NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The author and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the author nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

Foreword

After an initial disastrous introduction to neurology as a medical student, my lifelong affair with the specialty began in 1977 as a medical resident followed by my first year of neurology residency in 1978. From the start, the first edition of *Principles of Neurology* became my bible, which I and my co-trainees read from cover to cover. The field has changed immensely since that time, and widely distributed neurology textbooks are multiauthored by experts in the large number of neurology subspecialties that now dominate the field. This results in chapters providing considerable detail but often in a very patchy, inconsistent, and sometimes inaccurate fashion. The publication of the twelfth edition of *Adams and Victor's* celebrated text reaffirms that there is still an important place on the shelves of neurology trainees and practitioners for a volume that originated from the two remarkable neurological authorities, Raymond Adams and Maurice Victor, and is now written by four experienced authors sharing their clinical experience with a uniform approach to the presentation of the field that is typically lost in the world of multiauthored texts.

As in the original, the current edition starts by emphasizing the classical approach to neurological patients. The authors highlight the importance of a solid understanding of neuroanatomy and the possible symptomatology caused by dysfunction of the nervous system that is critical to the combined deductive and inductive (Holmesian) approach to neurological diagnosis that makes the specialty of neurology so interesting and stimulating to those who practice it. Patient-based learning became a defined teaching approach long after Adams and Victor first wrote their text. However, the recognition of the importance of the patient in the acquisition of knowledge about a field, especially as it applies to neurology, was clearly acknowledged and is paramount in subsequent editions, including this one.

With the remarkable advances in neuroscience and medicine in general, it is impossible for a single textbook to cover all aspects of neurology in detail. This emphasizes the importance of lifelong learning in medicine that and clearly requires an initial strong clinical basis upon which to build and learn, as provided in this book. Although technology and understanding of the biological basis of disease and therapeutics are ever-changing, the way the patient presents to the clinician has changed little since the origins of medicine. This further highlights the importance of the consistent, patient-based approach provided here as well as the historical perspectives included.

Finally, although the old portrayal of neurology as a "diagnose and adios" specialty is largely accepted as outmoded, the clinical knowledge-base and the coverage of research and therapeutic advances in *Adams and Victor's Principles of Neurology* proactively encourage the clinician seeing patients suffering from neurological diseases to diagnose and administer, ameliorate, and advocate.

This fitting 50th anniversary edition of the major textbook in neurology affirms the appeal and durability of an iconic vehicle for the transmission of knowledge and wisdom acquired through experience.

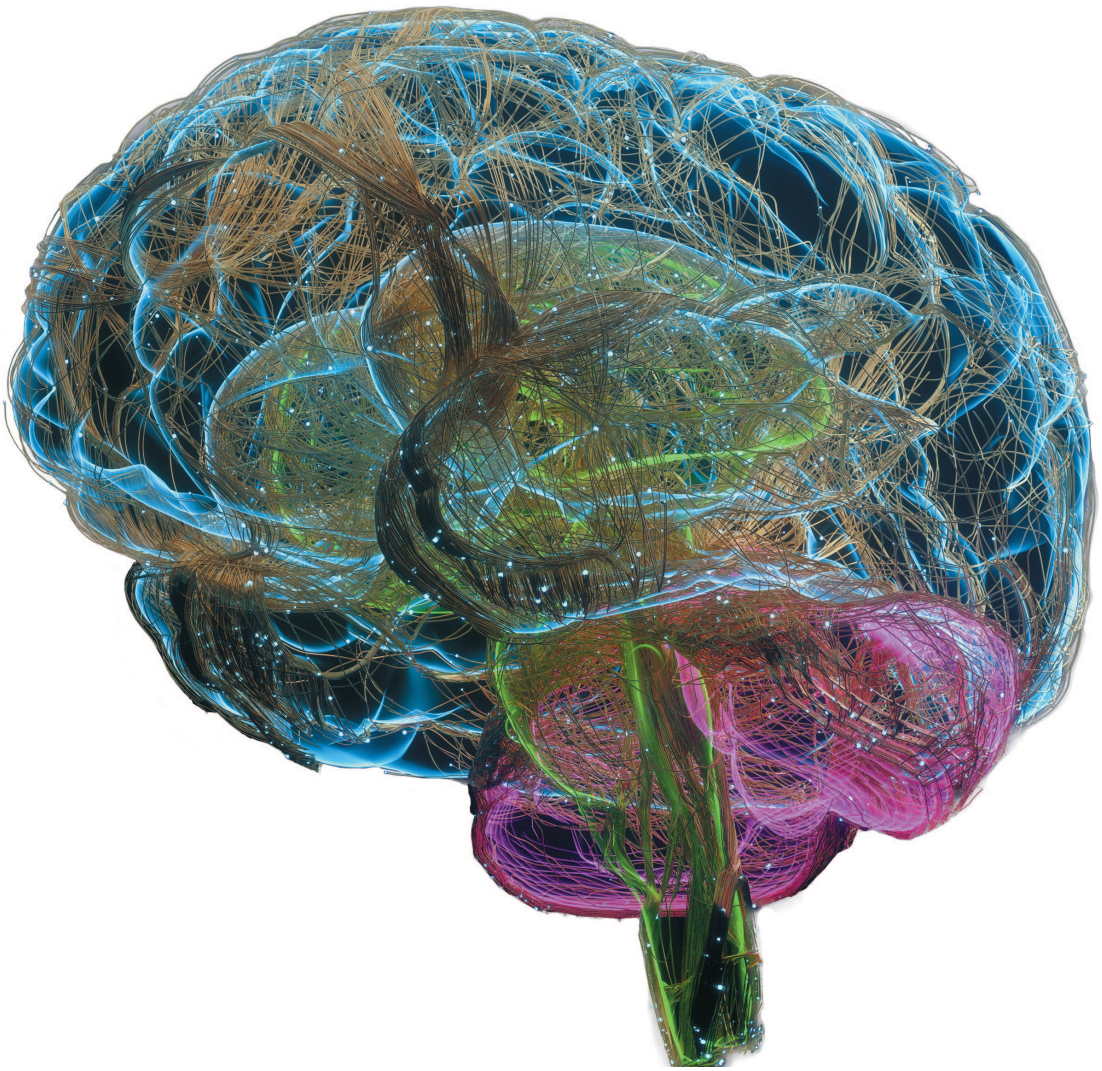
Preface

We are very pleased to bring you the twelfth edition of *Adams and Victor's Principles of Neurology*. The originators of this book, Raymond D. Adams and Maurice Victor, insisted that the basis of the practice of neurology as a medical discipline must always be related back to the patient. This guides the format and approach that we continue to adhere in the current edition. In the past few decades, there has been an explosion in understanding of the fundamental causes of neurological diseases. Just a few examples are the reclassification of brain tumors based on genetic changes and the novel autoantibody disorders that proliferate with each edition of major medical journals. In the present edition, there is hardly a category of disease that has not begun to yield to the tools of molecular biology and genetics

The well-educated neurologist must be familiar with these advances and develop a foundation upon which to absorb ongoing discoveries, particularly as they pertain to modern treatment. But these do not always provide the basis for excellence in clinical practice. There is not so much a gap between science and practice as there is a tenuous equilibrium. Finding the sweet spot between them is a goal of the book. This project begins with a firm grounding in the principles of anatomy, physiology, biochemistry, and genetics that are essential to understanding neurological symptoms and signs that are artfully extracted, processed, and abstracted by the clinician in proximity to the patient. The first parts of the book attach these principles to clinical symptoms and signs. In subsequent parts, diseases are grouped by their clinical manifestations: dementia, ataxia, visual loss, muscular weakness, headache, depression, convulsion, and so on. This is after all, how patients present to physicians, as patients are not in a position to express the fundamental underlying biological cause of their aliments. The final sections tackle the diseases themselves, decidedly from the perspective of how each affects the nervous system rather than as isolated entities. This affords the reader an opportunity to comprehend what can, and as importantly what cannot, happen to the nervous system, a powerful tool that sharpens diagnostic skills and avoids overly broad differential diagnoses.

More than laboratory science, clinical trials have continued to build the background of information that applies to large groups of patients with neurological disease, namely clinical trials that now guide practice. Clinicians are aware, however, that the results of a trial have less certain meaning for an individual patient. Our teacher C.M. Fisher was fond of the quip "There ain't no more than one average Englishman." Knowledge of trial design and statistical methods is helpful in gauging the certainty with which to apply information from trials and we try to point out the strengths and weaknesses of the results from major trials to provide a context for implementing their results. It is the skillful use of this information that this book aims to inform. Will the single patient be helped or harmed? Because medicine deals with the realities and complexities of illness in the individual, the clinician makes a best approximation of the correct course. The wise application of science, evidence from trials, closely coupled to the traditional value of the neurological history and examination—essentially the craft of neurology—are the main purpose of this edition of *Principles of Neurology*.

Furthermore, there is a vast territory that can only be explored in the human representations of disease. Aphasia, confusional states, headache, amnesia, developmental delay, in fact most of human behavior, have no animal models or only crude approximations. Examples of what makes us who we are fall in the purview of neurologists every day by demonstrating what is lost when the nervous system is damaged. Neurologists are inevitably clinical investigators and they depend on astute observation in the clinic and at the bedside. They have something to say on development, education, aging, the boundaries of what is normal and abnormal, and many other appended issues, if they choose to look at these subjects through the lens of daily practice. We also believe that teaching the skills of neurological observation is a trust that must not be broken and hope that a firm grounding in the way diseases affect patients will assist students, residents and early career neurologists in internalizing their experiences of each patient and the subsequent transgenerational transmission of knowledge about diseases of the nervous system.



As has been our tradition, the book is written in a conversational style and we do not eschew stating our personal preferences when they are based on experience. We continue to find that readers value the uniformity of voice and approach of a few individual authors, rather than a discursive list of topics and writers. We thank Dr. Tim Lachman and the many others who read portions of this and previous editions for invaluable assistance in pointing out errors and the readers who have written to us with corrections and suggestions for improving the book.

We hope this edition allows the physician to use the material as a basis for continued professional growth and enjoyment at all stages of professional life that will profit general and specialist clinicians. Welcome again to our world in this twelfth edition of *Adams and Victor's Principles of Neurology* on its 50th anniversary.

PART 1

THE CLINICAL METHOD OF NEUROLOGY

1

Approach to the Patient With Neurologic Disease

INTRODUCTION

Neurology is the practice and study of diseases of the nervous system. It is among the most complex and exacting medical specialties and yet it is perhaps the most rewarding, encompassing as it does all aspects of human behavior, cognition, memory, movement, pain, sensory experience, and the homeostatic functions of the body that are under nervous control. Among the provocative aspects of neurology is the manner in which diseases disrupt the functions of the mind, but the field also encompasses the study of the diseases of nerves, muscles, spinal cord, and cerebral hemispheres.

The neurologist occupies a special role by using extensive synthetic and analytical skill to explain neurologic symptoms and findings. Neurology is distinctive in allowing a type of detailed interpretation of signs and symptoms that, as a result of the fixed structure of the nervous system, provides certainty in diagnosis that is not possible in other fields. This is the method of *localization* that is almost unique to neurology.

Part of the excitement of modern neurology is the incorporation of advances in imaging, and in the neurosciences including neurogenetics, neurochemistry, neuroepidemiology, and neuropathology, which now offer deep insights into the fundamental nature of disease. The close connections among neurology and the fields of internal medicine, psychiatry, neuropathology, developmental medicine and pediatrics, critical care, neurorehabilitation, and neurosurgery extend the purview of clinical neurology. As has occurred in other branches of medicine, increased understanding of disease and therapeutic options has led to the emergence of numerous subspecialties of neurology (Table 1-1).

Neurologic symptoms, of course, do not present themselves as immediately referable to a part of the nervous system, and the neurologist must therefore be knowledgeable in all aspects of nervous system function and disease. The authors believe that a successful application of medical knowledge is attained by adhering to the principles of the clinical method, which has been retained to a greater degree in neurology than in other fields of medicine. Even the experienced neurologist faced with a complex clinical problem uses this basic approach.

THE CLINICAL METHOD

In most cases, the clinical method consists of an orderly series of steps:

1. The symptoms and signs are secured with as much confidence as possible by history and physical examination.
2. The symptoms and physical signs considered relevant to the problem at hand are interpreted in terms of physiology and anatomy—that is, one identifies the disorder of function and the anatomic structures that are implicated.
3. These analyses permit the physician to localize the disease process, that is, to name the parts of the nervous system affected. This is the *anatomic*, or *topographic* diagnosis, which often allows the recognition of a characteristic clustering of symptoms and signs, constituting a syndrome.
4. From the anatomic diagnosis and other specific medical data—particularly the mode of onset and speed of evolution of the illness, the involvement of nonneurologic organ systems, the relevant past and family medical histories, and the imaging and laboratory findings—one deduces the *etiologic diagnosis* and its *pathogenesis*.
5. Finally, the physician should assess the degree of disability and determine whether it is temporary or permanent (*functional diagnosis*); this is important in managing the patient's illness and judging the potential for restoration of function (*prognosis*).

The likely causes of a neurologic disease are judged in the context of a patient's personal and demographic characteristics, including their age, sex, race, ethnicity, and geographic circumstances. Knowledge of the incidence and prevalence of diseases among populations defined by these factors (base rates) is a valuable component of the diagnostic process. These change over time as, for example, during epidemics and may differ even within neighborhoods or regions of one country.

In recent decades, some of these steps have been eclipsed by imaging methods that allow precise localization of a lesion and, furthermore, often characterize the category of disease. Parts of the elaborate examination that were intended to localize lesions are no longer as necessary

Iatrogenic

in every patient. Nonetheless, insufficient appreciation of the history and examination and the resulting overdependence on imaging lead to diagnostic errors and have other detrimental consequences. A clinical approach is usually more efficient and far more economical than reflexively resorting to imaging. Images are also replete with spurious or unrelated findings, which elicit unnecessary further testing and needless worry on the part of the patient.

All of these steps are undertaken in the service of effective treatment, an ever-increasing aspect in neurology. As is emphasized repeatedly in later chapters, there is always a premium in the diagnostic process on the discovery of treatable diseases. Even when specific treatment is not available, accurate diagnosis may in its own right function as a therapy, as uncertainty about the cause of a neurologic illness may be as troubling to the patient than the disease itself.

Of course, the solution to a clinical problem need not always be schematized in this way. The clinical method offers several alternatives in the order and manner by which information is collected and interpreted. In fact, in some cases, adherence to a formal scheme is not necessary at all. In relation to syndromic diagnosis, the clinical picture of Parkinson disease, for example, is usually so characteristic that the nature of the illness is at once apparent. In other cases, it is not necessary to carry the clinical analysis beyond the stage of the anatomic diagnosis, which, in itself, may virtually indicate the cause of a disease. For example, when vertigo, cerebellar ataxia, unilateral Horner syndrome, paralysis of a vocal cord, and analgesia of the face occur with acute onset, the cause is an occlusion of the vertebral artery, because all the involved structures lie in the lateral medulla, within the territory of this artery. Thus, the anatomic diagnosis determines and limits the etiologic possibilities. Some signs themselves are almost specific for a particular disease. Nonetheless, one must be cautious in calling any single sign pathognomonic as exceptions are found regularly.

Ascertaining the cause of a clinical syndrome (etiologic diagnosis) requires knowledge of an entirely different order. Here one must be conversant with the clinical details, including the speed of onset, course, laboratory and imaging characteristics, and natural history of a multiplicity of diseases. When confronted with a constellation of clinical features that do not lend themselves to a simple or sequential analysis, one resorts to considering the broad division of diseases in all branches of medicine, as summarized in Table 1-2.

Irrespective of the intellectual process that one utilizes in solving a particular clinical problem, the fundamental steps in diagnosis always involve the accurate elicitation of symptoms and signs and their correct interpretation in terms of disordered function of the nervous system. Most often when there is uncertainty or disagreement as to diagnosis, it is found later that the symptoms or signs were incorrectly interpreted in the first place. Repeated examinations may be necessary to establish the fundamental clinical findings beyond doubt. Hence the aphorism: In a difficult neurologic case, a second examination is the most helpful diagnostic test.

It is advantageous to focus the clinical analysis on the principal symptom and signs and avoid being distracted by minor signs and uncertain clinical data. Of course, as mentioned, if the main sign has been misinterpreted—if a tremor has been mistaken for ataxia or fatigue for weakness—the clinical method is derailed from the start.

Expert diagnosticians make successively more accurate estimates of the likely diagnosis, utilizing pieces of the history and findings on the examination to either affirm or exclude specific diseases. It is perhaps not surprising that the method of successive estimations works well; evidence from psychology reveals that this is the mechanism that the nervous system uses to process information. As the lessons of cognitive psychology have been applied to medical diagnosis, several heuristics (cognitive shortcuts) have been identified as both necessary to the diagnostic process and as pitfalls for the unwary clinician (see Tversky and Kahneman). Awareness of these heuristics offers the opportunity to incorporate corrective strategies. We openly discuss these heuristics and their pitfalls with our colleagues and

trainees to make them part of clinical reasoning. Investigators such as Redelmeier have identified the following categories of cognitive mistakes that are common in arriving at a diagnosis:

1. The framing effect reflects excessive weighting of specific initial data in the presentation of the problem.
2. Anchoring heuristic, in which an initial impression cannot be subsequently adjusted to incorporate new data.
3. Availability heuristic, in which experience with recent cases has an undue impact on the diagnosis of the case at hand.
4. Representative heuristic refers to the lack of appreciation of the frequency of disease in the population under consideration, a restatement of the Bayes theorem.
5. Blind obedience, in which there is undue deference to authority or to the results of a laboratory test.

With our colleague Vickery, we have reviewed the workings of these heuristics in neurologic diagnosis. Any of these shortcuts produce a tendency to come to early closure in diagnosis. Often this is the result of premature fixation on some item in the history or examination, closing the mind to alternative diagnostic considerations. The first diagnostic formulation should be regarded as only a testable hypothesis, subject to modification when new items of information are secured.

When several of the main features of a disease in its typical form are lacking, an alternative diagnosis should always be entertained. In general, however, one is more likely to encounter rare manifestations of common diseases than the typical manifestations of rare diseases (a paraphrasing of the Bayes theorem). Should the disease be in a stage of transition, time will allow the full picture to emerge and the diagnosis to be clarified.

As pointed out by Chimowitz, students tend to err in failing to recognize a disease they have not seen, and experienced clinicians may fail to appreciate a rare variant of a common disease. There is no doubt that some clinicians are more adept than others at solving difficult clinical problems. Their talent is not intuitive, as sometimes is presumed, but is attributable to having paid close attention to the details of their experience with many diseases and having cataloged them for future reference. The unusual case is recorded in memory and can be resurrected when another one like it is encountered. To achieve expert performance in any area, whether cognitive, musical, or athletic, a prolonged period of personal experience and focused attention to the subject is required.

PREVALENCE AND INCIDENCE OF NEUROLOGIC DISEASE

To offer the physician the broadest perspective on the relative frequency of neurologic diseases, estimates of their approximate impact in the world, taken from the Global Burden of Disease Study, commissioned by the World Health Organization and World Bank, published in *Lancet* in 2010 are summarized in Fig. 1-1. The main analysis was

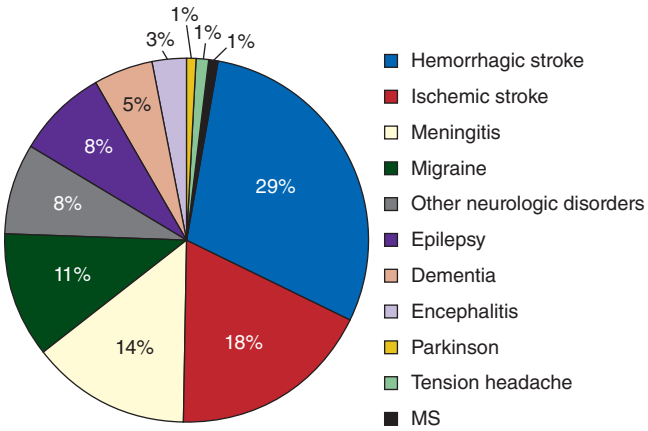

Figure 1-1. Contribution of neurologic conditions to the global burden of neurologic disease. The analysis, from WHO, includes communicable and noncommunicable diseases, but does not include traumatic brain injury or spine disease. (Reproduced with permission from Chin JH, Vora N. The global burden of neurologic diseases. *Neurology*, 2014; 83(4):349-351.)

of disability-adjusted life years (DALYs), which represent the years of life lost from premature death summed with the years of life lived with disability. Neurologic disease accounts for 8.6 percent of the total global DALY (including infections such as meningitis and encephalitis, and noncommunicable diseases such as stroke, epilepsy, dementia, and headache, but excluding traumatic brain injury). In summary, hemorrhagic stroke, ischemic stroke, and meningitis together account for approximately two-thirds of the total global burden caused by neurologic conditions. In relative terms, conditions such as Parkinson disease and multiple sclerosis were smaller contributors to the total global burden. Of course, these statistics differ markedly between developing and developed areas of the world. In addition, many neurologic conditions encountered in daily practice are not accounted for in these surveys and these frequencies of disease throughout the world were ascertained by various methods and must be considered approximations.

Donaghy and colleagues provided a more detailed listing of the incidence of various neurologic diseases that are likely to be seen in the outpatient setting by a physician practicing in the United Kingdom. They noted stroke as far and away the most commonly encountered condition. More focused surveys, such as the one conducted by Hirtz and colleagues, give similar rates of prevalence, with migraine, epilepsy, and multiple sclerosis being the most common neurologic diseases in the general population, with 121, 7.1, and 0.9 per 1,000 persons in a year; stroke, traumatic brain injury, and spinal injury occurring in 183, 101, and 4.5 per 100,000 per year; and Alzheimer disease, Parkinson disease, and amyotrophic lateral sclerosis (ALS) among older individuals at rates of 67, 9.5, and 1.6 per 100,000 yearly. Data such as these assist in allocating societal resources, and they may be helpful in leading the physician to the correct diagnosis insofar as they emphasize the oft-stated dictum that "common conditions occur commonly" and therefore should be considered a priori to be more likely diagnoses (Table 1-3).

