although the illness has some features of delirium, it may merge with a schizophrenic or depressive type of psychosis that persists for months. In a series of such cases, approximately 40 percent were predominantly affective, 20 percent schizophreniform, and the remainder self-limited confusional psychoses (Boyd). Some experts have argued that a delirium with fluctuating attention and cognitive difficulties are characteristic of the disorder. There certainly may be perceptual alterations but the outstanding and most dangerous aspects in patients we have seen are suicidal and infanticidal thoughts. New approaches to the treatment of

postpartum depression using "neuro-steroids" are being investigated but it is not clear if they will be applicable to postpartum psychosis.

In the diagnosis of postpartum psychosis, one must keep in mind the possibility of eclampsia, the consequences of pituitary infarction, cerebral vein thrombosis or transitory stroke of arterial type, ergot-induced psychosis, and hypotensive-hypoxic cerebral injury. The treatment of such patients follows the methods described in Chap. 48 and in the following text.

THE ENDOCRINE PSYCHOSES

One of the most provocative observations in contemporary psychiatry had been that healthy individuals may become psychotic when they develop hyper- or hypothyroidism or Cushing syndrome, or less often, adrenal insufficiency, or when they receive therapeutic doses of corticosteroids. If these conditions were no more than examples of drug-induced psychosis, they would be interesting enough. The fact is, however, that they differ considerably from the usual toxic deliria or confusional states. The syndrome comprises features that are suggestive of bipolar disorder with psychosis or schizophrenia on the one hand and of confusional psychosis on the other. These endocrine psychoses have far-reaching medical significance, for they provide artificial models and a neurologic perspective of psychoses created by the manipulation of metabolic and exogenous factors. It is appropriate that they are in the last chapter in a neurology book.

Corticosteroid (Glucocorticoid) and Adrenocorticotropic Hormone Psychosis

First described in arthritic patients being treated with cortisone, these syndromes now occur far less frequently than when corticosteroids were introduced into medical practice. The psychosis usually develops over a period of a few days after the patient has received the medication for a week or more. The features are extremely variable. Depression and insomnia are the most frequent early symptoms, but some patients become elated, agitated, excited, and talkative, as though under pressure to speak, whereas others are mute; or the prevailing emotional response may be one of anxiety and panic. Thinking may be slightly illogical, tangential, or incoherent. Hallucinations and sensory misinterpretations may appear. However, clouding of the sensorium and disorientation, the hallmarks of deliria and the confusional states, have been less prominent. Nevertheless, the state of awareness may not be altogether normal, and at times the patient is bewildered. If administration of the drug is discontinued as soon as symptoms appear, the psychosis subsides but only gradually over several days to weeks, with complete recovery.

In patients with Cushing disease, mental changes are similarly known. In some patients there is a combination of affective disorder and impairment of cognitive function, usually apparent during mental status testing. Also, among athletes taking anabolic steroids, some develop affective and psychotic symptoms—reduced sleep, irritability, aggression, paranoid delusions, auditory hallucinations, and euphoria or depression. Mental changes in *Addison disease* are less frequent and more varied. Irritability, confusion, disorientation, and convulsions, with or without symptoms of hypoglycemia, have been the main features. Low energy from pituitary of adrenal failure simulates depression but may not have an affective component.

The mechanisms are not well understood. From the few available studies, it has been deduced that the occurrence of psychosis is not related to the premorbid personality. Although the dosage of corticosteroid or adrenocorticotropic hormone (ACTH) has usually been high, there has been no definite correlation between the dosage and the occurrence, severity, and duration of psychosis. In a study of patients with systemic lupus erythematosus, 5 percent of patients became psychotic with steroid treatment, and for an obscure reason, only hypoalbuminemia was found by statistical analysis to be an associated factor and this is not entirely plausible (Chau and Chi). A history of anxiety or of a family history of psychiatric disease had only a marginal predictive value for steroid-induced psychosis. The notion held by many neurologists that dexamethasone is less frequently associated with psychosis than other corticosteroids is unproven. Lithium is often effective in controlling manic symptoms, allowing continuation of the corticosteroid therapy if necessary for the underlying medical condition (Falk et al).

"Thyroid Psychosis"

A great deal has been written about the pervasive effects of abnormal thyroid function on all organs, including the neuromuscular apparatus and central nervous system. These are discussed in Chap. 39 with other acquired metabolic diseases of the nervous system, but mental changes with these endocrinopathies are not nearly as frequent or prominent as for adrenal and pituitary disorders.

The hyperthyroid patient shows minor changes in emotions and mentation. Restlessness, irritability, apprehension, emotional lability, and at times even agitation and a generalized chorea may occur. Either of two trends may be observed in the relatively rare thyrotoxic patient who develops psychosis. There may be a mild manic state, with its characteristic increase in psychomotor activity, excessive talkativeness, and flight of ideas, or there may be depression, with its somber mood, weeping, and anxiety. Visual and auditory hallucinations may be present in both groups. Usually there is something more than simple mania or agitated depression, that is, some clouding of the sensorium with perplexity and confusion, suggestive of delirium. The condition is said to be related to the premorbid personality, some personality types being more vulnerable, but this is disputed. It can be stated that the psychiatric changes are not directly related to the severity of the thyrotoxicosis. Treatment of the hyperthyroidism does not result in prompt arrest of the psychic disorder; recovery usually takes place over a period of months. One must distinguish this illness from other types of recurrent psychoses that happen to be coincidental with or precipitated by hyperthyroidism and from the steroid-responsive

encephalopathy called "Hashimoto encephalopathy" mentioned below.

With *myxedema* there is a characteristic slowness and thickness of speech and in extremes, drowsiness, hypothermia, mental dullness, listlessness and apathy, irritability, and sometimes suspiciousness. The patient may sleep much of the time, having to be awakened for meals. A disturbance of memory and the lack of genuine symptoms of depression, such as feelings of hopelessness and loss of self-esteem, help to distinguish the mental disorder of myxedema from that of a depressive illness. Nevertheless, unless one thinks of myxedema in cases of psychomotor retardation, the diagnosis will be missed. Reduced cerebral blood flow and metabolism have been found in myxedema; with specific therapy, these functions are restored to normal within 2 to 3 weeks.

An entirely different type of mental disturbance characterized by intermittent delirium and stupor often associated with myoclonus and autoimmune in nature may occur in patients with thyroiditis or at least, with the autoantibodies associated with this disorder ("Hashimoto encephalopathy," Chap. 39). The illness is responsive to glucocorticoids. The diagnosis is confirmed by the finding of circulating antibodies to thyroglobulin and thyroid peroxidase but there are high rates of false positive tests, particularly in middle-aged and older women.