Table 1-3

PREVALENCE OF THE MAJOR NEUROLOGIC DISORDERS IN THE UNITED STATES

	INDIVIDUALS AFFECTED
Degenerative diseases

Manic depressive illness	3×10^6

TAKING THE HISTORY

In neurology, the physician is highly dependent on the cooperation of the patient for a reliable history, especially for a description of those symptoms that are unaccompanied by observable signs of disease. If the symptoms are in the sensory sphere, only the patient can tell what he sees, hears, or feels. The first step in the clinical encounter is to enlist the patient's trust and cooperation and make him realize the importance of the history and examination procedure. Of course, no matter how reliable the history appears to be, verification of the patient's account by a knowledgeable and objective informant is always desirable. When the patient's cooperation is not possible, as for example in a comatose or confused individual or in a young child, an attempt should be made to acquire the necessary information from other sources.

The following points about taking the neurologic history deserve further comment:

1. Special care must be taken to avoid suggesting to the patient the symptoms that one seeks. The patient should be discouraged from framing his symptom(s) in terms of a diagnosis that he may have heard; rather, he should be urged to give a simple description—being asked, for example, to choose a word that best describes his pain and to report precisely what he means by a particular term such as dizziness, imbalance, or vertigo. Otherwise there is a disposition on the part of the patient to emphasize aspects of the history that support a superficially plausible diagnosis. This problem is now amplified by the wide array of medical information available to patients through various sources such as the Internet. The patient who is given to highly circumstantial and rambling accounts can be kept on the subject of his illness by directive questions that draw out essential points. One should avoid suggesting terms to the patient, particularly those that prematurely confirm the physician's preconceived diagnoses ("leading the witness").
2. The setting in which the illness occurred, its mode of onset and evolution, and its course are of major importance. One must attempt to learn precisely how each symptom began and progressed. Often the nature of the disease process can be decided from these data alone, such as the typical sudden onset of stroke. If such information cannot be supplied by the patient or his family, it may be necessary to judge the course of the illness by what the patient was able to do at different times (e.g., how far he could walk, when he could no longer negotiate stairs or carry on his usual work) or by changes in the clinical findings between successive examinations.
3. In general, one tends to be careless in estimating the mental capacities of patients. Attempts are sometimes made to take histories from patients who are cognitively impaired or so confused that they have no idea why they are in a doctor's office or a hospital. Young physicians and students have a natural tendency to "normalize" the patient's cognitive performance, often collaborating with a hopeful family in the misperception that no real problem exists. This attempt at sympathy does not serve the patient and may delay the diagnosis of a potentially treatable disease. A common error is to pass lightly over inconsistencies in history and inaccuracies about dates and symptoms, only to discover later that these flaws in memory were the essential features of the illness.
4. Asking the patient to give his own interpretation of the possible meaning of symptoms sometimes exposes concern, depression, anxiety, suspiciousness, or even delusional thinking. This also may allow the patient to articulate fears about certain diseases such as brain tumor, dementia, motor neuron disease, or multiple sclerosis. Exposing these fears allows the physician to allay these concerns forthrightly.

THE NEUROLOGIC EXAMINATION

The neurologic examination begins with observations in the waiting room, and continues as the patient proceeds to the examination room and while the history is being obtained. The manner in which the patient tells the story of his illness may betray confusion or incoherence in thinking, impairment of memory or judgment, or difficulty in comprehending or expressing ideas. A more extensive examination of attention, memory, cognitive ability, and language is undertaken if the history or the manner in which it is given indicates the problem lies in those spheres. Otherwise, asking the date and place, repeating and recalling words, and simple arithmetic are adequate screening procedures.

One then proceeds from an examination of the cranial nerves to the testing of motor, reflex, and sensory functions of the upper and lower limbs. This is followed by an assessment of gait and station (standing position) observed before or after the rest of the examination.

The thoroughness and focus of the neurologic examination must be governed by the type of clinical problem presented by the patient. To spend a half hour or more testing cerebral, cerebellar, cranial nerve, and sensorimotor function in a patient seeking treatment for a simple compression palsy of an ulnar nerve is pointless and uneconomical. Conversely, if the main problem relates to hand function, a detailed examination of the motor, sensory, and higher-order functions of the hand is undertaken. The examination must also be modified according to the condition of the patient. Obviously, many parts of the examination cannot be carried out in a comatose patient; also, infants and small children, as well as patients with psychiatric disease, must be examined in special ways. Similarly, the examination in acute situations that require urgent resolution must be necessarily compressed to an essential minimum that allows intelligent initial steps.

When an abnormal finding is detected, whether cognitive, motor, or sensory, it becomes necessary to analyze the problem in a more elaborate fashion. Details of these sensitive examinations are addressed in appropriate chapters of the book and, cursorily, below.

The neurologic examination is ideally performed and recorded in a relatively uniform manner to avoid omissions and facilitate the subsequent analysis of records. Some variation in the order of examination from physician to physician is understandable, but each examiner over time establishes a consistent pattern. If certain portions are intentionally not performed, these omissions should be stated so that those reading the description at a later time are not left wondering whether an abnormality was not previously detected.

Portions of the general physical examination that may be particularly informative in the patient with neurologic disease should be included. For example, examination of the heart rate and blood pressure, as well as carotid and cardiac auscultation, may be essential in a patient with stroke. Likewise, the skin and eyes can reveal a number of conditions that pertain to congenital, metabolic, and infectious causes of neurologic disease. Aspects of general appearance, such as obesity or cachexia, may offer guidance to the likelihood of certain systemic illnesses.

The Detailed Examination of Patients With Neurologic Symptoms

An inordinately large number of tests of neurologic function have been devised, and it is not proposed to review all of them here. Many tests are of doubtful value or are repetitions of simpler ones and to perform all of them on one patient would be unproductive. The danger with all clinical tests is to regard them as indicators of a particular disease rather than as ways of uncovering disordered functioning of the nervous system. The following approaches are relatively simple and provide the most useful information.

Numerous guides to the examination of the nervous system are available (see the references at the end of this chapter). For a full account of these methods, the reader is referred to monographs on the subject, including those of Biller and colleagues (DeMyer's), Spillane (Bickerstaff's) Campbell (DeJong's *The Neurological Examination*), and of the staff members of the Mayo Clinic, each of which approaches the subject from a different point of view.

Testing of Higher Cortical Functions

Broadly speaking, the mental status examination has two main components, although the separation is somewhat artificial: the psychiatric aspects, which incorporate affect, mood, and normality of thought processes and content; and the cognitive aspects, which include the level of consciousness, awareness (attention), language, memory, visuospatial, and other executive abilities. These functions are tested in detail if the patient's history or behavior has provided a reason to suspect some defect.

Questions are first directed toward determining the patient's orientation in time and place and insight into his current medical problem. Attention, speed of response, ability to give relevant answers to simple questions, and the capacity for sustained and coherent mental effort all lend themselves to straightforward observation. The patient's account of his recent illness, dates of hospitalization, and day-to-day recollection of recent incidents are excellent tests of memory; the narration of the illness and the patient's choice of words (vocabulary) and syntax provide information about language ability and coherence of thinking. There are many useful bedside tests of attention, concentration, memory, and cognition, for example, repetition of a series of digits in forward and reverse order, serial subtraction of 3s or 7s from 100, and recall of three items of information or a short story after an interval of 3 min. More detailed examination procedures appear in Chaps. 19 to 21.

If there is any suggestion of a speech or language disorder, the nature of the patient's spontaneous speech should be noted. In addition, the accuracy of reading, writing, and spelling, executing spoken commands, repeating words and phrases spoken by the examiner, naming objects, and parts of objects should be assessed.

The ability to carry out commanded tasks (praxis) is pertinent to the evaluation of several aspects of cortical function. For example, commonly used tests are carrying out commanded and imitated gestures such as hammering a nail, blowing out a candle, throwing dice, and copying sequential hand positions. Visuospatial abilities may be tested by asking the patient to bisect a line, draw the numbers and hands of a clock face or the floor plan of one's home or a map of one's country, and copying figures. Recognition (gnosis) is tested by naming objects or pictures and describing their use.

Testing of Cranial Nerves

The function of the cranial nerves is tested as a component of most examinations, in part because defects in their function are so easily recognizable and because certain

abnormalities allow precise localization of a lesion. If one suspects a lesion in the anterior cranial fossa, the sense of smell should be tested and it should be determined whether odors can be discriminated. Visual fields can be outlined by having the patient indicate when the examiner's finger moves or by counting fingers at the periphery of vision (confrontation testing), ideally by testing each eye separately. If an abnormality is suspected, perimetry provides a more sensitive method of confirming and mapping the defect. Pupil size and reactivity to light, direct, consensual, and during convergence, the position of the eyelids, and the range of ocular movements should next be observed. Details of these tests and their interpretations are given in Chaps. 11 to 13.

Sensation over the face is tested with a pin and wisp of cotton. Also, the presence or absence of the corneal reflexes, direct and consensually, may be determined. Care must be taken to avoid eliciting blinking by a visual stimulus.

Facial movements should be observed in repose and as the patient speaks and smiles, for a slight weakness may be more evident in these circumstances than on movements to command. Direct testing of facial power can be accomplished by asking the patient to forcefully close the eyes, purse the lips, and raise the brow.

The auditory meatus and tympanic membranes should be inspected with an otoscope if there is a problem with hearing. A high-frequency (512 Hz) tuning fork held next to the ear and compared to applying it to the mastoid discloses hearing loss and distinguishes middle-ear (conductive) from neural deafness. An additional test of impaired bone or air conduction is performed by placing a high-frequency tuning fork in the center of the forehead and having the patient report any asymmetry in the sound. Audiograms and other special tests of auditory and vestibular function are needed if there is any suspicion of disease of the vestibulocochlear nerve or of the cochlea or labyrinths (see Chap. 14).

The vocal cords may be inspected with special instruments in cases of suspected medullary or vagus nerve disease, especially when there is hoarseness. Voluntary pharyngeal elevation and elicited reflexes are meaningful if there is an asymmetrical response; bilateral absence of the gag reflex is seldom significant. Inspection of the tongue, both protruded and at rest, is helpful; atrophy and fasciculations may be seen and weakness detected. A slight deviation of the protruded tongue as a solitary finding can usually be disregarded, but a major deviation represents under action of the hypoglossal nerve and muscle on that side. The pronunciation of words should be noted. The jaw jerk (masseter tendon reflex) should be evaluated to localize the source of dysphagia, dysarthria, or dysphonia. In adults, abnormal reactions to tactile contact (reflexes) of the mouth and lips (such as sucking, snouting, rooting) reflect the reemergence of developmental reflexes and usually indicate the disease of frontal lobes. Failure to inhibit blinking in response to repetitive tapping of the brow (glabella) may indicate extrapyramidal or frontal disorders.

The abnormal quality of speech and articulation, dysarthria, may give indications of weakness or other disorders of the lips, tongue, larynx, and pharynx. Certain patterns also conform to disorders of the cerebellum and parts of the brain stem and cerebrum. The abnormal speech patterns of spastic, ataxic, extrapyramidal, and neuromuscular disorders are elaborated mainly in Chap. 22.

Testing of Motor Function

In the assessment of motor function, the most informative aspects are observations of the speed, power, muscle bulk, tone, and coordination. The maintenance of the supinated arms against gravity is a useful test; the weak arm, tiring first, soon begins to sag, or, in the case of a corticospinal lesion, to resume the more natural pronated position ("pronator drift"). An additional sign of subtle weakness of one side is the asymmetric "orbiting" of one forearm around the other when the patient is asked to rotate the fists or index fingers around the other. The strength of the legs can be tested with the patient prone and the knees flexed and observing downward drift of the weakened leg. In the supine position at rest, weakness due to an upper motor neuron lesion causes external rotation of the hip. In testing the power of the legs, it should be kept in mind that the hip flexors and quadriceps of most adults are stronger than the arm of the examiner.

It is useful to have the limbs exposed and to inspect them for atrophy and fasciculations. Abnormalities of movement and posture as well as tremors may be revealed by observing the limbs at rest and in motion (see Chaps. 4 and 5). This is accomplished by watching the patient maintain the arms and move them from the prone to the supine positions; perform simple tasks, such as alternately touching his nose and the examiner's finger; make rapid alternating movements that necessitate sudden acceleration and deceleration and changes in direction, such as tapping one hand on the other while alternating pronation and supination of the forearm; rapidly touch the thumb to each fingertip; and accomplish simple tasks such as buttoning clothes, opening a safety pin, or handling common tools. Estimates of the strength of leg muscles with the patient in bed may be unreliable; there may seem to be little or no weakness even though the patient cannot arise from a chair or from a kneeling position without help. Running the heel down the front of the shin, alternately touching the examiner's finger with the toe and the opposite knee with the heel, and rhythmically tapping the heel on the shin are the only tests of coordination that need to be carried out in bed.

The limbs are observed to determine if during natural activities, there is excessive or reduced quantity, speed or excursion of movement, tremor, and normal postural adjustments. The resistance of muscles during passive movement by the examiner (tone) gives information about spasticity and extrapyramidal rigidity.

Testing of Reflexes

Testing of the tendon reflexes at the biceps, triceps, supinator-brachioradialis, patellar, and Achilles tendon are an adequate sampling of reflex activity. Underactive or barely elicitable reflexes can be facilitated by voluntary

contraction of other muscles, such as pulling the grasped hands against each other (Jendrassik maneuver).

The plantar reflexes, particularly the elicitation of the Babinski sign by stroking the lateral sole of the foot from heel to toe, are an essential part of most examinations. The sign is a dependable marker of damage to the corticospinal system as described in Chap. 3. The main features of the Babinski sign are dorsiflexion of the large toe and fanning of the other toes. Interpretation of the plantar response poses some difficulty because reactions besides the Babinski sign can be evoked. These include a quick withdrawal response of the foot and leg that does not signify disease; and a pathologic slower, spinal flexor reflex (flexion of knee and hip and dorsiflexion of toes and foot, "triple flexion") that has similar significance to the Babinski sign. Avoidance and withdrawal responses interfere with the interpretation of the Babinski sign and can sometimes be overcome by utilizing alternative stimuli (e.g., squeezing the calf or Achilles tendon, flicking the fourth toe, downward scraping of the shin, lifting the straight leg, and others) or by having the patient scrape his own sole.

Absence of the superficial cutaneous reflexes of the abdominal, cremasteric, and other muscles are useful ancillary tests for detecting corticospinal lesions, particularly when unilateral.

Testing of Sensory Function

Because this part of the examination is attainable only through the subjective responses of the patient, it requires considerable cooperation. At the same time, it is subject to overinterpretation and suggestibility. Usually, sensory testing is reserved for the end of the examination and, if the findings are to be reliable, should not be prolonged. Each test should be explained briefly; too much discussion with a meticulous, introspective patient encourages the reporting of meaningless minor variations of stimulus intensity.

It is not necessary to examine all areas of the skin surface. A quick survey of the face, neck, arms, trunk, and legs with a pin takes only a few seconds. Usually one is seeking differences between the two sides of the body (it is better to ask whether stimuli on opposite sides of the body feel the same than to ask if they feel different), a level below which sensation is lost, or a zone of relative or absolute analgesia (loss of pain sensibility) or anesthesia (loss of touch sensibility). Regions of sensory deficit can then be tested more carefully and mapped. Moving the stimulus from an area of diminished sensation into a normal area is recommended because it enhances the perception of a difference. The finding of a zone of heightened sensation ("hyperesthesia") also calls attention to a disturbance of superficial sensation.

The ability to perceive vibration may be tested by comparing the thresholds at which the patient and examiner lose perception at comparable bony prominences. We suggest recording the number of seconds for which the examiner appreciates vibration at the malleolus, toe, or finger after the patient reports that the fork has stopped buzzing. Joint position and the perception of movement of a digit can be tested by holding the body part at the sides and making small excursion at the adjacent joint.

Variations in sensory findings from one examination to another reflect differences in the technique of examination as well as inconsistencies in the responses of the patient. Sensory testing is considered in greater detail in Chaps. 7 and 8.

Testing of Gait and Stance

The examination is completed by observing the patient arise from a chair, stand and walk. An abnormality of stance or gait may be the most prominent or only neurologic abnormality, as in certain cerebellar or frontal lobe syndromes; and an impairment of posture and highly automatic adaptive movements in walking may provide diagnostic clues in the early stages of diseases such as Parkinson disease. Having the patient walk in tandem on a straight line may bring out a lack of balance and walking on the sides of the soles may elicit dystonic postures in the hands and trunk. Hopping or standing on one foot may also betray a lack of balance or weakness. Standing with feet together and eyes closed will bring out disequilibrium due to sensory loss (Romberg test) that is usually attributable to a disorder of the large diameter sensory fibers in the nerves and posterior columns of the spinal cord. Disorders of gait are discussed in Chap. 6.

The Screening Neurological Examination

In the situation of a patient without neurologic symptoms, brevity is desirable but any test that is undertaken should be done carefully and recorded. Accurate recording of negative data may be useful in relation to some future illness that requires examination. As indicated in Table 1-4, the patient's orientation, insight, judgment, and the integrity of language function are readily assessed in the course of taking the history. With respect to the cranial nerves, the size of the pupils and their reaction to light, ocular movements, visual and auditory acuity, and movements of the face, palate, and tongue should be tested. Observing the bare outstretched arms for atrophy, weakness (pronator drift), tremor, or abnormal movements; checking the strength

Table 1-4

BRIEF NEUROLOGIC EXAMINATION IN THE GENERAL MEDICAL OR SURGICAL PATIENT

1. Orientation, insight into illness, and language assessed during taking of the history
2. Size of pupils, reaction to light, and visual and auditory acuity
3. Movement of eyes, face, tongue
4. Examination of the outstretched hands for atrophy, pronating or downward drift, tremor, power of grip, and wrist dorsiflexion
5. Biceps, supinator, and triceps tendon reflexes
6. Inspection of the legs during active flexion and extension of the hips, knees, and feet
7. Patellar, Achilles, and plantar responses
8. Vibration sensibility in the fingers and toes
9. Finger-to-nose and heel-to-shin testing of coordination
10. Gait

of the extended and outstretched fingers; inquiring about sensory disturbances; and eliciting the biceps, brachioradialis, and triceps reflexes are usually sufficient for the upper limbs. Inspection and resistance of the muscles of the legs while the feet, toes, knees, and hips are actively flexed and extended; elicitation of the patellar, Achilles, and plantar responses testing of vibration and position sense in the fingers and toes; and assessment of coordination by having the patient alternately touch his nose and the examiner's finger and run his heel up and down the front of the opposite leg, and observation of walking complete the essential parts of the neurologic examination.

This entire procedure adds only a few minutes to the physical examination but the routine performance of these simple tests provides clues to the presence of a disease of which the patient is not aware. For example, the finding of absent Achilles reflexes and diminished vibratory sense in the feet and legs alerts the physician to the possibility of diabetic or nutritional neuropathy, even when the patient does not report symptoms.

THE COMATOSE PATIENT

Although subject to obvious limitations, careful examination of the stuporous or comatose patient yields considerable information concerning the function of the nervous system. It is remarkable that, with the exception of cognitive function, almost all parts of the nervous system, including the cranial nerves, can be evaluated in the comatose patient. The demonstration of signs of focal cerebral or brain stem disease or of meningeal irritation is useful in the differential diagnosis of diseases that cause stupor and coma. The adaptation of the neurologic examination to the comatose patient is described in Chap. 16.

THE ANXIOUS, DEPRESSED, PSYCHOTIC, OR HYSTERICAL PATIENT

One is compelled in the examination of psychiatric patients to be unusually critical of their statements and reports or symptoms. Many people, even those without psychiatric conditions, are highly suggestible and may display changes in sensory and motor function. The depressed patient, for example, may perceive impaired memory or weakness when actually there is neither amnesia nor reduced power, or the sociopath or hysteric may feign paralysis. The opposite is as often true: Psychotic patients may make accurate observations of their symptoms, only to have them ignored because of their mental state. It is well to keep in mind that patients with even the most extreme psychiatric disease are subject to all of the neurologic conditions typical of others of their age.

By the manner in which the patient expresses ideas and responds to spoken or written requests, it is possible to determine whether there are hallucinations or delusions, defective memory, or other recognizable symptoms of brain disease merely by watching and listening to the patient. On occasion, mute and resistive patients judged to be psychotic prove to have some widespread cerebral disease.

INFANTS AND SMALL CHILDREN

The reader is referred to the special methods of examination described by Volpe and the staff members of the Mayo Clinic, which are listed in the references and described in Chap. 27. Many of these tests address the developmental aspects of the child's nervous system, and although some signs may be difficult to obtain because of the age of the patient, they still stand as the best reflections of the child's neurologic state.

THE GENERAL MEDICAL EXAMINATION

The general medical examination often reveals evidence of an underlying systemic disease that has secondarily affected the nervous system. In fact, many of the most serious neurologic problems are of this type. Two common examples will suffice: adenopathy or a lung infiltrate implicates neoplasia or sarcoidosis as the cause of multiple cranial nerve palsies, and the presence of low-grade fever, anemia, a heart murmur, and splenomegaly in a patient with unexplained stroke points to a diagnosis of bacterial endocarditis with embolic occlusion of cerebral arteries. The examination of a patient with stroke includes a determination of blood pressure, auscultation for carotid bruits, heart murmurs, and palpation of the pulse for heart rhythm.

INTEGRATION OF NEUROANATOMY, NEUROPHYSIOLOGY, MOLECULAR GENETICS, NEUROIMAGING, AND NEUROPATHOLOGY WITH THE CLINICAL METHOD

Once the technique of obtaining reliable clinical data is attained, knowledge of the basic sciences of neurology is necessary to determine the cause of disease and its treatment. For this reason, each of the later chapters dealing with the motor system, sensation, special senses, consciousness, memory, and language is introduced by a review of the anatomic and physiologic facts that are necessary for understanding the associated clinical disorders.

Physicians wishing to master neurology should be familiar with the anatomy of the corticospinal tract; motor unit (anterior horn cell, nerve, and muscle); basal ganglionic and cerebellar motor connections; main sensory pathways; cranial nerves; hypothalamus and pituitary; reticular formation of brain stem and thalamus; limbic system; areas of cerebral cortex and their major connections; visual, auditory, and autonomic systems; and cerebrospinal fluid pathways. A working knowledge of neurophysiology should include an understanding of neural excitability

and nerve impulse propagation, neuromuscular transmission, and contractile process of muscle; spinal reflex activity; central neurotransmission; processes of neuronal excitation, inhibition, and release; and cortical activation and seizure production. The genetics and molecular biology of neurologic disease have assumed increasing importance in the past few decades. The practitioner should be familiar with the terminology of mendelian and mitochondrial genetics and the main aberrations in the genetic code that give rise to neurologic disease.

The physician must be familiar with the imaging characteristics of the multitude of clinical diseases encountered in practice, and the risk and pitfalls of each technique, including computed tomography (CT), magnetic resonance imaging (MRI), radiographs, including those incorporating contrast agents, and ultrasound as discussed in Chap. 2.

We believe the neurologist is greatly aided by knowledge of the neuropathologic changes that are produced by processes such as infarction, hemorrhage, demyelination, physical trauma, inflammation, neoplasm, and infection, to name the more common ones. Experience with the gross and microscopic appearances of these disease processes greatly enhances one's ability to explain their clinical effects. The ability to mentally visualize the abnormalities of disease in nerve and muscle, brain and spinal cord, meninges, and blood vessels gives one a strong sense of which clinical features to expect of a particular process and which features are untenable or inconsistent with a particular diagnosis. An additional advantage of being exposed to neuropathology is, of course, that the clinician is able to intelligently evaluate pathologic changes and reports of material obtained by biopsy. For many conditions, there is a parallel representation of neuropathology through various imaging techniques. This allows the clinician to deduce the pathology from the imaging appearance and vice versa.

From the foregoing description of the clinical method, it is evident that the use of laboratory aids, including imaging in the diagnosis of diseases of the nervous system, is ideally preceded by rigorous clinical examination. As in all of medicine, laboratory study can be planned intelligently only based on clinical information. To reverse this process is wasteful of medical resources and prone to the discovery of irrelevant information, and in some cases exposes a patient to unnecessary risk.

In the prevention of neurologic disease, however, one resorts to two other approaches, namely, the use of genetic information and laboratory screening tests. Biochemical screening tests are applicable to an entire population and permit the identification of neurologic diseases in individuals, mainly infants and children, who have yet to show their first symptom; in some diseases, treatment can be instituted before the nervous system has suffered damage. Similarly in adults, screening for atherosclerosis and its underlying metabolic causes is profitable in certain populations as a way of preventing stroke. Genetic information enables the neurologist to arrive at the diagnosis of certain illnesses and to identify patients and relatives at risk of developing certain diseases.

The laboratory methods that are available for neurologic diagnosis are discussed in Chap. 2. The relevant principles of genetic and laboratory screening methods for the prediction of disease are presented in the discussion of the disease to which they are applicable.

THERAPEUTICS IN NEUROLOGY

There are a growing number of neurologic diseases for which specific therapy is available. Through advances in neuroscience, their number is steadily increasing. Among the most sweeping changes, now that many infectious diseases of the nervous system are being addressed, have been novel medications for stroke, multiple sclerosis, Parkinson disease, migraine, neuropathy, brain tumor, and epilepsy as summarized in a review of 200 years of neurology by Ropper. These therapies and the dosages, timing, and manner of administration of particular drugs are considered in later chapters in relation to the description of individual diseases and detailed in Samuels's *Manual of Neurologic Therapeutics*, cited in the references. The neurologist should also be familiar with the proper application of surgical treatment when it is an integral part of the amelioration or cure of disease, as it is for brain tumor, degenerative and neoplastic diseases of the spine, cerebral aneurysm, extracranial arterial stenosis, and some congenital disease of the brain and spinal cord. There are, in addition, many diseases in which neurologic function can be restored to a varying degree by appropriate rehabilitation measures or by the judicious use of therapeutic agents.

Randomized controlled trials play an ever-increasing role in therapeutic decisions. Claims for the effectiveness of a particular therapy based on statistical analysis of large-scale clinical studies must be treated circumspectly. Was the study well conceived as reflected in a clearly stated hypothesis and outcome criteria; was there adherence to the plan for randomization and admission of cases into the study; were the statistical methods appropriate; and were the controls truly comparable? It has been our experience that the results of early stage trials must be accepted with caution and it is prudent to wait until further studies confirm the benefits that have been claimed.

There are, of course, many instances in which evidence is not available or is not applicable to difficult individual therapeutic decisions. This is in part true because small albeit statistically significant effects in large groups may be of little consequence when applied to an individual patient. It goes without saying that data derived from trials must be used in the context of a patient's overall physical and mental condition and age. Furthermore, for many neurologic conditions there is, at the moment, inadequate evidence on which to base treatment. Here, the physician makes judgments based on partial or insufficient data. Even deciding purposefully to wait before committing to an intervention displays wisdom.

Even when no effective treatment is possible, neurologic diagnosis is more than an intellectual pastime. The first step in the scientific study of any disease process is the identification or all its manifestations in the living patient.

In closing this introductory chapter, a comment regarding the extraordinary burden of diseases of the

nervous system is appropriate. Conditions such as brain and spinal cord trauma, stroke, epilepsy, developmental delay, psychiatric diseases, and dementia are not just ubiquitous, but are highly disabling and often chronic in nature, altering in a fundamental way the lives of affected individuals. Furthermore, the promise of cure or amelioration by new techniques such as molecular biology, genetic therapy, and brain–computer interfaces has excited vast interest, for which reason aspects of the current scientific insights are included in appropriate sections of the book.

Diagnostic Testing in Neurologic Disease

Neurologic diagnosis is frequently determined solely on the basis of careful history and examination. In that case, ancillary testing is unnecessary or simply corroborates the clinical impression. It also happens that the diagnoses can be reduced to a few possibilities, but that testing is necessary to arrive at the correct one. The aim of the neurologist is to arrive at a diagnosis by artful integration of clinical data with laboratory procedures. Commonly, the clinician already has at his disposal some laboratory information when the patient presents for a consultation. This may orient or distract from the correct course of action.

Only a few decades ago, the only laboratory tests available to the neurologist were examination of a sample of cerebrospinal fluid (CSF), radiography of the skull and spinal column, contrast myelography, pneumoencephalography, and electrophysiologic tests. The physician's armamentarium has since been expanded to include a multitude of neuroimaging modalities, biochemical and immunologic assays, and genetic analyses. Some of these new methods give the impression of such accuracy that there is a temptation to substitute them for a detailed history and physical examination. Moreover, it is common in practice for laboratory testing to reveal abnormalities that are of no significance to the problem at hand or for imaging studies to show incidental lesions that have no bearing on the patient's presenting symptoms. Consequently, the physician should always judge the relevance and significance of laboratory data only in the context of clinical findings. Hence, the neurologist must be familiar with all laboratory procedures relevant to neurologic disease, their reliability, and their hazards.

What follows is a description of laboratory tests that have application to a diversity of neurologic diseases. Certain procedures that are pertinent to a particular category of disease—for example, audiography to study deafness; electronystagmography (ENG) in cases of vertigo; as well as nerve and muscle biopsy, where there is neuromuscular disease—are presented in the chapters devoted to these disorders.

EXAMINATION OF CEREBROSPINAL FLUID

The information yielded by examination of the CSF is crucial in the diagnosis of certain neurologic diseases, particularly infectious and inflammatory conditions, subarachnoid hemorrhage, and processes that alter intracranial pressure. Patterns of findings, or "formulas," in the CSF generally denote particular classes of disease; these are summarized in Table 2-1. The fluid is most often obtained by lumbar puncture (LP), the technique and indications for which are described below.

Lumbar Puncture

The LP is performed to obtain pressure measurements and procure a sample of the CSF for cellular, cytologic, chemical, bacteriologic, and other examinations. It is also utilized in special circumstances for the instillation of anesthetics, antibiotics, antitumor agents, or for drainage in order to reduce CSF pressure. Another diagnostic use is the injection of radiopaque substances and in myelography, or radioactive agents and in radionuclide cisternography.

It is advisable to determine that the patient's coagulation function is adequate. In general, it is safe to perform LP on patients without history or overt signs of coagulopathy and those who are not taking anticoagulant medications. An international normalized ratio (INR) less than or equal to 1.4 and platelet count greater than 50,000/mm^3 are generally acceptable, as is the use of aspirin in conventional doses. Individuals with impaired platelet function from diseases such as alcoholism or uremia may have bleeding complications. For patients receiving non-vitamin K antagonists, it is appropriate, when possible to wait for the anticoagulant effect to wear off but it is more practical to use a reversal agent if time is essential. For patients receiving heparin by continuous infusion, the LP is best performed after the infusion has been discontinued for a period of time, and if possible, the partial thromboplastin time is in a safe range. There are circumstances, however, where these provisions are not practical.

LP carries some risks if the CSF pressure is very high (evidenced mainly by headache and papilledema), as it increases the possibility of cerebellar or transtentorial herniation. The risk is considerable when there is an intracranial mass that distorts and displaces brain tissue, particularly asymmetric mass lesions near the tentorium or foramen magnum. The risk is much lower in patients with subarachnoid hemorrhage, in hydrocephalus with communication among all the ventricles, or with pseudotumor cerebri. Indeed, these are conditions in which repeated LPs may be therapeutic measures. In patients with purulent

Table 2-1

CHARACTERISTIC CSF FORMULAS

CONDITION	CELLS	PROTEIN	GLUCOSE	OTHER FEATURES
Bacterial infection	WBC > 50/mm^3, often greatly increased	100–250 mg/dL	20–50 mg/dl; usually lower than half of blood glucose level	Gram stain shows organisms; pressure increased
Viral, fungal, spirochetal infection	WBC 10–100/mm^3	50–200 mg/dL	Normal or slightly reduced	Special culture techniques required; pressure normal or slightly increased
Tuberculous infection	WBC > 25/mm^3	100–1,000 mg/dL	<50, often markedly reduced	Special culture techniques and PCR may be needed to detect organisms
Subarachnoid hemorrhage	RBC > 500/mm^3; slight increase in WBC	60–150 mg/dL	Normal; slightly reduced later	Must be distinguished from traumatic lumbar puncture by presence of xanthrochromia of spun sample; greatly increased pressure
Cerebral hemorrhage, trauma	RBC 50–200/mm^3; higher if ventricular rupture of blood	50–150 mg/dL	Normal	Pressure may be elevated
Ischemic stroke	Normal or few WBC	Normal	Normal	Normal pressure unless brain swelling
Multiple sclerosis	Normal or few WBC	Normal or slightly increased	Normal	Increased IgG fraction and oligoclonal bands
Meningeal neoplasm	WBC 10–100/mm^3	Usually elevated	Normal or depressed	Neoplastic cells in CSF; elevation of certain protein markers (e.g., β_2-microglobulin)

IgG, immunoglobulin G; PCR, polymerase chain reaction; RBC, red blood cells; WBC, white blood cells.

meningitis, there is also a small risk of herniation, but this is outweighed by the need for a definitive diagnosis and the institution of appropriate treatment at the earliest moment. With this last exception, LP should generally be preceded by computed tomography (CT) or magnetic resonance imaging (MRI) whenever an elevation of intracranial pressure is suspected.

If imaging procedures disclose a mass lesion that poses a risk of herniation, yet it is considered essential to have the information yielded by CSF examination, the LP may be performed—with certain precautions. If the pressure proves to be very high, one should obtain the smallest necessary sample of fluid, adequate for the diagnosis of the suspected disease, administer mannitol or another hyperosmolar agent, and ideally observe a fall in pressure on the manometer. Dexamethasone or an equivalent corticosteroid may also be given in order to produce a more sustained reduction in intracranial pressure. Corticosteroids are particularly useful in situations in which the increased intracranial pressure is caused by vasogenic cerebral edema (e.g., tumor-associated edema).

Cisternal (foramen magnum) puncture and lateral cervical subarachnoid puncture are infrequently performed but are safe in the hands of an expert. LP is preferred except in obvious instances of spinal block requiring a sample of cisternal fluid or for myelography above the lesion. In critical care practice, CSF may be obtained from external ventricular drains, and care is taken to maintain a closed drainage system and antiseptic technique.

Technique and Complications of LP

Experience teaches the importance of meticulous technique and proper positioning of the patient. LP should be done under locally sterile conditions. The patient is placed in the lateral decubitus position, preferably on the left side for right-handed physicians, with hips and knees flexed, and the head as close to the knees as comfort permits. The patient's hips should be vertical, the back aligned near the edge of the bed. The puncture is usually easiest to perform at the L3-L4 interspace, which corresponds in many individuals to the axial plane of the iliac crests, or at the interspace above or below. In infants and young children, in whom the spinal cord may extend to the level of the L3-L4 interspace, lower levels should be used.

Xylocaine is typically injected in and beneath the skin to reduce local discomfort. Warming of the analgesic by rolling the vial between the palms seems to diminish the burning sensation that accompanies cutaneous infiltration. The bevel of the LP needle should be oriented in the longitudinal plane of the dural fibers (see below regarding atraumatic needles). It is sometimes possible to appreciate a palpable "give" as the needle approaches the dura, followed by a subtle "pop." At this point, the trocar should be removed slowly from the needle to avoid sucking a nerve rootlet into the lumen and causing radicular pain. Sciatic pain during the insertion of the needle indicates that it is placed too far laterally. If the flow of CSF slows, the head of the bed can be elevated slowly. Rarely one resorts to gentle aspiration with a small-bore syringe to overcome the resistance of proteinaceous and viscous CSF. Failure to enter the lumbar subarachnoid space after two or three trials usually can be overcome by performing the puncture with the patient in the sitting position and then helping him to lie on one side for pressure measurements and fluid removal. The "dry tap" is more often the result of an improperly placed needle than of obliteration of the subarachnoid space by a compressive lesion of the cauda equina or by adhesive arachnoiditis. In an obese patient, in whom palpable spinal landmarks cannot be

appreciated, or after several unsuccessful attempts in any patient, fluoroscopy can be employed to position the needle.

LP has few serious complications. The most common is headache, estimated to occur in one-third of patients but in severe form in far fewer. A history of migraine headaches may increase the incidence of prolonged or severe post-LP headache. The headache becomes apparent when the patient assumes the upright posture and is presumably the result of a reduction of CSF pressure from leakage of fluid at the puncture site and tugging on cerebral and dural vessels. Prolonged recumbency immediately after the procedure has not been shown to prevent headache, but is often implemented nonetheless. In contrast, the use of an atraumatic needle almost halved the incidence of headache (Strupp and colleagues). Curiously, headaches are twice as frequent after diagnostic LP as they are after spinal anesthesia. Severe headache can be associated with vomiting and mild neck stiffness. Unilateral or bilateral sixth nerve palsy occurs rarely after LP, even at times without headache, and rare cases of hearing loss, facial numbness, or facial palsy have been reported. The syndrome of low CSF pressure, its treatment by injection of a "blood patch" into the epidural space, and other complications of LP are considered further in Chap. 29.

Bleeding into the spinal meningeal or epidural spaces after LP can occur in patients with abnormal coagulation, as discussed earlier. Treatment of bleeding complications is by reversal of the coagulopathy and, in rare cases, surgical evacuation of the clot. Purulent meningitis and disc space infections rarely complicate LP.

Examination Procedures for CSF

Once the subarachnoid space has been entered, the pressure and fluctuations with respiration of the CSF are observed, and samples of fluid are obtained. The gross appearance of the fluid is noted, after which the CSF, in separate tubes, can be examined for a number of features. The standard determinations are the number and type of cells, protein and glucose content, and microscopy and bacterial culture. In addition, the following can be studied: (1) tumor cells (cytology and flow cytometry); (2) presence of oligoclonal bands or content of gamma globulin; (3) serologic (immunological) tests; (4) substances elaborated by some tumors (e.g., β_2 microglobulin); (5) markers pertaining to certain infections such as fungi, cryptococcal and other antigen and India ink preparations, mycobacteria, DNA of herpesviruses, cytomegalovirus and other organisms (by polymerase chain reaction [PCR]), markers of certain infections (e.g., 14-3-3 protein), and viral isolation; (6) biomarkers of neurodegenerative diseases (e.g., tau, phosphorylated tau, amyloid beta, and neurofilament light); and (7) metagenomic sequencing for detection of occult microorganisms.

Pressure

With the patient in the lateral decubitus position, the CSF pressure is measured by a manometer attached to the needle in the subarachnoid space. In the normal adult, the opening pressure varies from 100 to 180 mm H_2O, or 8 to 14 mm Hg. In children, the pressure is in the range of 30 to 60 mm H_2O. A pressure above 200 mm H_2O with the patient relaxed and legs straightened generally reflects increased intracranial pressure. In an adult, a pressure of 50 mm H_2O or below indicates intracranial hypotension, generally caused by leakage of spinal fluid or systemic dehydration (Avery and colleagues). When measured with the needle in the lumbar sac and the patient in a sitting position, the fluid in the manometer rises to the level of the cisterna magna (pressure is approximately double that obtained in the recumbent position). It fails to reach the level of the ventricles because the latter are in a closed system under slight negative pressure, whereas the fluid in the manometer is influenced by atmospheric pressure. Normally, with the needle properly placed in the subarachnoid space, the fluid in the manometer oscillates through a few millimeters in response to the pulse and respiration and rises promptly with coughing, straining, and with jugular vein or abdominal compression. An apparent low pressure can also be the result of a needle aperture that is not fully within the subarachnoid space; this is evidenced by the lack of expected fluctuations in pressure with these maneuvers.

The presence of a spinal subarachnoid block was in the past confirmed by jugular venous compression (Queckenstedt test, which tests for a rapid rise in CSF pressure after application of the pressure on the vein). The maneuver risks worsening of a spinal block or of raised intracranial pressure and is of historical interest.

Gross Appearance and Pigments

Normally, the CSF is clear and colorless. Minor degrees of color change are best detected by comparing test tubes of CSF and water against a white background (by daylight rather than by fluorescent illumination) or by looking down into the tubes from above. The presence of red blood cells (RBCs) imparts a hazy or ground-glass appearance; at least 200 RBCs per cubic millimeter (mm^3) must be present to detect this change. The presence of 1,000 to 6,000 RBCs per cubic millimeter imparts a hazy pink to red color, depending on the amount of blood; centrifugation of the fluid or allowing it to stand causes sedimentation of the RBCs. Several hundred or more white blood cells (WBCs) in the fluid (pleocytosis) may cause a slight opaque haziness.

A traumatic tap, in which blood from the epidural venous plexus has been introduced into the spinal fluid, may seriously confuse the diagnosis if it is incorrectly interpreted as indicating a subarachnoid hemorrhage. To distinguish between these two types of "bloody taps," two or three serial samples of fluid may be collected. With a traumatic tap, there is usually a decreasing number of RBCs in the subsequent tubes. Also with a traumatic tap, the CSF pressure is usually normal, and if a large amount of blood is mixed with the fluid, it will clot or form fibrinous webs. These changes are not seen with preexistent hemorrhage because the blood has been greatly diluted with CSF and defibrinated by enzymes in the CSF. In subarachnoid hemorrhage, the RBCs begin to hemolyze within a few hours, imparting a pink-red discoloration (*erythrochromia*) to the supernatant fluid; if the spinal fluid is sampled more than a day following the hemorrhage, the fluid will have become yellow-brown (*xanthochromia*). Prompt

centrifugation of bloody fluid from a traumatic tap will yield a colorless supernatant; only with large amounts of venous blood (RBC > 100,000/mm^3) will the supernatant fluid be faintly xanthochromic due to contamination with serum bilirubin and lipochromes.

The fluid from a traumatic tap should contain approximately one or two WBCs per 1,000 RBCs assuming that the hematocrit and peripheral WBC count are normal, but in reality, this ratio varies. With subarachnoid hemorrhage, the proportion of WBCs rises as RBCs hemolyze, sometimes reaching a level of several hundred per cubic millimeter; but the vagaries of this reaction are such that it, too, cannot be relied upon to distinguish traumatic from preexistent bleeding. The same can be said for crenation of RBCs, which occurs in both types of bleeding. Why red corpuscles undergo rapid hemolysis in the CSF is not clear. It is surely not because of osmotic differences, as the osmolarity of plasma and CSF is essentially the same. Fishman suggested that the low protein content of CSF disequilibrates the red cell membrane in some way.

The pigments that discolor the CSF following subarachnoid hemorrhage are oxyhemoglobin, bilirubin, and methemoglobin (Barrows and colleagues). In pure form, these pigments are colored red (orange to orange-yellow with dilution), canary yellow, and brown, respectively. Oxyhemoglobin appears within several hours of hemorrhage, becomes maximal in approximately 36 h, and diminishes over a 7- to 9-day period. Bilirubin begins to appear in 2 to 3 days and increases in amount as the oxyhemoglobin decreases. Methemoglobin appears when blood is loculated or encysted and isolated from the flow of CSF. Spectrophotometric techniques can be used to distinguish the various hemoglobin breakdown products and thus determine the approximate time of bleeding.

Not all xanthochromia of the CSF is caused by hemolysis of RBCs. With severe jaundice, both conjugated and unconjugated bilirubin diffuse into the CSF. The quantity of bilirubin in the CSF ranges from one-tenth to one-hundredth that in the serum. Elevation of CSF protein from any cause results in a faint opacity and xanthochromia. Only at protein levels greater than 150 mg/100 mL does the coloration become visible to the naked eye. Hypercarotenemia and hemoglobinemia (through hemoglobin breakdown products, particularly oxyhemoglobin) also impart a yellow tint to the CSF, as do blood clots in the subdural or epidural space of the cranium or spinal column. Myoglobin does not appear in the CSF because a low renal threshold for this pigment permits rapid clearing from the blood.

Cellularity

During the first month of life, the CSF contains a larger number of mononuclear cells than in adults. Beyond this period, the CSF is normally nearly acellular (i.e., fewer than 5 lymphocytes or other mononuclear cells per cubic millimeter). An elevation of WBCs in the CSF signifies a reactive process, either to infectious agents, blood, chemical substances, an immunologic inflammation, a neoplasm, or vasculitis. The WBCs can be counted in an ordinary counting chamber, but their identification requires centrifugation of the fluid and staining of the sediment. Identification of malignant cells by the cytology laboratory is usually done by cytocentrifugation or other semiautomated liquid-based method, followed by cell fixation and staining. One can recognize and differentially count neutrophilic and eosinophilic leukocytes (the latter being prominent in some parasitic infections, neurosyphilis, and cholesterol emboli), lymphocytes, plasma cells, mononuclear cells, macrophages, and tumor cells. Bacteria and fungi can be seen in routinely stained preparations. An India ink preparation helps to distinguish between lymphocytes and *Cryptococcus* organisms. Acid-fast bacilli will be found in appropriately stained samples. The monograph by Ali and Cibas is an excellent reference on CSF cytology. Flow cytometry permits the distinction between polyclonal and monoclonal proliferations, thus aiding in the detection of leukemia and lymphoma, and immunostaining techniques help identify metastatic solid tumors. These and other methods for the examination of cells in the CSF are discussed in the appropriate chapters.

Proteins

In contrast to the high-protein content of blood (5,500 to 8,000 mg/dL), that of the lumbar spinal fluid is 45 to 50 mg/dL or less in the adult. The protein content of CSF from the basal cisterns is 10 to 25 mg/dL and that from the ventricles is 5 to 15 mg/dL. Based on work by Fishman and colleagues, this gradient may reflect the fact that CSF proteins leak to a greater degree at the lumbar roots than at higher levels of the neuraxis. An alternative explanation derives from the manner in which the spinal fluid is an ultrafiltrate of blood made by the choroid plexus in the lateral and the fourth ventricles, analogous to the formation of urine by the glomerulus. The amount of protein in the CSF would then be proportional to the length of time the fluid is in contact with the blood–CSF barrier. Thus, shortly after it is formed in the ventricles, the protein is low. More caudally in the basal cisterns, the protein is higher and in the lumbar subarachnoid space it is highest of all. In children, the protein concentration is somewhat lower at each level (<20 mg/dL in the lumbar subarachnoid space). Levels higher than normal indicate a pathologic process in or near the ependyma or meninges—in either the brain, spinal cord, or nerve roots—although the cause of modest elevations of the CSF protein, in the range of 75 mg/dL, frequently remains obscure.

As one would expect, bleeding into the ventricles or subarachnoid space results in spillage not only of RBCs but of serum proteins. If the serum protein concentrations are normal, the CSF protein should increase by about 1 mg/1,000 RBCs. The same holds for a traumatic puncture that allows seepage of venous blood into the CSF at the puncture site. However, in the case of subarachnoid hemorrhage, caused by the irritating effect of hemolyzed RBC upon the leptomeninges, the CSF protein may be increased by many times this ratio.

The protein content of the CSF in bacterial meningitis may reach 500 mg/dL or more. Viral infections induce a less intense and mainly lymphocytic reaction and a lesser elevation of protein—usually 50 to 100 mg/dL but sometimes up to 200 mg/dL; in some instances of viral meningitis and encephalitis, the protein content is normal. Brain tumors, by opening the blood–CSF barrier, can

raise the total protein. Protein values as high as 500 mg/dL are found in exceptional cases of the Guillain-Barré syndrome and in chronic inflammatory demyelinating polyneuropathy. Values in the lumbar CSF of 1,000 mg/dL or more usually indicate a block to CSF flow, typically in the spinal canal; the fluid is then deeply yellow and clots readily because of the presence of fibrinogen, a phenomenon called *Froin syndrome*. Partial CSF blocks by ruptured discs or tumors may elevate the protein to 100 to 200 mg/dL. Low CSF protein values are sometimes found in meningismus (a febrile illness in children with signs of meningeal irritation but normal CSF), in hyperthyroidism, or in conditions that produce low CSF pressure (e.g., after a recent LP as indicated in Chap. 29).

The quantitative partition of CSF proteins by electrophoretic and immunochemical methods demonstrates the presence of most of the serum proteins with a molecular weight of less than 150 to 200 kDa. The protein fractions that have been identified electrophoretically are prealbumin and albumin as well as alpha$_1$, alpha$_2$, beta$_1$, beta$_2$, and gamma globulin fractions, the last of these being accounted for mainly by immunoglobulins (the major immunoglobulin in normal CSF is IgG). The gamma globulin fraction in CSF is approximately 70 percent of that in serum. Table 2-2 gives the quantitative values of the different fractions. Immunoelectrophoretic methods have also demonstrated the presence of glycoproteins, ceruloplasmin, hemopexin, beta-amyloid, and tau proteins. Large molecules—such as fibrinogen, IgM, and lipoproteins—are mostly excluded from the CSF unless generated there by disease states.

There are other notable differences between the protein fractions of CSF and plasma. The CSF always contains a prealbumin fraction and the plasma does not. Although derived from plasma, this fraction, for an unknown reason, concentrates in the CSF, and its level is greater in ventricular than in lumbar CSF, perhaps because of its concentration by choroidal cells. Also, tau (also identified as beta$_2$-transferrin) is detected only in the CSF and not in other fluids; its concentration is higher in the ventricular than in the spinal fluid. The concentration of tau protein, and, in particular, the ratio of tau to beta-amyloid, has found use in the diagnosis of Alzheimer disease, as discussed in Chap. 38. At present, only a few of these proteins are known to be associated with specific diseases of the nervous system. The most important is IgG, which may exceed 12 percent of the total CSF protein in diseases such as multiple sclerosis, neurosyphilis, subacute sclerosing panencephalitis (SSPE), and other chronic viral meningoencephalitides. The serum IgG is not correspondingly increased, which means that this immune globulin originates in (or perhaps is preferentially transported into) the nervous system. However, an elevation of serum gamma globulin—as occurs in cirrhosis, sarcoidosis, myxedema, and multiple myeloma—will be accompanied by a rise in the CSF globulin. Therefore, in patients with an elevated CSF gamma globulin, it is necessary to determine the electrophoretic pattern of the serum proteins as well. Certain qualitative changes in the CSF immunoglobulin pattern, particularly the demonstration of several discrete (oligoclonal) electrophoretic "bands," each representing a specific immune globulin, and the ratio of IgG to total protein, are of special diagnostic importance in multiple sclerosis, as discussed in Chap. 36.

The albumin fraction of the CSF increases in a wide variety of central nervous system (CNS) and craniospinal nerve root diseases that increase the permeability of the blood–CSF barrier, but no specific clinical correlations can be drawn. Certain enzymes that originate in the brain, especially the brain-derived fraction of creatine kinase (CK-BB) but also enolase and neopterin, are found in the CSF after stroke, global ischemic hypoxia, or trauma and have been used as markers of brain damage in experimental work. Other special markers such as elevation of the 14-3-3 protein, which has some diagnostic significance in prion disease, β_2-microglobulin in meningeal lymphomatosis, and alpha-fetoprotein in embryonal tumors of the brain, may be useful in specialized circumstances.

Table 2-2

AVERAGE VALUES OF CONSTITUENTS OF NORMAL CSF AND SERUM

	CEREBROSPINAL FLUID	SERUM
Osmolarity	295 mOsm/L	295 mOsm/L
Sodium	138.0 mEq/L	138.0 mEq/L
Potassium	2.8 mEq/L	4.1 mEq/L
Calcium	2.1 mEq/L	4.8 mEq/L
Magnesium	2.3 mEq/L	1.9 mEq/L
Chloride	119 mEq/L	101.0 mEq/L
Bicarbonate	23.0 mEq/L	23.0 mEq/L
Carbon dioxide tension	48 mm Hg	38 mm Hg (arterial)
pH	7.31–7.33	7.41 (arterial)
Nonprotein nitrogen	19.0 mg/dL	27.0 mg/dL
Ammonia	30.0 g/dL	70.0 g/dL
Uric acid	0.24 mg/dL	5.5 mg/dL
Creatinine	4.7 mmol/L	5.4 mmol/L
Phosphorus	1.1 mg/dL	1.8 mg/dL
Total lipid	1.6 mg/dL	4.0 mg/dL
Total cholesterol	1.5 mg/dL	750.0 mg/dL
Cholesterol esters	0.4 mg/dL	180.0 mg/dL
Glucose	0.3 mg/dL	126.0 mg/dL
Lactate	60 mg/dL	90.0 mg/dL
Total protein	1.6 mEq/L	1.0 mEq/L
Prealbumin	15–50 mg/dL	6.5–8.4 g/dL
Albumin	1–7%	Trace
Alpha$_1$ globulin	49–73%	56%
Alpha$_2$ globulin	3–7%	4%
Alpha$_2$ globulin	6–13%	10%
Beta globulin (beta1 plus tau)	9–19%	12%
Gamma globulin	3–12%	14%

Glucose

The CSF glucose concentration is normally in the range of 45 to 80 mg/dL, that is, about two-thirds of that in the blood (0.6 to 0.7 of serum concentrations). Higher levels parallel the blood glucose in this proportion; but with marked hyperglycemia, the ratio of CSF to blood glucose is reduced (0.5 to 0.6). With extremely low serum glucose, the ratio becomes higher, approximating 0.85. In general, CSF glucose values below 35 mg/dL are usually abnormal. After

the intravenous injection of glucose, 2 to 4 h is required to reach equilibrium with the CSF; a similar delay follows the lowering of blood glucose. For these reasons, samples of CSF and blood for glucose determinations should ideally be drawn simultaneously in the fasting state or the serum should be obtained a few hours before the puncture (but this is often not practical). Low values of CSF glucose (hypoglycorrhachia) in the presence of pleocytosis usually indicate bacterial, tuberculous, or fungal meningitis, although similar reductions are observed in some patients with widespread neoplastic infiltration of the meninges and occasionally with sarcoidosis, subarachnoid hemorrhage (usually in the first week) and in chemically induced inflammation.

For a long time, it was assumed that in meningitis the bacteria or cellular reaction lowered the CSF glucose by their active metabolism, but the fact that the glucose remains at a subnormal level for 1 to 2 wk after effective treatment of the meningitis suggests that another mechanism is operative. Theoretically at least, an inhibition of the entry of glucose into the CSF because of an impairment of the membrane transfer system can be implicated. As a rule, viral infections of the meninges and brain do not lower the CSF glucose, although low glucose values have been reported in a small number of patients with mumps meningoencephalitis, and rarely in patients with herpes simplex and zoster infections. The almost invariable rise of CSF lactate in purulent meningitis probably suggests that some of the glucose is undergoing anaerobic glycolysis by polymorphonuclear leukocytes and by cells of the meninges and adjacent brain tissue.

Serologic and Virologic Tests

CSF testing for cryptococcal surface antigen has become widely available as a rapid method if this infection is suspected. On occasion, a false-positive reaction is obtained in the presence of high titers of rheumatoid factor or antitreponemal antibodies, but otherwise, the test is diagnostically more dependable than the formerly used India ink preparation. The nontreponemal antibody tests of the blood—Venereal Disease Research Laboratories (VDRL) test and rapid plasma reagin (RPR) agglutination test—can also be performed on the CSF. When positive, these tests are usually diagnostic of neurosyphilis, but false-positive reactions may occur with collagen diseases, malaria, and yaws, or with contamination of the CSF by seropositive blood. Tests that depend on the use of treponemal antigens, including the Treponema pallidum immobilization test and the fluorescent treponemal antibody test, are more specific and assist in the determination of false-positive RPR and VDRL reactions. The value of CSF examinations in the diagnosis and treatment of neurosyphilis is discussed in Chap. 31, but testing of CSF for treponemal antibodies is no longer routine with CSF sampled for reasons other than syphilis. Serologic tests for the Lyme spirochete may be useful in circumstances of suspected infection of the CNS with this agent.

The utility of serum serologic tests for viruses is limited by the time required to obtain results, but they are useful in determining retrospectively the source of meningitis or encephalitis. More rapid tests that use the PCR in CSF, which amplifies viral DNA fragments, are now widely available for diagnosis, particularly for herpesviruses, cytomegalovirus, and JC virus. These tests are most useful in the first week of infection when the virus is being reproduced and its genomic material is most prevalent; after this time, serologic techniques for viral infection are more sensitive. Amplification of DNA by PCR is particularly useful in the rapid detection of tubercle bacilli in the CSF, the conventional culture of which takes several weeks at best. Tests for the detection of 14-3-3 protein that reflects the presence of prion agents in the spinal fluid are available and may aid in the diagnosis of the spongiform encephalopathies, but the results have been erratic (Chap. 32). Testing for anti-Hu and anti-NMDA and other antibodies has become practical for paraneoplastic and non-paraneoplastic encephalitides (Chap. 30), as has metagenomic sequencing, in certain circumstances, for detection of occult or unusual microorganisms (Wilson and colleagues).

Changes in Solutes and Other Components

Solute concentrations in the CSF can be measured and may be informative alone and in comparison to serum solute concentrations. Table 2-2 lists the CSF and serum levels of sodium, potassium, calcium, and magnesium. Neurologic disease does not alter the CSF concentrations of these constituents in any characteristic way.

The ammonia content of the CSF is one-third to one-half that of the arterial blood; it is increased in hepatic encephalopathy, the inherited hyperammonemias, and the Reye syndrome; the concentration corresponds roughly with the severity of the encephalopathy. The uric acid content of CSF is approximately 5 percent of that in serum and varies with changes in the serum level (high in gout, uremia, and meningitis, and low in Wilson disease). The urea concentration in the CSF is slightly lower than that in the serum; in uremia, it rises in parallel with that in the blood. An intravenous injection of urea raises the blood level immediately and the CSF level more slowly, exerting an osmotic dehydrating effect on the central nervous tissues and CSF. All 24 amino acids have been isolated from the CSF. The concentration of amino acids in the CSF is approximately one-third of that in plasma. Elevations of glutamine are found in all the portosystemic encephalopathies, including hepatic coma and the Reye syndrome. Concentrations of phenylalanine, histidine, valine, leucine, isoleucine, tyrosine, and homocystine are increased in the corresponding aminoacidurias.

Many of the enzymes found in serum are known to rise in CSF under conditions of disease, usually in relation to a rise in the CSF protein. None of the enzyme changes has proved to be a specific indicator of neurologic disease with the possible exception of lactic dehydrogenase, especially isoenzymes 4 and 5, which are derived from granulocytes and are elevated in bacterial meningitis but not in aseptic or viral meningitis. Lactic dehydrogenase is also elevated in cases of meningeal tumor infiltration, particularly lymphoma, as is carcinoembryonic antigen; the latter, however, is not elevated in bacterial, viral, or fungal meningitis. As to lipids, the quantities in CSF are small and their measurement is difficult.

The catabolites of the catecholamines can be measured in the CSF. Homovanillic acid (HVA), the major catabolite of dopamine, and 5-hydroxyindoleacetic acid (5-HIAA), the major catabolite of serotonin, are normally present in the spinal fluid; both are five or six times higher in the ventricular than the lumbar CSF. The levels of both catabolites are reduced in patients with idiopathic and drug-induced parkinsonism.

IMAGING TECHNIQUES

A century ago, Harvey Cushing introduced the use of plain x-ray films of the cranium as part of the study of the neurologic patient. Plain skull films demonstrate fractures, changes in contour of the skull, bony erosions and hyperostoses, infection in paranasal sinuses and mastoids, and changes in the basal foramina. Calcified structures such as the pineal gland were time-honored landmarks of midline structures, allowing measurements of the displacement of intracranial contents. Plain films of the spine are able to demonstrate destructive lesions resulting from degenerative processes as well as neoplastic, dysplastic, and infectious diseases. It also detects fracture dislocations, spondylolistheses, and spinal instability, utilizing images acquired during flexion and extension maneuvers. However, refinements of imaging techniques have greatly increased the yield of valuable information. Without question the most important advances in neuroradiology have come about with the development of CT and MRI.

Computed Tomography (CT)

In this procedure, x-radiation is attenuated as it passes successively through the scalp, skull, CSF, cerebral gray and white matter, and blood vessels. The intensity of the exiting radiation relative to the incident radiation is measured, the data are integrated, and two-dimensional images are reconstructed by computer. This major achievement in methodology, attributed to Hounsfield and others, permitted the technologic advance from plain radiographs of the skull to reconstructed images of the cranium and its contents in any plane. The differing densities of bone, CSF, blood, and gray and white matter are distinguishable in the resulting picture with great clarity. One can see and measure the sizes of hemorrhage, infarction, contusion, edematous brain, abscess, and tumor and also determine the shape and position of the ventricles and midline structures. The radiation exposure is only modestly greater than that from plain skull films. The machinery can be manipulated to reduce radiation exposure where this limitation is desirable, for example, in children.

As illustrated in Fig. 2-1, in transverse (axial) section of the brain, one sees the cortex and underlying subcortical white matter, the caudate and lenticular nuclei, and the internal capsules and thalami. The position and width of all the major sulci and fissures can be measured, and the optic nerves and medial and lateral rectus muscles stand out clearly in the posterior parts of the orbit. The brainstem, cerebellum, and spinal cord are easily visible in the scan at appropriate levels. The scans are also useful in imaging parts of the body that surround peripheral nerves and plexuses, thereby demonstrating tumors, inflammatory lesions, and hematomas that involve these nerves. Intravenous administration of radiopaque material (contrast) can be used with CT to visualize regions where the blood–brain barrier has been disrupted from tumors, demyelination, and infection.

In imaging of the head, CT has a number of advantages over MRI, the most important being safety when metal may be present in the body, shorter examination time, and the clarity of blood from the moment of bleeding. Other appealing aspects are its broader availability, lower cost, larger aperture of the machine that reduces patient claustrophobia, and equivalent or superior visualization of calcium, fat, and bone, particularly of the skull base and vertebrae (see Fig. 2-1*D*). If constant monitoring and use of life support equipment required during the imaging procedure, it is accomplished more readily by CT than by MRI. Advances in CT technology have greatly increased the speed of the scanning procedure and have also made possible the visualization, with great clarity, of the cerebral vasculature (CT angiography; see further on).

CT also demonstrates the bony structures of the vertebral column in greater detail than is available with conventional x-ray. Herniated lumbar and cervical discs, cervical spondylotic bars, and bony spurs encroaching on the spinal cord or roots, and spinal cord tumors can be visualized with clarity. MRI provides even sharper visualization of the spinal canal and its contents, as well as the vertebrae and intervertebral discs, as discussed further on.

Contrast Myelography

Myelography utilizes intrathecal contrast material to demonstrate the contours of the spinal cord and spinal roots. It can be accomplished either by conventional fluoroscopy or by CT. By injecting water-soluble radiopaque contrast through an LP needle and then placing the patient in the Trendelenberg position, the entire spinal subarachnoid space can be visualized (Fig. 2-2*A*–*C*). The procedure is almost as harmless as the LP except for cases of complete spinal block, in which high concentrations of contrast near the block can cause pain and regional myoclonus. Iophendylate (Pantopaque) and other fat-soluble contrast dyes were formerly used for myelography, but their use was limited by a risk of arachnoiditis due to retained contrast in the subarachnoid space, among other technical issues. MRI, because of its ability to clearly demonstrate intrathecal structures has largely supplanted contrast myelography, as discussed in a later section.

Risks of CT

The primary risk of CT is radiation exposure, and overexposure can have clinical consequences ranging from relatively benign alopecia to leukomalacia and neoplasia. The interested reader should refer to FDA guidelines on the subject (https://www.fda.gov/radiation-emitting-products/medical-x-ray-imaging/computed-tomography-ct). Given the need for repeated CT examinations in certain patients, consultation with a radiation technologist and

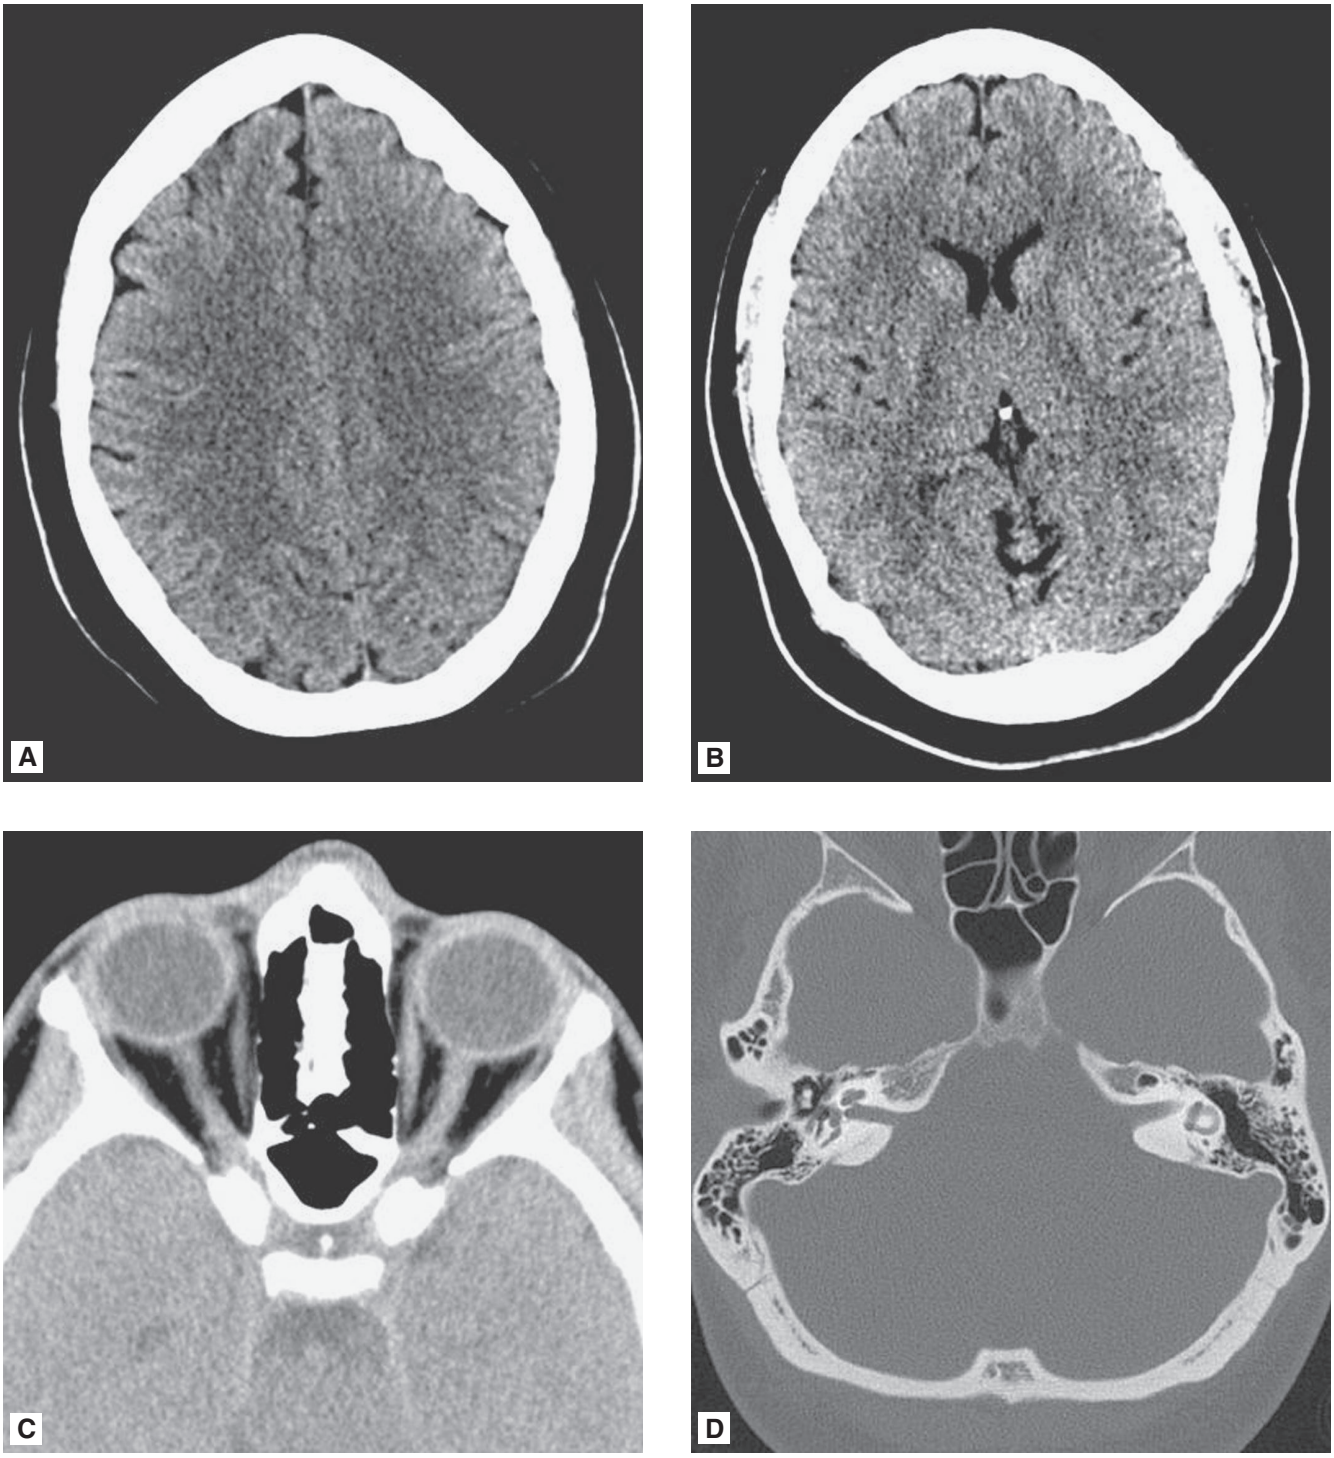

Figure 2-1. Normal CT in the axial plane of the brain, orbits, and skull base. *A*. Image through the cerebral hemispheres at the level of the corona radiata. The dense bone of the calvarium is white, and fat-containing subcutaneous tissue is dark. Gray matter appears denser than white matter due to its lower lipid content. *B*. Image at the level of the lenticular nuclei. The caudate and lenticular nuclei are denser than the adjacent internal capsule. CSF within the frontal horns of the lateral ventricles, as well as surrounding the slightly calcified pineal body, appears dark. *C*. Image through the mid-orbits. The sclera appears as a dense band surrounding the globe. The optic nerves are surrounded by dark orbital fat. The medial and lateral rectus muscles lie along the orbital walls and have a fusiform shape. Air within the nasopharynx and paranasal sinuses appears dark. *D*. Image at the base of the skull, digitally adjusted to visualize bone ("bone window"), showing the basal occipital and temporal bones, clivus, the bony structures of the posterior nasopharynx, aerated mastoid air cells, internal auditory canals, and inner ear structures, as well as the sutures in the occipital bone.

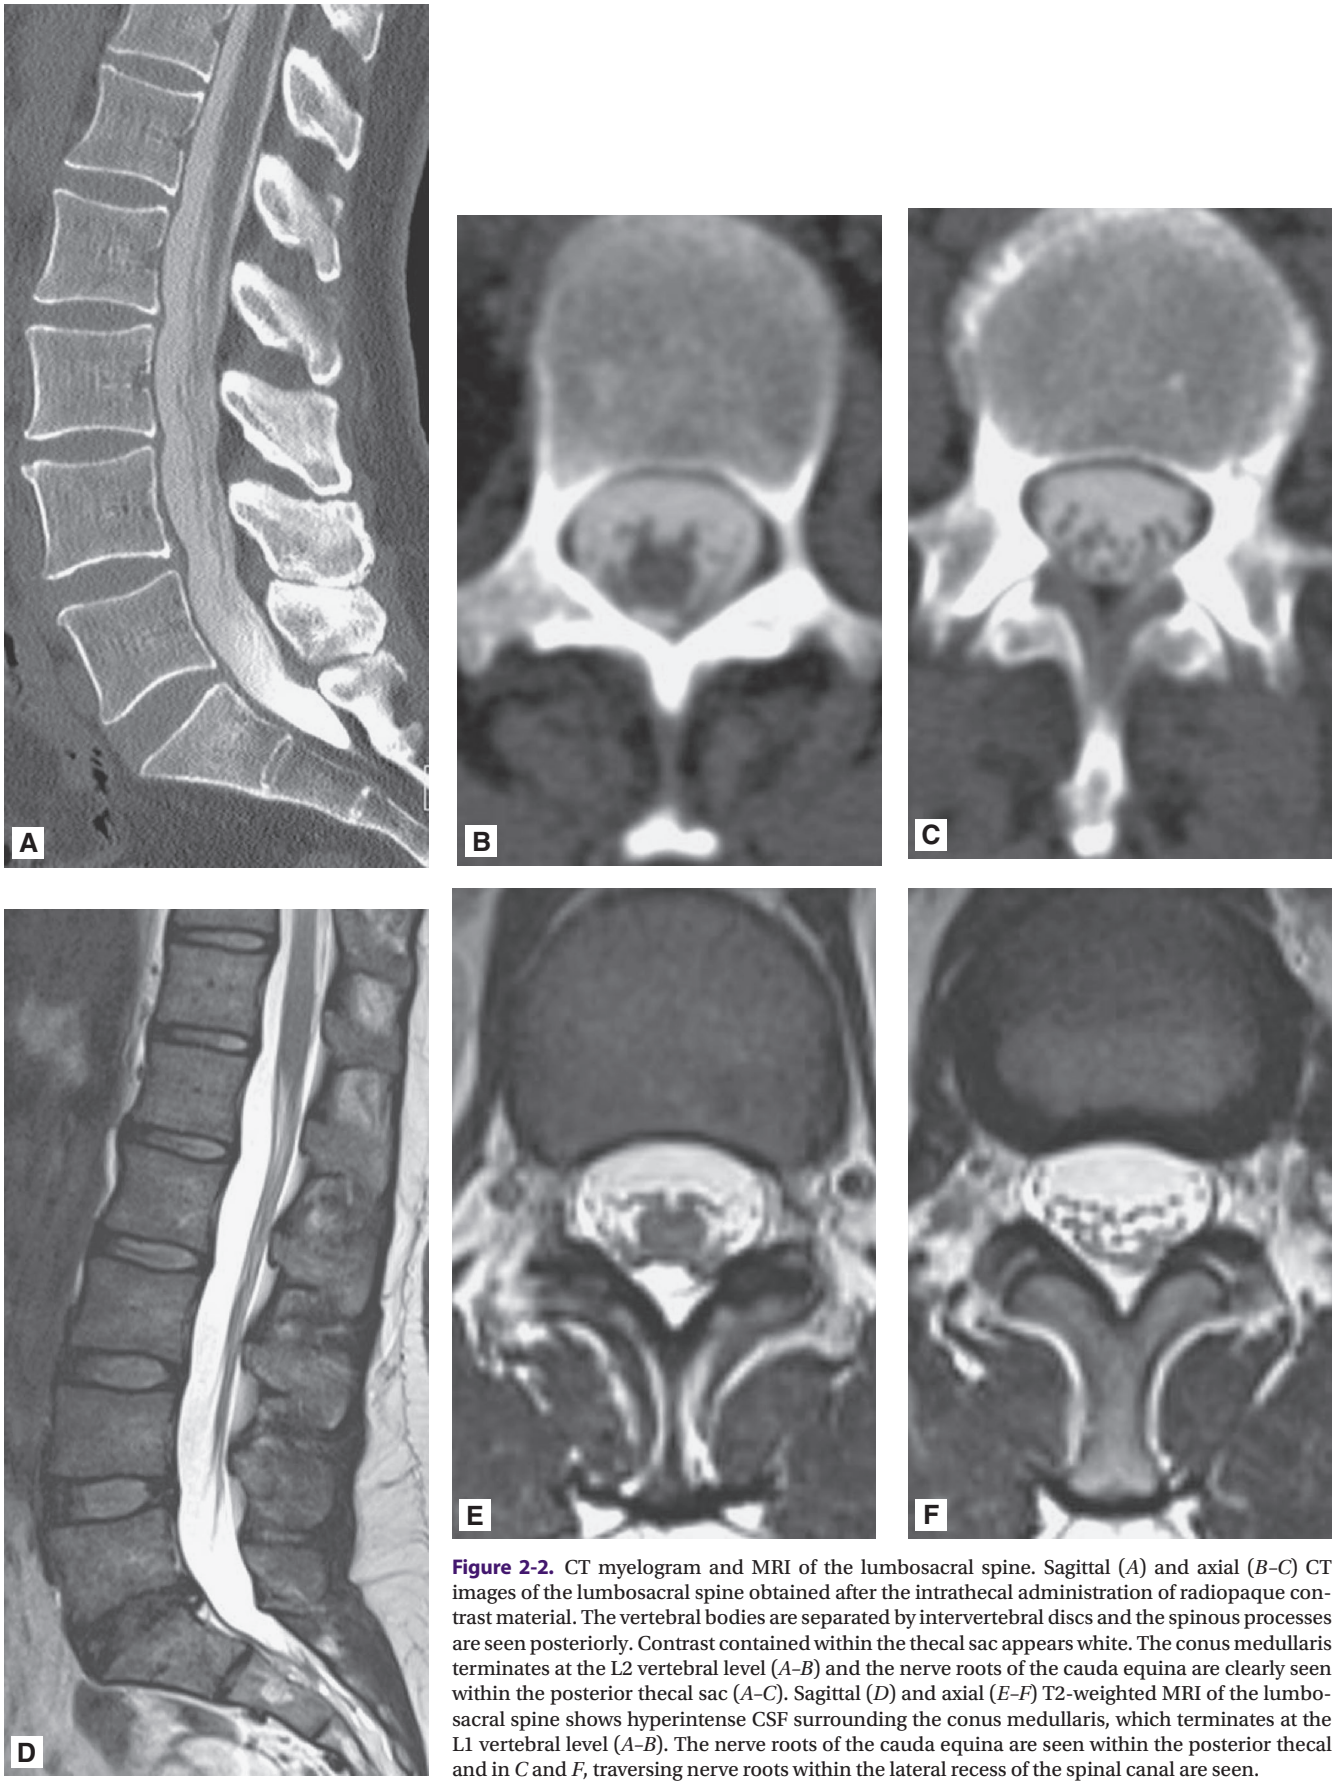

Figure 2-2. CT myelogram and MRI of the lumbosacral spine. Sagittal (*A*) and axial (*B–C*) CT images of the lumbosacral spine obtained after the intrathecal administration of radiopaque contrast material. The vertebral bodies are separated by intervertebral discs and the spinous processes are seen posteriorly. Contrast contained within the thecal sac appears white. The conus medullaris terminates at the L2 vertebral level (*A–B*) and the nerve roots of the cauda equina are clearly seen within the posterior thecal sac (*A–C*). Sagittal (*D*) and axial (*E–F*) T2-weighted MRI of the lumbosacral spine shows hyperintense CSF surrounding the conus medullaris, which terminates at the L1 vertebral level (*A–B*). The nerve roots of the cauda equina are seen within the posterior thecal and in *C* and *F*, traversing nerve roots within the lateral recess of the spinal canal are seen.

tracking of total accumulated radiation exposure may be advisable. CT is usually deferred during pregnancy unless the mother's health is at imminent risk (i.e., following trauma or in the setting of acute stroke). The potential harm to a fetus from radiation depends on gestational age and total absorbed dose. It is noteworthy that the fetal radiation dose from a maternal cranial CT is much lower than from a maternal pelvic CT.

The risks of contrast infusion include allergic reactions and nephropathy, which is most often transient and reversible but can be more severe in patients with underlying renal dysfunction. Intravenous contrast generally withheld if the glomerular filtration rate (calculated GFR) is less than 30 mL/min/1.73 m^2; if GFR is 30 to 60 mL/min/1.73 m^2, hydration and discontinuation of potentially nephrotoxic medications should precede the administration of contrast, particularly nonsteroidal anti-inflammatory agents, cisplatin-containing chemotherapy and aminoglycoside antibiotics. Repeated infusions of contrast should be done cautiously.

Table 2-3

CT AND MRI IMAGING CHARACTERISTICS OF VARIOUS TISSUES

TISSUE	CT GRAYSCALE	MRI T1 SIGNAL	MRI T2 SIGNAL
Brain	Gray	Gray	Gray
Air	Black	Black	Black
CSF	Black	Black	White
Fat	Black	White	Less white
Calcium	White	Black	Black
Bone	Very white	Black	Black
Extravasated blood	White	White	Black
Inflammation	Dark gray, contrast enhancing	Gray, gadolinium enhancing	White
Edema	Dark gray	Gray	White
Tumor	Gray or white and contrast enhancing	Gray or white and gadolinium enhancing	White

Magnetic Resonance Imaging (MRI)

For visualization of most lesions in and around the brain and spinal cord, MRI is more sensitive than CT. MRI has the advantage over CT in using nonionizing energy and providing improved contrast between different structures within the nervous system.

Many engineers, mathematicians, and physicists made contributions to the technology of MRI, and a Nobel Prize was awarded to Lauterbur and Mansfield for its development. Nuclear magnetic resonance can be detected from several isotopes, but current technology uses mainly signals derived from hydrogen atoms because hydrogen is the most abundant element in tissue and yields the strongest magnetic signal. The image is essentially a map of the hydrogen content of tissue, therefore reflecting largely the water concentration but influenced also by the physical and chemical environment of the hydrogen atoms. MRI is accomplished by placing the patient within a powerful magnetic field, causing certain endogenous isotopes to be aligned in the longitudinal orientation of the magnetic field. Application of a brief (few milliseconds) radiofrequency (RF) pulse into the field changes the axis of alignment of the atoms. When the RF pulse ceases, the atoms return to their original alignment and the RF energy that was absorbed is then emitted by the isotopes, producing an electric signal that is detected by receiver coils. To create contrasting tissue images from these signals, the RF pulse must be repeated many times (a pulse sequence), the signals being measured after the application of each pulse. The scanner stores the signals as a matrix of data, which is subjected to computer analysis that allows the reconstruction of two-dimensional images.

The terms T1- and T2-weighting refer to the time constants for proton relaxation; these may be altered to highlight certain features of tissue structure. In T1-weighted images, CSF appears dark and gray matter is hypointense to white matter. In T2-weighted images, CSF appears bright, and gray matter is hyperintense to white matter. Lesions within the white matter, such as the demyelinative lesions of multiple sclerosis, are more easily seen on T2-weighted images, appearing hyperintense (brighter) against normal white matter (darker) (Table 2-3).

A high degree of contrast is seen between white and gray matter on both T1- and T2-weighted images, allowing the identification of many discrete anatomic structures (Fig. 2-3). Lesions near the skull base and within the posterior fossa, in particular, are seen with greater clarity on MRI compared to CT, unmarred by signals from adjacent skeletal structures. The products of disintegrated RBCs—oxyhemoglobin, deoxyhemoglobin, methemoglobin, and hemosiderin—can be recognized, enabling one to approximate the age of hemorrhages and to follow their resolution, as discussed in Chaps. 33 and 34. Gradient-echo (GRE), or susceptibility weighted imaging (SWI), is especially sensitive to blood and its breakdown products that appear hypointense.

As mentioned earlier, MRI of the spine provides clear images of the vertebral bodies, intervertebral discs, spinal cord, and cauda equina (Fig. 2-2*D–F*). Abnormalities such as syringomyelia, herniated discs, tumors, epidural or subdural hemorrhages, areas of demyelination, and abscesses are well delineated (Modic).

Additional RF pulses can be applied to T1- and T2-weighted images in order to selectively suppress signal from fluid or fat. The fluid-attenuated inversion recovery (FLAIR) sequence is a T2-weighted sequence in which the bright signal of fluid that is not contained within tissues is suppressed. This is a particularly useful sequence for visualizing lesions located near CSF compartments. Fat suppression sequences can be used to improve visualization of inflammation of the optic nerve, pathologic inflammation within vertebral bodies, and thrombus within the false lumen of a cervical arterial dissection.

Diffusion-weighted imaging (DWI) is a technique that measures the free diffusion of water molecules within the tissue. Preferential movement of water molecules in a particular direction, for example, parallel to white matter tracts, is referred to as anisotropy (i.e., non-isotropic movement). Many pathologic processes can produce high degrees of

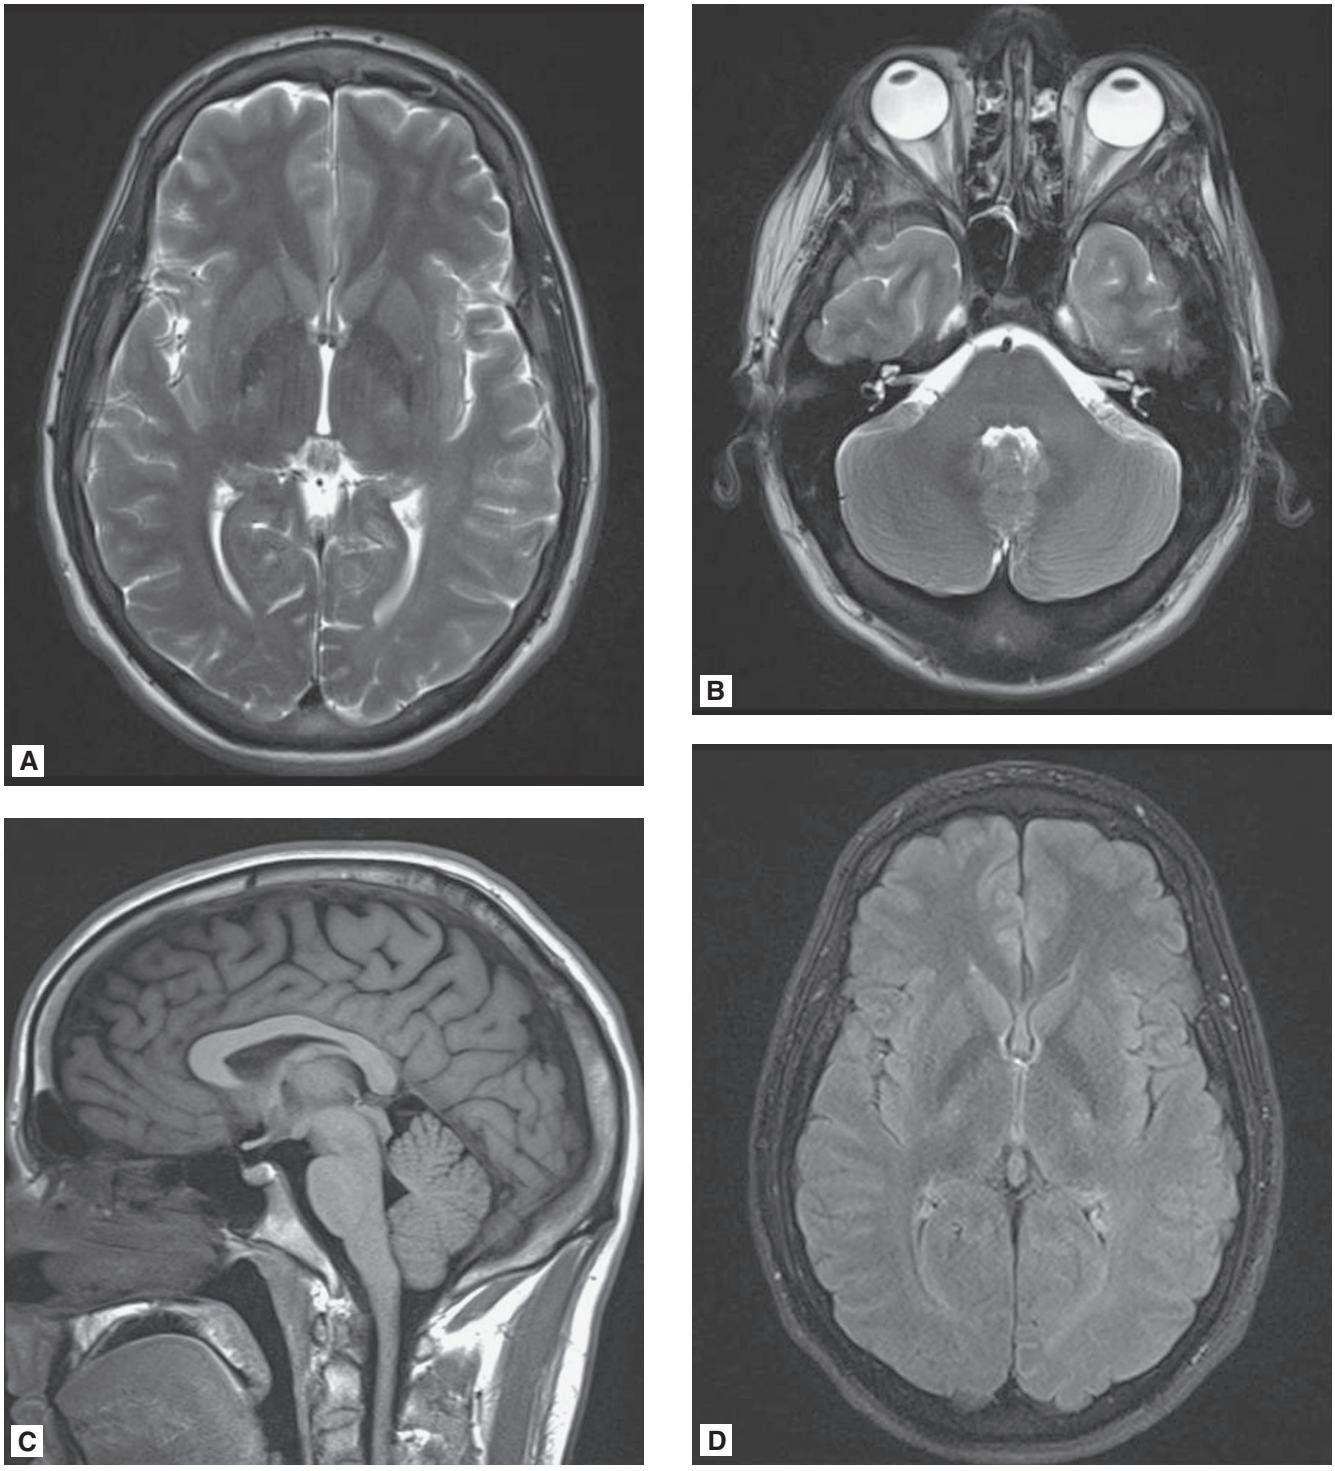

Figure 2-3. Normal brain MRI. *A*. Axial T2-weighted MRI at the level of the lenticular nuclei. Gray matter appears brighter than white matter. CSF within the ventricles and cortical sulci is very bright. The caudate nuclei, putamen, and thalamus appear brighter than the internal capsule. *B*. Axial T2-weighted MRI at the level of the pons. CSF within the fourth ventricle and prepontine cistern, endolymph within the cochlea and semicircular canals, and ocular vitreous fluid appears very bright. Signal is absent (i.e., a "flow void") within the basilar artery. *C*. Midline sagittal T1-weighted MRI of the brain. Note that white matter appears brighter than gray matter and the corpus callosum is well defined. The pons, medulla, and cervicomedullary junction are well delineated, and the pituitary gland is demonstrated with a normal posterior pituitary bright spot. The cerebral aqueduct is seen between the ventral midbrain and the tectum. The clivus and upper cervical vertebrae are noted as well. *D*. Axial T2-weighted FLAIR MRI of the brain at the same level as in *A*. Note that the hyperintense fluid signal from CSF in standard T2-weighted sequences is now suppressed, and the differentiation between brighter gray matter and darker white matter is accentuated.

anisotropy. In acute ischemic stroke, failure of the sodium-potassium-ATPase pump leads to intracellular swelling and reduced intercellular space, thus limiting the free movement of water and producing hyperintensity on DWI. This imaging technique reveals the abnormalities of ischemic stroke earlier than standard T1- or T2-weighted MRI, or CT, and with greater sensitivity and resolution. Pus-filled abscesses and dense tumors can also show DWI hyperintensity, reflecting not ischemia but rather the limitation of free diffusion of water in these densely cellular lesions.

True restricted diffusion, appearing hyperintense on the DWI sequence in acute infarction, is *hypointense* on a related sequence termed the apparent diffusion coefficient (ADC) map. If the hyperintense DWI signal is also *hyperintense* on ADC, then diffusion is termed facilitated or enhanced rather than restricted. This phenomenon is seen when the free movement of water within a tissue becomes increasingly isotropic, as with vasogenic edema. Therefore, the interpretation of DWI signal hyperintensity must be gauged in the context of the ADC signal in the same region.

The administration of gadolinium, a paramagnetic agent that accelerates the process of proton relaxation during the T1 sequence of MRI ("T1-shortening"), permits even sharper definition and highlights regions surrounding many types of lesions where the blood–brain barrier may be disrupted in the brain, spinal cord, or nerve roots.

Limitations and Safety of MRI

The degree of cooperation in holding still that is required to perform MRI limits its use in young children and in the cognitively impaired. Some form of sedation may be required in these individuals and most hospitals have services to safely accomplish conscious sedation for this purpose. Studying a patient who requires a ventilator is also difficult but manageable by using either manual ventilation or nonferromagnetic ventilators.

The main dangers in the use of MRI are torque, dislodgement or heating of metal clips on blood vessels, of dental devices and other ferromagnetic objects, and of small metal fragments in the orbit, the last of these often acquired unnoticed by operators of machine tools. For this reason it is wise, in appropriate patients, to obtain plain radiographs of the orbits so as to detect occult metal in these regions. Corneal metal fragments can be removed by an ophthalmic surgeon if an MRI is necessary. The presence of a cardiac pacemaker, defibrillator, or implanted stimulator in the brain or spinal cord was, in the past, an absolute contraindication to the use of MRI, as the magnetic field induces electrical currents in the device and the wires exiting from it. However, many new implantable medical devices have been developed that are unaffected by and do not distort the magnetic field. Most of the newer, weakly ferromagnetic prosthetic heart valves, joint prostheses, some cochleae implants, intravascular access ports, aneurysm clips, and ventricular shunts and adjustable valves do not represent an untoward risk for magnetic imaging although shunt valves may require resetting after MRI. An extensive and continually updated list of devices that have been tested for their ferromagnetic susceptibility and their safety in the MRI machine can be found at www.mrisafety.com. MRI entails some risk in these situations unless there is direct knowledge of the type of material contained in the device. It should be noted that devices or materials that are deemed safe for 1.0 or 1.5 Tesla scanners may not necessarily be compatible with higher magnetic field strength scanners.

Because of the development of cataracts in the fetuses of animals exposed to MRI, there has been hesitation in performing MRI in pregnant patients, especially in the first trimester. However, current data indicate that imaging may be performed safely provided that the study is medically indicated. In a study of 1,000 pregnant MRI technicians who entered the magnetic field frequently (the magnet remains on between procedures), no adverse effects on the fetus could be discerned (Kanal and colleagues).

An additional risk of the administration of gadolinium is *nephrogenic systemic fibrosis*, a severe cutaneous sclerosing disease. Most instances occur in patients with preexisting renal failure, for which reason it has become common to obtain BUN, creatinine, and GFR measurements before administering gadolinium. The problem had not been appreciated initially in part because of its rarity (the frequency has not been well established) and because of a delay in the appearance of sclerosis in the kidney and skin, of several days to months.

Many types of MRI image artifacts are known, most having to do with technical aspects of the electronic characteristics of the magnetic field or of the mechanics involved in the imaging procedure (Morelli and colleagues). Among the most common and problematic are CSF flow artifacts in the thoracic spinal cord, giving the impression of an intradural mass; distortions of the appearance of structures at the base of the brain from ferromagnetic dental appliances; and lines across the entire image induced by vascular pulsations and patient movement.

The increasing use of MRI and the sensitivity of current machines have had the unintended effect of revealing a large number of unimportant findings that create undue worry and often trigger neurologic consultation. Moreover, many lesions are not referable to the clinical problem at hand. A surprising number of incidental brain lesions are exposed by indiscriminate use of imaging. For example, a large survey of asymptomatic adults who were being followed in the Rotterdam Study is in accord with several prior studies in which cerebral aneurysms were found in approximately 2 percent, meningiomas in 1 percent, and a smaller but not insignificant number of vestibular schwannomas and pituitary tumors; the meningiomas, but not the aneurysms, increased in frequency with age. One percent had the Chiari type I malformation, and a similar number had arachnoid cysts. In addition, 7 percent of adults older than age 45 years had occult strokes, mostly lacunar. Because this survey was performed without gadolinium infusion, it might be expected that even more small asymptomatic lesions could be revealed (Vernooij and colleagues). A meta-analysis of brain MRI findings in the pediatric population reported incidental findings in 16.4 percent of healthy children, with intracranial cysts

being the most frequently encountered (10.2 percent), followed by non-specific white matter hyperintensities (1.9 percent), Chiari 1 malformation (0.8 percent), and neoplasms (0.2 percent) (Dangouloff-Ros and colleagues).

Magnetic Resonance and Computed Tomographic Angiography

These are noninvasive techniques for visualizing the intracranial and cervical arteries. They can reliably detect intracranial vascular lesions and extracranial arterial stenosis and are supplanting conventional angiography. They approach the radiographic resolution of catheter-based angiography but do not engender the risk of selective arterial catheterization (Fig. 2-4). Visualization of the cerebral veins is also possible by CT (Fig. 2-4*D*) and MRI.

CT angiography requires contrast administration. In comparison, MR angiography can be performed without contrast, using the *time-of-flight* technique. This data can be reconstructed into an image that reflects flow-related enhancement. The signal obtained from time-of-flight MRA represents flow through the lumen of a vessel rather than the actual structure of the lumen of the vessel as obtained by contrast opacification. The use of these and other methods for the investigation of carotid artery disease is discussed further below and in Chap. 35, on cerebral vascular disease.

Catheter Angiography

This technique is a valuable method for the diagnosis and treatment of aneurysms, vascular malformations, narrowed or occluded arteries and veins, arterial dissections, and angiitis. To a large extent, CT and MRI angiographic techniques have supplanted the diagnostic role of catheter angiography, but the latter remains necessary for a variety of conditions, particularly small vascular malformations. It is also possible to introduce thrombolytic substances and mechanical devices through catheters for the treatment of cerebrovascular disease.

A needle is placed in the femoral or brachial artery; a cannula is then threaded through the needle and along the aorta and the arterial branches to be visualized. In this way, a contrast agent is injected to visualize the arch of the aorta, the origins of the carotid and vertebral systems, and the extensions of these systems through the neck and into the cranial cavity and the vasculature in and surrounding the spinal cord. Through a process called digital subtraction, the soft tissues can be eliminated from the image, leaving only the contrast-enhanced vasculature visible. Catheter angiography allows for the visualization of the cerebral and spinal cord vessels to a resolution of less than 1 mm in lumen diameter. With refinements in technique, it is possible to produce images of the major cervical and intracranial arteries with relatively limited amounts of contrast medium introduced through small catheters.

Angiography carries certain small risks. Overall morbidity from the procedure is approximately 2.5 percent, mainly in the form of worsening of a preexistent vascular lesion or from complications at the site of artery puncture. Occasionally, cerebral or systemic ischemic lesions are produced, the result of either particulate atheromatous material dislodged by the catheter, dissection of the artery by the catheter, thrombus formation at or near the catheter tip, vasospasm, or disruption of the blood–brain barrier. A cervical myelopathy is a rare but disastrous complication of vertebral artery contrast injection; the problem is heralded by pain in the back of the neck immediately after injection. Progressive cord ischemia from an ill-defined vascular process ensues over the following hours. For these reasons, the procedure should not be undertaken unless it is deemed necessary to obtain a clear diagnosis or in anticipation of surgery that requires a definition of the location of the vessels.

Additional Imaging Techniques

Perfusion Imaging

This imaging modality is a contrast-based technique that can be performed with both CT and MRI. Images are rapidly and serially acquired as the contrast transits through the vasculature and parenchyma. A time-intensity curve is produced, from which measurements of cerebral blood flow, cerebral blood volume, and transit time can be derived. Perfusion imaging has provided a means of detecting regions of ischemic tissue and to monitor the elevated blood volume associated with certain brain tumors.

Magnetic Resonance Spectroscopy

The tissue concentrations of a variety of cellular metabolites can be determined with the technique of magnetic resonance spectroscopy (MRS). Among these substances, *N*-acetyl aspartate (NAA) is a marker of neuronal integrity and is decreased in both destructive lesions and in circumstances in which there is a reduction in the density of neurons (e.g., edema or glioma that increases the distance between neurons). Choline (Cho), a marker of membrane turnover, is elevated in some rapidly dividing tumors. Compared to normal white matter, the spectrogram of a glioma characteristically shows decreased NAA and increased Cho concentrations. It is possible to measure a number of other metabolites such as myoinositol, creatine, and lactate that find occasional clinical utility.

Diffusion Tractography

A technique based on DWI, termed diffusion tensor imaging (DTI), integrates measurements of the amount of anisotropy with its directionality to model axonal tracts in the brain. Tractography is the technique that has been used to visualize the human *connectome*, the comprehensive map of all neural connections in the brain. Clinically, diffusion tractography detects damage to or displacement of white matter tracts resulting from trauma, vascular injury, or tumor. Tractography is also occasionally used in surgical planning to localize critical white matter tracts in order to avoid their transection during operations.

Functional Imaging

In the last decades, several techniques of functional imaging have been introduced to study the activation of regions of cerebral cortex during mental and physical

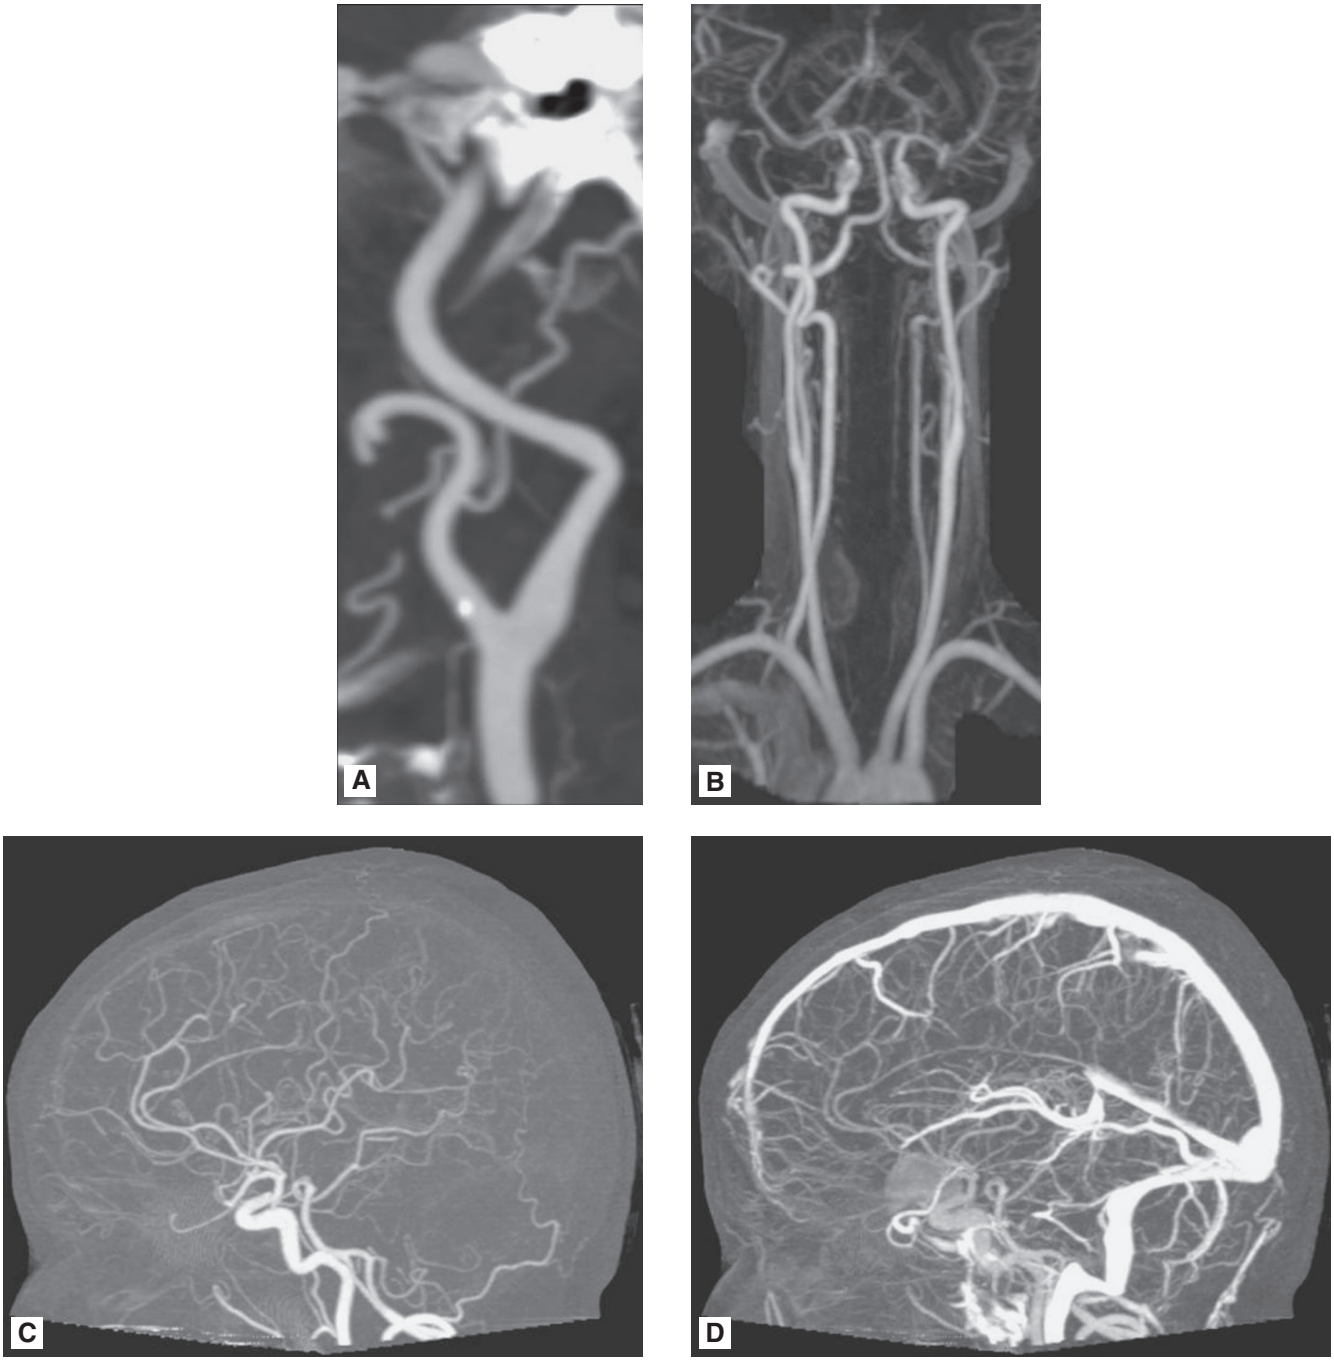

Figure 2-4. Intracranial and cervical angiography. *A*. Oblique CT angiogram of the neck showing the carotid bifurcation and the cervical segments of the internal and external carotid arteries. Note the slightly dilated carotid bulb at the initial segment of the internal carotid artery. A small focus of calcified atherosclerosis is noted near the origin of the external carotid artery. Note that the external carotid artery has multiple branches within the neck. *B*. Coronal MR angiogram of the neck showing the aortic arch, the origins and cervical courses of the carotid and vertebral arteries, and the vertebrobasilar junction. The sigmoid sinuses and internal jugular veins are faintly visible. *C–D*. Sagittal dynamic CT angiography of the head. Bony and soft tissue structures, as well as brain parenchyma, have been digitally subtracted. Image *C* was acquired during the arterial phase; the carotid and basilar termini and the anterior cerebral arteries are enhanced. Venous phase imaging (*D*) shows enhancement of the superior and inferior sagittal sinuses, straight sinus, vein of Galen, internal cerebral veins, basal veins of Rosenthal, and the transverse and sigmoid sinuses.

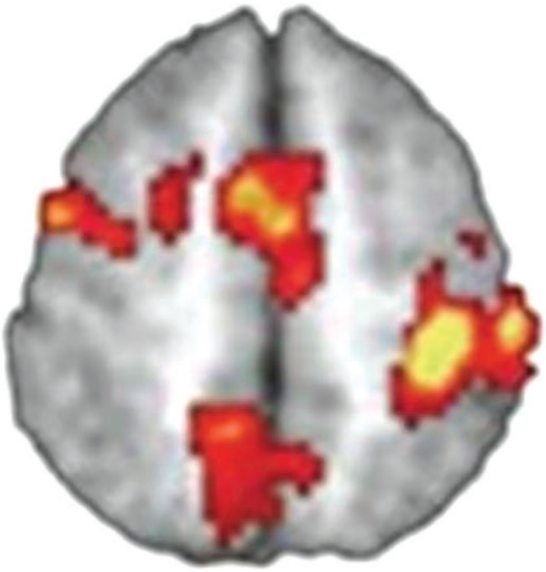

Figure 2-5. Blood oxygen level-dependent (BOLD) functional MRI. The image shown is from a subject performing repetitive motor functions (tapping a button) with his right finger. Superimposed upon the grayscale structural MRI image are areas of altered BOLD signal, in color, associated with the task. The most prominent signal (yellow) is in the left lateral cerebral cortex, corresponding to the right-hand area of the precentral and postcentral gyri. Other sites of lesser signal (red, orange) include the supplementary motor area, which is near the midline anteriorly. (Reprinted by permission from Springer Nature: Springer. Nature Neuroscience. Coherent spontaneous activity accounts for trial-to-trial variability in human evoked brain responses. Michael D Fox et al. © 2006.)

actions or experiences. The MRI-based functional imaging technique (*functional MRI* or *fMRI*) shows changes in local cerebral blood oxygenation, a surrogate for local neuronal metabolic activity. These changes are quantified as the blood oxygen level-dependent (BOLD) signal and evolve over 10 to 15 s following a change in neuronal activity (Fig. 2-5). In addition to its research application in cognitive neuroscience, this technique also has clinical utility, including presurgical planning in tumor and epilepsy surgery. Functional MRI data paired with connectome maps has been used to visualize task-associated and resting state network activation maps in the brain (Fox and colleagues).

Positron emission tomography (PET) produces images that reflect the regional concentration of systemically administered radioactive compounds. Positron emitting isotopes (mainly ^{11}C, ^{18}F, and ^{15}O) are produced in a cyclotron or linear accelerator, incorporated into biologically active compounds (radioligands), and injected into the patient. The concentration of these tracers in various parts of the brain is determined by an array of radiation detectors and tomographic images are constructed by techniques similar to those used in CT and MRI.

Local patterns of cerebral blood flow, oxygen uptake, and glucose utilization can also be measured by PET, and the procedure has proved to be of value in both detecting and grading brain tumors, distinguishing tumor tissue from radiation necrosis, localizing epileptic foci, and, in differentiating types of degenerative diseases. The technique has been applied to specially labeled ligands of beta-amyloid and tau, producing images of the deposition of these proteins in Alzheimer disease. This approach may become increasingly important in the study of degenerative diseases and their response to treatment. The ability of the technique to quantitate neurotransmitters and their receptors also promises to be of importance in the study of Parkinson disease and other degenerative conditions. A representative PET of the brain is shown in Fig. 2-6.

Single-photon emission computed tomography (SPECT), a similar technique, uses isotopes that do not require a cyclotron for their production. Radioligands (usually containing iodine) are incorporated into biologically active compounds, which, as they decay, emit a single photon. This procedure allows the study of regional cerebral blood flow under conditions of cerebral ischemia and in degenerative diseases of the cortex or during increased tissue metabolism (e.g., seizures and actively growing tumors). Once injected, the isotope localizes rapidly in the brain, with regional absorption proportional to blood flow, and is then stable for an hour or more. It is thus possible, for example, to inject the isotope at the time of a seizure while the patient is undergoing video and electroencephalographic monitoring, and to scan the patient soon after. The limited anatomic resolution provided by SPECT limits its clinical usefulness, but it is more easily available than other functional imaging techniques. PET and SPECT techniques that use I^{123} labeled dopamine offer the possibility of imaging striatal dopamine and assisting in the diagnosis of parkinsonian disorders (see Chap. 38).

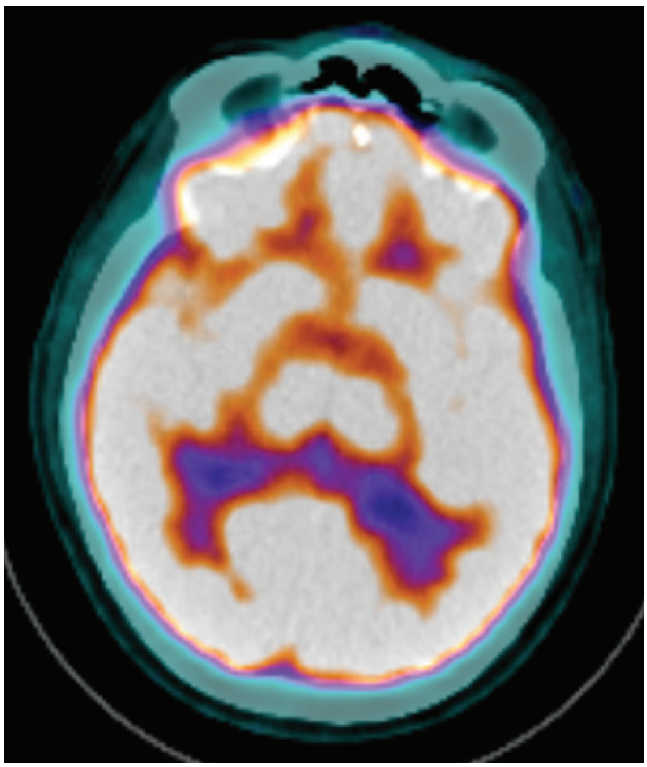

Figure 2-6. Axial ^{18}FDG-PET of a normal brain. The PET data is colorized and overlaid on a CT image. Brain areas with higher metabolic activity such as cortex and deep gray nuclei appear bright, and areas with lower metabolic activity such as white matter appear purple.

Ultrasonography

An ultrasound technique may be used to insonate the cervical carotid and vertebral arteries and the temporal arteries for the study of cerebrovascular disease. Their greatest use is in detecting and estimating the degree of stenosis of the origin of the internal carotid artery. In addition to providing an acoustic image of the vascular structures, the Doppler frequency shift caused by the flowing RBCs creates a display of velocities at each site in a vessel. The two techniques combined have been called "carotid duplex"; they allow an accurate localization of the locus of maximal stenosis as reflected by the highest rates of flow and turbulence. The display scale for the Doppler shift is color coded so as to make the insonated image and flow map easier to view and interpret.

This ultrasound technique using different sound frequencies and intensities has also become a principal methodology for the clinical study of the fetal and neonatal brain. Different tissues have specific acoustic impedances and send echoes back to the transducer, which displays them as waves of variable height or as points of light of varying intensity. In this way, one can obtain images in the neonate of choroid plexus, ventricles, and central nuclear masses. Usually, several coronal and parasagittal views are obtained by placing the transducer over open fontanelles or the child's thin calvarium. Intracerebral and subdural hemorrhages, mass lesions, and congenital defects can readily be visualized.

Similar instruments are used to insonate the basal vessels of the circle of Willis in adults ("transcranial Doppler"). The transcranial Doppler uses a 2-MHz pulsed signal that is able to pass through the calvarial bone and then receives a frequency-shifted signal from the blood flowing in the lumen of the basal vessels. This allows the detection of vascular stenoses and the greatly increased blood flow velocity caused by vasospasm from subarachnoid hemorrhage.

Ultrasound has several advantages, notably that it is noninvasive, harmless (hence can be used repeatedly, but caution is required in applying it to the globe), convenient because of the portability of the instrument, and inexpensive. More specific applications of this technique are discussed in Chap. 37, on developmental diseases of the nervous system, and in Chap. 33, on stroke. The related technique of echocardiography has also assumed a central role in the evaluation of stroke, as indicated in Chap. 33.

ELECTROENCEPHALOGRAPHY (EEG)

The electroencephalographic examination, for many years a standard laboratory procedure in the study of all forms of cerebral disease, has been supplanted by CT and MRI for the purposes of localization of structural lesions. It continues to be an essential part of the assessment of patients with seizures and those suspected of having seizures, as well as in brain death, and for the study of sleep (polysomnography) as described in the American Electroencephalographic Society Guidelines. It is also used in evaluating the encephalopathy of many systemic metabolic diseases and in the operating room to monitor cerebral activity in anesthetized patients. For a few diseases, such as Creutzfeldt-Jakob (prion) disease, it is a useful adjunctive laboratory test. The technique is described here in some detail, as its general use in neurology cannot suitably be assigned to any other single chapter.

The electroencephalograph was developed by Hans Berger in 1929. It records spontaneous electrical activity generated in the cerebral cortex. This activity reflects the electrical currents that flow in the extracellular spaces of the brain that are the summated effects of innumerable excitatory and inhibitory synaptic potentials upon cortical neurons. This spontaneous activity of cortical neurons is highly influenced and synchronized by subcortical structures, particularly the thalamus and high brainstem reticular formation. Efferent impulses from these deep structures are probably responsible for entraining cortical neurons to produce characteristic rhythmic brain-wave patterns, such as alpha rhythm and sleep spindles (see further on).

Electrodes, which are typically silver or silver-silver chloride discs 0.5 cm in diameter, are placed on the scalp using a conductive medium. The electroencephalograph has 8 to 32 or more amplifying units capable of recording from many areas of the scalp at the same time. The amplified brain rhythms are seen as waveforms of brain activity in the frequency range of 0.5 to 30 Hz (cycles per second) on a standard display that runs at 3 cm/s. In the past, the amplified signals were recorded on paper by a bank of pens, but now, a digital format of the rhythms can be displayed on a computer screen and stored electronically. MRI-compatible EEG electrodes are available.

The favored configuration of electrode pairs, or montage, is the "International 10-20" system, which uses 10 electrodes on each side of the cranium and emphasizes contiguous regions of the brain for ease of visual inspection of the record (Fig. 2-7*A*).

The resulting EEG, essentially a voltage-versus-time graph, consists of a number of simultaneous parallel wavy lines, or "channels" (Fig. 2-7*B*). Each channel represents the difference in electrical potential between two electrodes (a common or ground electrode may be used as one recording site, but the channel still represents a bipolar recording). A positive voltage potential deflects the signal downward, and a negative one upward by convention. The channels are arranged for viewing into standard montages that generally allow comparison of the activity from one region of the cerebral cortex to others and particularly to the corresponding region of the contralateral hemisphere.

Patients are usually examined with their eyes closed and while relaxed. Consequently, the ordinary EEG represents the electrocerebral activity that is recorded under restricted circumstances, usually during the waking or sleeping state, from several parts of the cerebral convexities during an almost infinitesimal segment of the person's life.

In addition to the resting record, a number of activating procedures are usually employed. First, the patient is asked to breathe deeply 20 times a minute for 3 min.

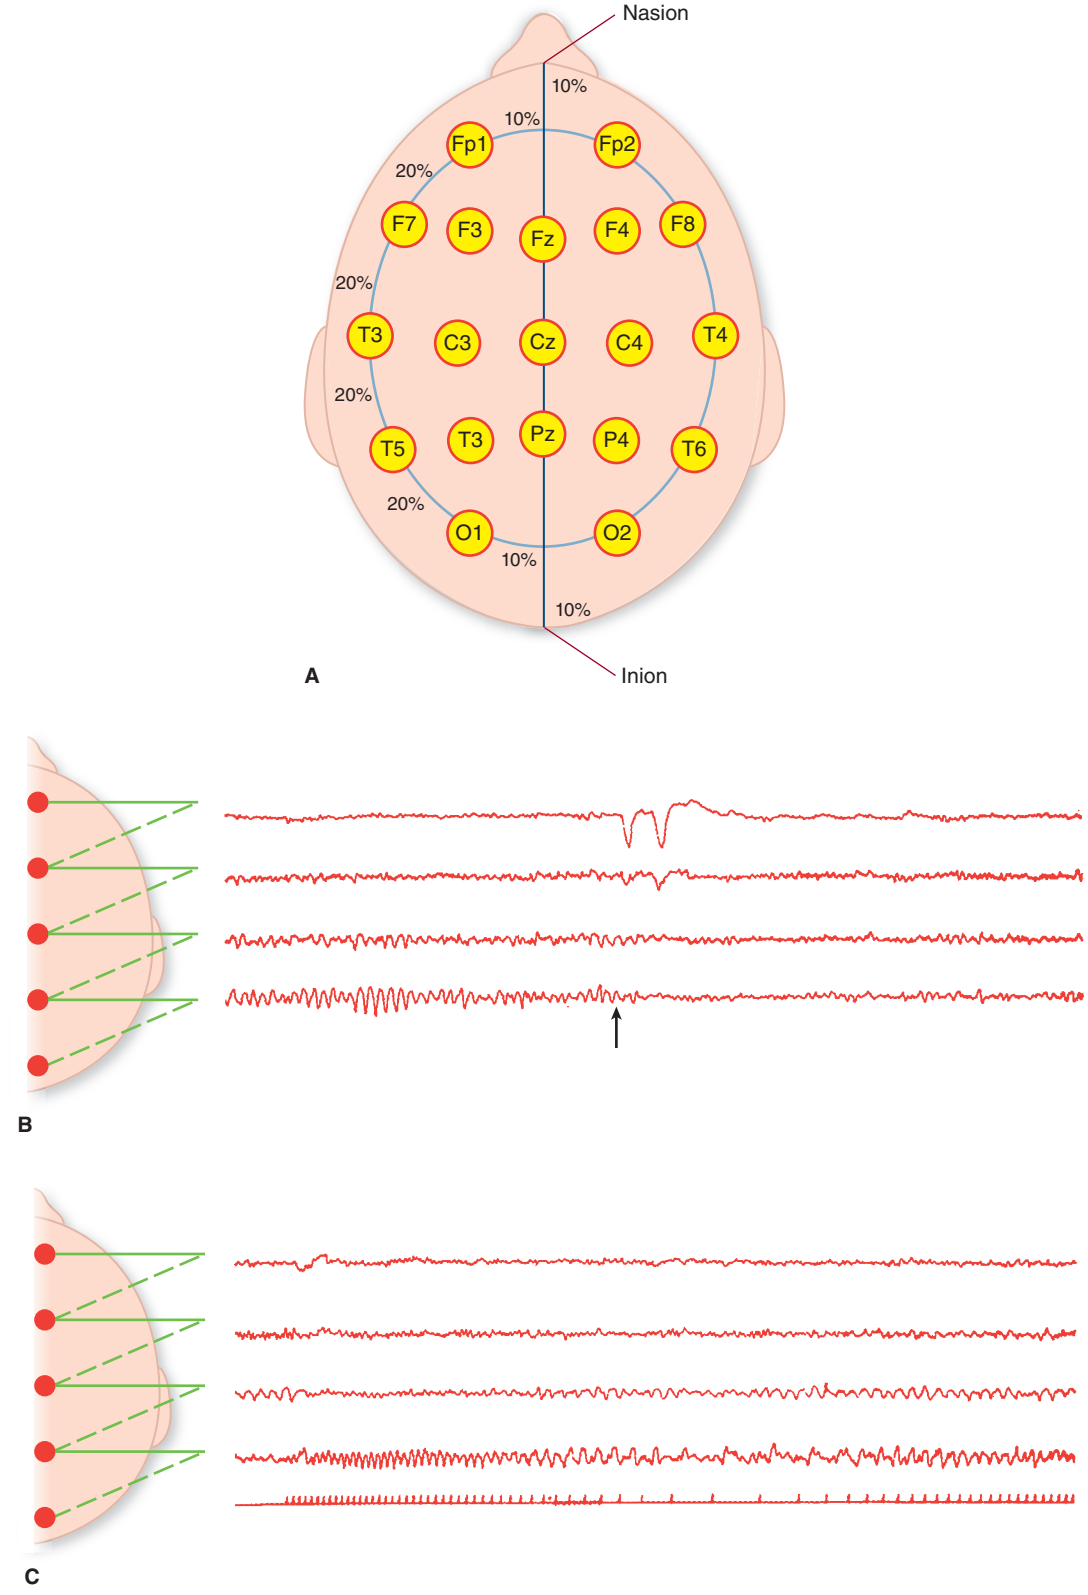

Figure 2-7. *A.* "10-20" is a measurement system designed to reliably reproduce electrode positions on different patients, regardless of head size. Electrodes are placed at intervals of either 10 or 20 percent of the hemi-circumference of the head. (Reproduced with permission from Dr. Jay S. Pathmanathan.) *B.* Each channel represents the amplified recording of voltage changes over time between two electrodes. Normal alpha (8 to 12 per second) activity is present posteriorly (bottom channel). The top channel contains a large blink artifact. Note the striking reduction of the alpha rhythm with eye opening (*arrow*). *C.* Photic driving. During stroboscopic stimulation of a normal subject, a visually evoked response is seen posteriorly after each flash of light (signaled on the bottom channel). (*continued*)

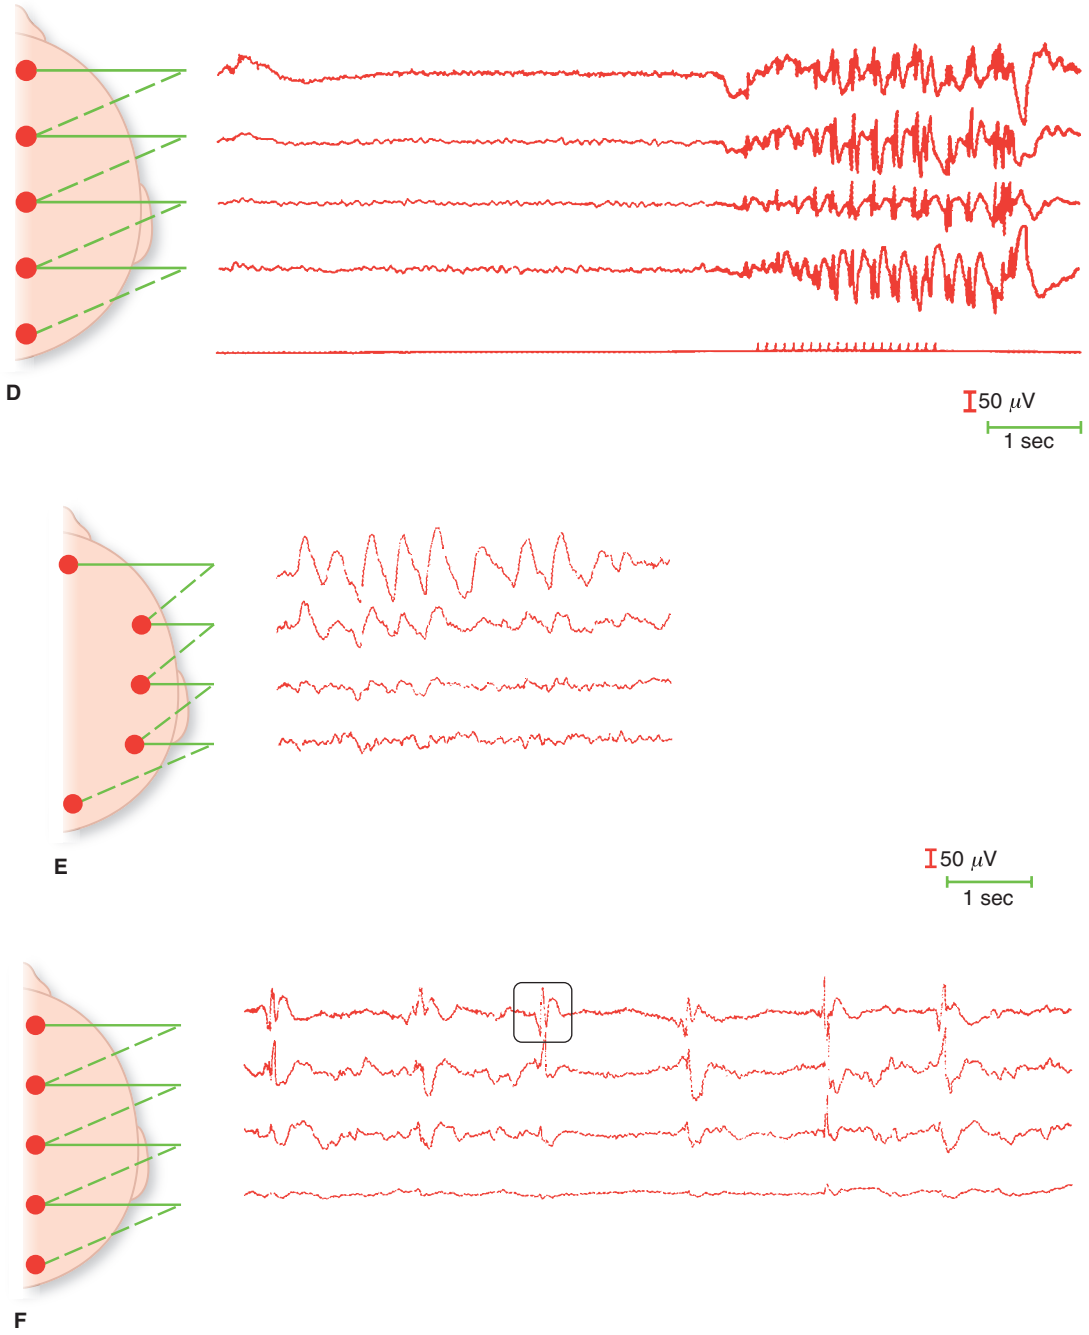

Figure 2-7. (*Continued*) *D*. Stroboscopic stimulation at 14 flashes per second (bottom channel) has produced a photoparoxysmal response in this epileptic patient, evidenced by the abnormal spike and slow-wave activity toward the end of the period of stimulation. *E*. Large, slow, irregular delta waves are seen in the right frontal region (channels 1 and 2). In this case, a glioblastoma was found in the right cerebral hemisphere, but the EEG does not differ basically from that produced by a stroke, abscess, or contusion. *F*. An EEG is showing focal spike-and-wave discharges over the right frontal region (channels 1 to 3). The box isolates a single spike–wave transient. (*continued*)

Hyperventilation, through a mechanism yet to be determined, may activate characteristic seizure patterns or other abnormalities. Second, a powerful strobe light is placed about 15 inches from the patient's eyes and flashed at frequencies of 1 to 20 per second with the patient's eyes open and closed. In a healthy subject, the occipital EEG leads show waves corresponding to each flash of light (photic driving, Fig. 2-7*C*).

The EEG is recorded while the patient is drowsy and after the patient is allowed to fall asleep. The drowsy state and the transition to and from deeper stages of sleep can reveal abnormalities.

Many abnormalities associated with sleep are more evident with long-term, continuous EEG monitoring (hours to days) as described in Chap. 18. EEG activity can be synchronized with videographically recorded seizure

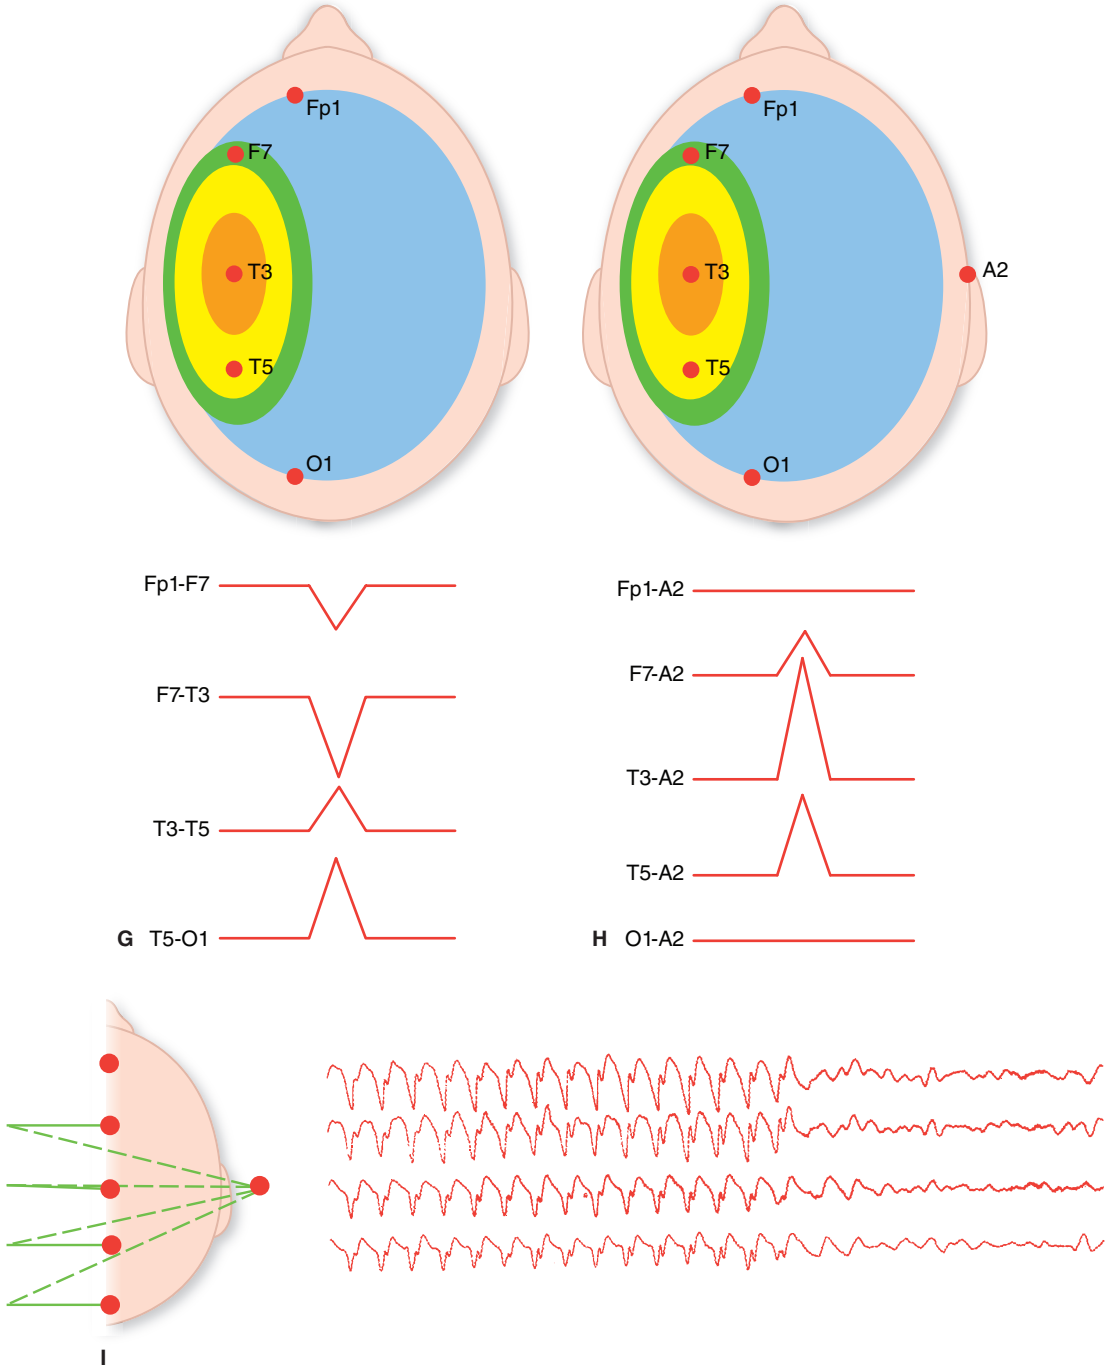

Figure 2-7. (*Continued*) *G.* Phase reversal is shown between electrode pairs, F7-T3 and T3-T5, implying that the site of the spike generator is under the T3 electrode. (Reproduced with permission from Dr. Jay S. Pathmanathan.) *H.* Localization of a spike in a montage that utilizes the right ear (A2) as a reference electrode. The amplitude of the transient at T3 is greater than at other locations, implying that the source of the spike is closest to the T3 electrode. (Reproduced with permission from Dr. Jay S. Pathmanathan.) *I.* Absence seizures, showing generalized 3-per-second spike-and-wave discharge. The abnormal activity ends abruptly and normal background activity appears. (*continued*)

activity in order to characterize the nature of a seizure. EEGs recorded by small digital devices or telemetry from freely moving ambulatory patients may be similarly useful in cases of suspected seizure disorders. Chapter 15 discusses these techniques in detail. Chapter 18 contains information on the use of EEG to analyze disorders of sleep (polysomnography).

Certain preparations are necessary if electroencephalography is to be most useful. The patient should not be sedated and should not have been without food for a long time, for both sedative drugs and relative hypoglycemia may modify the normal EEG pattern, and caffeine should be avoided if a sleep EEG study is planned. When dealing with patients who are suspected of having epilepsy and

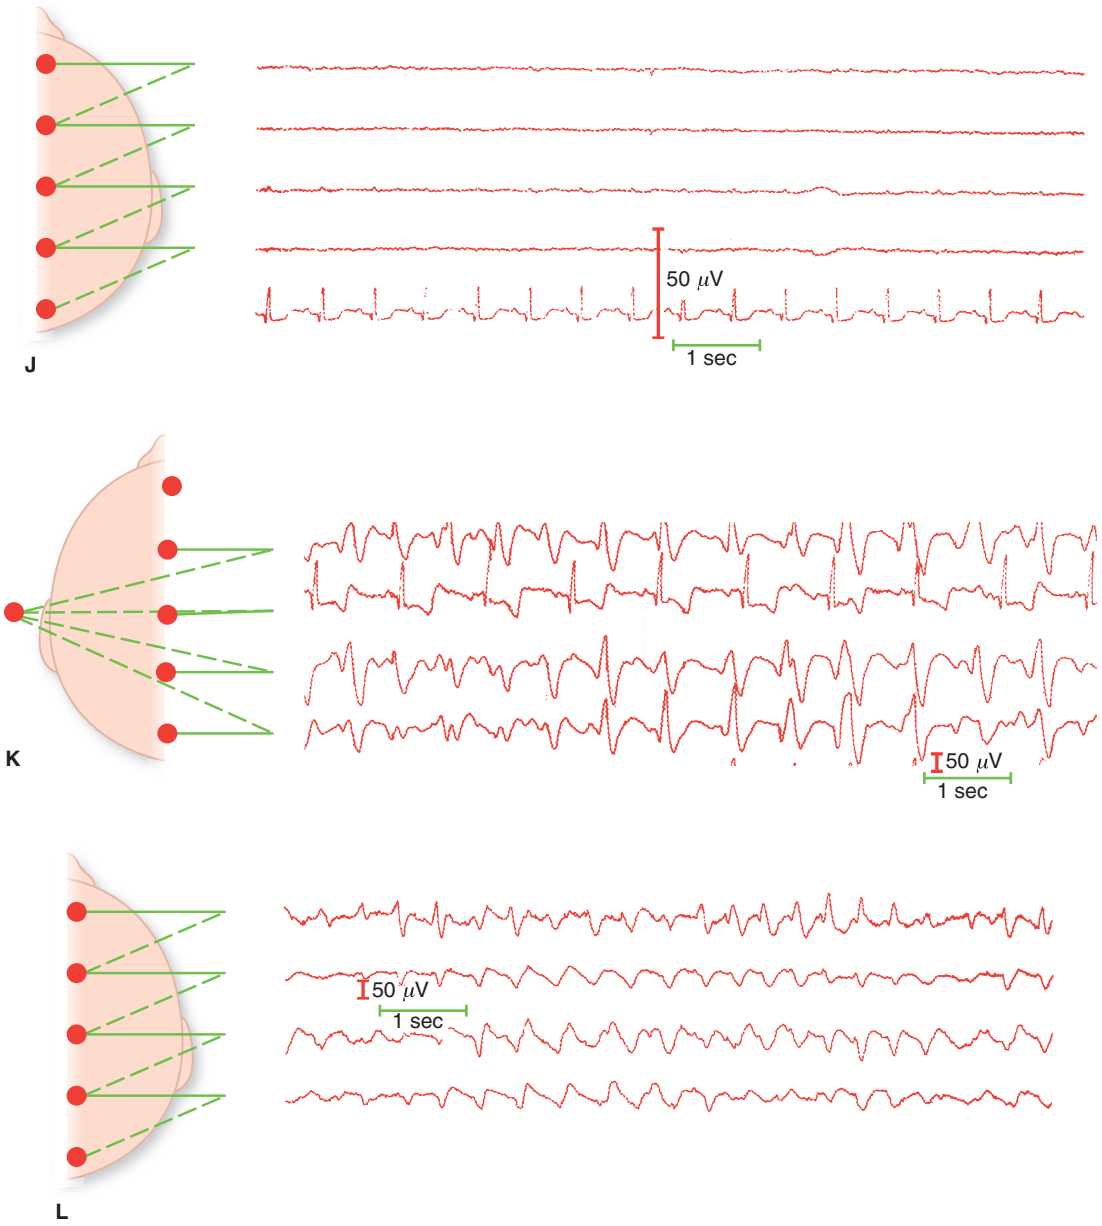

Figure 2-7. (*Continued*) *J*. Deep coma following cardiac arrest, showing electrocerebral silence. With the highest amplification, electrocardiogram (ECG) and other artifacts may be seen so that the record is not truly "flat" or isoelectric. However, no cerebral rhythms are visible. Note the ECG (lower channel). *K*. Grossly disorganized background activity interrupted by repetitive "pseudoperiodic" discharges consisting of large, sharp waves from all leads about once per second. This pattern is characteristic of Creutzfeldt-Jakob disease. *L*. Advanced hepatic coma. Slow (about 2 per second) waves have replaced the normal activity in all leads. This record demonstrates the triphasic waves often seen in this disorder.

are already being treated for it, most physicians prefer to record the EEG while the patient continues to receive antiepileptic medications. During inpatient monitoring, these drugs are often temporarily weaned or discontinued in order to increase the likelihood of recording a seizure discharge, but this requires careful clinical monitoring.

The interpretation of EEGs involves the recognition of several characteristic normal and abnormal patterns and background rhythms (in accordance with the age of the patient), the detection of asymmetries and periodic changes in rhythm, and, importantly, the differentiation of artifacts from genuine abnormalities.

Normal EEG Patterns

The normal record in adults shows slightly asymmetrical 8- to 12-per-second 50-mV sinusoidal *alpha waves* in both occipital and posterior parietal regions. These waves wax and wane in amplitude spontaneously and are attenuated or suppressed completely with eye opening or mental activity (see Fig. 2-7*B*). In contrast, the frequency of the alpha rhythm is almost invariant for an individual patient, although the rate slows with aging. Waves faster than 12 Hz and of lower amplitude (10 to 20 mV), called *beta waves*, are normally recorded from the frontal

regions symmetrically. If benzodiazepines or other sedating drugs have been administered, an increase in the fast frequencies is typically observed. When the normal subject falls asleep, the alpha rhythm slows symmetrically and characteristic waveforms consisting of vertex sharp waves and sleep spindles appear (see Fig. 18-1). A small amount of theta (4- to 7-Hz) activity may normally be present over the temporal regions, somewhat more so in persons older than 60 years of age. Delta (1- to 3-Hz) activity is not present in the normal waking adult.

The presence of a photic driving response indicates that some of the visual pathways are preserved. Spread of the occipital response induced by photic stimulation, with the production of abnormal sharp or paroxysmal waves, provides evidence of abnormal cortical excitability (Fig. 2-7*D*). Seizure patterns may be produced during this type of EEG testing, accompanied by gross myoclonic jerks of the face, neck, and limbs (photomyoclonic response), by electrographic seizure activity that outlasts the photic stimulation (photoparoxysmal response), or by a convulsion (photoconvulsive response). Such effects occur often during periods of withdrawal from alcohol and other sedative drugs.

Children and adolescents are more sensitive than adults to all the activating procedures previously mentioned. It is customary for children to develop delta waves (3 to 4 Hz) during the middle and latter parts of a period of hyperventilation. This EEG activity, referred to as "breakdown" or "buildup," disappears soon after hyperventilation has stopped. The frequency of the dominant rhythms in infants is normally about 3 Hz, and they are very irregular. With maturation, there is a gradual increase in frequency and regularity of these occipital rhythms; an alpha rhythm appears by age 6 years and the adult frequency is reached by the age of 10 to 12 years (see Chap. 27 for further discussion of maturation of the brain as expressed in the EEG). The interpretation of records of infants and children requires considerable experience because of the wide range of normal patterns at each age period (Hahn and Tharp, and Ebersole and colleagues). Nevertheless, grossly asymmetrical records or seizure patterns are clearly abnormal in children of any age. Normal patterns in the fetus, from the seventh month onward, have been established. Certain changes in these patterns are indicative of a developmental disorder or disease (Stockard-Pope and colleagues, and deWeerd).

Types of Abnormal Recordings

Localized regions of greatly diminished or absent brain waves are seen overlying large areas of cerebral infarction, traumatic necrosis, tumor, or extensive clot. These findings allow gross localization of the abnormality—but, of course, the nature of the lesion is not disclosed. Two types of abnormal waves, already mentioned, are of lower frequency and higher amplitude than normal. Waves below 4 Hz with amplitudes from 50 to 350 mV are called *delta waves* (Fig. 2-7*E*); those with a frequency of 4 to 7 Hz are called *theta waves*. Fast (beta) activity tends to be prominent frontally and usually reflects the effects of sedative drugs or, if focal, an immediately underlying skull defect called a "breach rhythm" (bone normally filters the abundant fast activity of the cortex).

Spikes are transient high-voltage waveforms that have a pointed peak at recording speeds and a duration of 20 to 70 ms; a sharp wave is a similarly configured transient with a duration of 70 to 200 ms (Fig. 2-7*F*). Spikes or sharp waves that occur interictally are referred to as *epileptiform discharges*. At times, it is possible to infer localization from the reversal of the polarity of a sharp transient or spike in the EEG record. This "phase reversal" between two channels implies that the electrical activity originates near the site of the position of the common electrode (Fig. 2-7*G, H*).

The paroxysmal interruption of normal background EEG activity by a run of fast or slow waves is suggestive of seizures. When this paroxysmal discharge is composed of spikes and sharp waves, it signifies a seizure with greater certainty. The electrical discharges associated with absence seizures have a more stereotyped pattern of 3-per second spike-and-wave complexes that characteristically appear abruptly in all leads of the EEG simultaneously and disappear almost as suddenly at the end of the seizure (Fig. 2-7*I*).

The absence of EEG activity, or "electrocerebral silence," is a component of brain death but may be simulated by deep sedation with drugs or by profound hypothermia (Fig. 2-7*J*). Artifacts of various types should be apparent as the amplifier gains are increased; if not, there is a risk that the leads are not properly connected to the machine or of another technical fault. In the absence of nervous system depressants or extreme degrees of hypothermia, a record that is isoelectric (<2 uV except for artifacts) over all parts of the head is almost always a result of profound cerebral hypoxia, ischemia, massive cerebral hemorrhage or of trauma and raised intracranial pressure. Such a patient—without EEG activity, brainstem reflexes, and spontaneous respiratory or muscular activity of any kind—is said to be brain dead, as discussed in Chap. 16.

Neurologic Conditions Causing Abnormal Electroencephalograms

Epilepsy

Epileptic seizures (see Chap. 15) are almost by definition associated with some abnormality in the EEG provided that it is being recorded at the time of the seizure. Rare exceptions are seizure states that originate in deep temporal, medial, or orbital frontal foci, from which the discharge fails to reach the scalp in sufficient amplitude to be seen against the normal background activity of the EEG. Most often, a completely normal EEG during a convulsion indicates a *psychogenic nonepileptic seizure* (*PNES*).

Some of the different types of seizure patterns are shown in Fig. 2-7*F* and *I* are associated with particular clinical syndromes in Chap. 16. The absence, myoclonic, and grand mal EEG patterns correlate closely with the clinical seizure type and may be present in milder form in the EEG during periods between clinically evident seizures (interictally). Seizures appear as generalized discharges throughout the cerebrum or as localized to one region.

Between seizures, a single EEG recording will show a normal pattern in as many as 30 percent of patients with absence seizures and 50 percent of those with generalized tonic-clonic (grand mal) epilepsy (this percentage is less with repeated recordings). Antiepileptic therapy may mask interictal EEG abnormalities, but the extent to which this occurs is not known. The records of 30 to 40 percent of those with epilepsy, although abnormal between seizures are nonspecifically so; consequently, the diagnosis of epilepsy can be made only by the correct interpretation of clinical data in relation to the EEG abnormality.

Focal Brain Lesions (Brain Tumor, Abscess, Subdural Hematoma, Stroke, and Encephalitis)

In a high proportion of patients, intracranial mass lesions are associated with focal or localized slow-wave activity (usually delta, as in Fig. 2-7*E*) or, occasionally, seizure activity. EEG is of considerable value in the diagnosis of herpes simplex encephalitis in which periodic high-voltage sharp waves and slow-wave complexes at intervals of 1 to 3 per second in the temporal regions are characteristic. The other encephalitides are also often associated with sharp or spike activity, particularly if there have been seizures. The EEG is particularly helpful in the diagnosis of prion disease as also noted below. Figure 2-7*K* shows the characteristic pattern of almost periodic sharp waves seen in Creutzfeldt-Jakob disease.

The EEG is now little used in the differential diagnosis of stroke, except to distinguish a transient ischemic attack from a seizure. In the past, one practical value was in the ability to differentiate an acute ischemic lesion in the distribution of the middle cerebral artery, which produces a large area of slowing, from lacunar infarction deep in the cerebrum or brainstem, in which the surface EEG is usually normal despite prominent clinical abnormalities. After 3 to 6 months, in roughly 50 percent of patients with infarction in the territory of the middle cerebral artery, the focal EEG slowing becomes normal. Perhaps half of these patients will have had normal EEGs even in a week or two following the stroke. A persistent abnormality is generally associated with a poor prognosis for further recovery. Large lesions of the diencephalon or midbrain produce bilaterally synchronous slow waves, but those of the pons and medulla (i.e., below the mesencephalon) are usually associated with a normal or near-normal EEG pattern despite catastrophic clinical changes.

A brief episode of cerebral concussion in animals produces focal EEG slowing similar to those described for cerebral infarction. Sharp waves or spikes sometimes emerge as the focal slow-wave abnormality resolves and these seizure-like changes may precede posttraumatic epilepsy; serial EEGs may be of value in this regard. During syncope, the EEG is slowed and of reduced amplitude even to the point of becoming "flat." Upon recovery, a number of patterns have been described, as discussed further in Chap. 17.

Diseases That Cause Coma and States of Impaired Consciousness

The EEG is abnormal in almost all conditions in which there is an impairment of the level of consciousness. There is, for example, a fairly close correspondence between the severity of acute anoxic damage from cardiac arrest and the degree of EEG slowing. The mildest forms are associated with generalized theta activity, intermediate forms with widespread delta waves and the loss of normal background activity, and the most severe forms with *burst suppression*, in which brief isoelectric periods are followed by high-voltage sharp and irregular delta activity. The latter pattern usually progresses to the electrocerebral silence of brain death, a condition discussed earlier.

The term *alpha coma* refers to a unique EEG pattern in which an apparent alpha activity in the 8- to 12-Hz range is distributed widely over the hemispheres rather than in its normal location posteriorly. When analyzed carefully, this background activity, unlike the normal monorhythmic alpha, is found to vary slightly in frequency. This is usually a transitional pattern after global anoxia; less often, alpha coma occurs with large acute pontine lesions. With severe hypothyroidism, the brain waves are normal in configuration but usually of decreased amplitude and frequency.

In altered states of alertness, the more profound the depression of consciousness, in general, the more abnormal and slower the EEG rhythms. In states of deep stupor or coma, the slow (delta) waves are bilateral and of high amplitude and tend to be more conspicuous over the frontal regions (Fig. 2-7*L*). This pertains in such differing conditions as acute meningitis or encephalitis and disorders that severely alter blood gases, glucose, electrolytes, and water balance; uremia; diabetic coma; and impairment of consciousness accompanying the large cerebral lesions discussed above. In hepatic coma, the degree of abnormality in the EEG corresponds roughly to the degree of confusion, stupor, or coma. Characteristics of hepatic coma are paroxysms of bilaterally synchronous large, sharp *triphasic waves* (Fig. 2-7*L*), although such waveforms may also be seen with less regularity in encephalopathies related to renal or pulmonary failure and with acute hydrocephalus (intermittent biphasic frontal slowing is more typical of hydrocephalus).

An EEG may also be of help in the diagnosis of coma that is due to ongoing seizures ("nonconvulsive status epilepticus") or when the pertinent history is not available and there was an unobserved convulsion. It may also point to an otherwise unexpected cause of coma, such as hepatic encephalopathy, intoxication with barbiturates or other sedative-hypnotic drugs, the effects of diffuse anoxia–ischemia, catatonia, or hysteria (in which the EEG is normal).

Diffuse Degenerative Diseases

Alzheimer disease and other degenerative diseases that cause serious impairment of cerebrocortical function are accompanied by relatively slight degrees of diffuse slow wave abnormality in the theta (4- to 7-Hz) range; many recordings are normal in the early and midstages of illness. More rapidly progressive disorders—such as SSPE, Creutzfeldt-Jakob disease, and to a lesser extent the cerebral lipidoses—often have, in addition, very characteristic and almost pathognomonic EEG changes consisting of periodic bursts of high-amplitude sharp waves, usually bisynchronous and symmetrical (Fig. 2-7*K*). In a negative

sense, a normal EEG in a patient who is profoundly apathetic is a point in favor of the diagnosis of hysteria, catatonia, or schizophrenia.

Other Diseases of the Cerebrum

Many disorders of the brain cause little or no alteration in the EEG. Multiple sclerosis and other demyelinating diseases are examples, although as many as 50 percent of patients with advanced disease will have an abnormal record of nonspecific type (mild focal or diffuse slowing). Delirium tremens and Wernicke-Korsakoff disease, despite the dramatic nature of the clinical picture, cause little or no change in the EEG. Interestingly, the psychoses (bipolar disorders or schizophrenia), intoxication with hallucinogenic drugs such as lysergic acid diethylamide (LSD), and the majority of cases of mental retardation are associated either with no modification of the normal record or with only minor nonspecific abnormalities unless seizures are present.

Clinical Significance of Minor Electroencephalogram Abnormalities

The gross EEG abnormalities discussed above are by themselves clearly abnormal, and any formulation of the patient's clinical state should attempt to account for them. Lesser degrees of abnormality form a continuum between the undoubtedly abnormal and the completely normal and are of correspondingly less significance. Findings such as 14- and 6-per-second positive spikes or small sharp waves during sleep, scattered 5- or 6-per second slowing, minor voltage asymmetries, and persistence of "breakdown" for a few minutes after hyperventilation are interpreted as normal variants or borderline abnormalities. Whereas borderline deviations in an otherwise entirely normal person have no clinical significance, the same minimal EEG findings associated with particular clinical signs and symptoms become important. The significance of a normal or "negative" EEG in certain patients suspected of having a cerebral lesion was discussed above.

As a general clinical principle, the results of the EEG, like those of the EMG and electrocardiogram, are meaningful only in relation to the illnesses under consideration and to the clinical state of the patient at the time the recordings were made.

EVOKED POTENTIALS

The stimulation of sense organs or peripheral nerves evokes an electrical response in the corresponding cortical receptive areas and in a number of subcortical relay stations. However, one cannot place a recording electrode near the nuclear relay stations, nor can one detect tiny potentials of only a few microvolts among the much larger background activity in the EEG. The use of computerized averaging methods, introduced by Dawson in 1954, has provided a means of overcoming these problems. Initially, emphasis was on the study of late waves (over 100 ms after the stimulus) because they are of high amplitude and easy to record. However, there is more clinical utility in recording the much smaller, short-latency waveforms, which are received at each nuclear relay within the main sensory systems. These waveforms are maximized by the computer to a point where their latency and voltage can easily be measured. One of the remarkable properties of evoked potentials is their resistance to anesthesia, sedative drugs, and in states of reduced consciousness such as hypoxic-ischemic encephalopathy. This permits their use for monitoring the integrity of cerebral pathways in situations that limit the value of the EEG.

The interpretation of evoked potentials (visual, auditory, and somatosensory) is based on the prolongation of the latencies of the waveforms after the stimulus, the interwave latencies, and asymmetries in timing. Norms for latencies have been established, but it is advisable to confirm these in each laboratory. Typically, 2.5 or 3 standard deviations above the mean latency for any measurement is taken as the definition of abnormal (Table 2-4). The amplitudes of the waves are less informative for clinical work.

Table 2-4

MAIN SENSORY EVOKED POTENTIAL LATENCIES FROM STIMULUS (MILLISECONDS)[a]

TYPE OF EVOKED POTENTIAL	MEAN	UPPER LIMIT (MEAN + 3 SD)
PSVER (*70-min check size*)		
P100 absolute latency	104	118
Intereye difference	2	8
BAER (*60 dBSL, 10/s monaural stimuli*)		
Interwave latency		
I–III	2.1	2.6
III–V	1.9	2.4
I–V	4.0	4.7
Interside difference for most latencies	0.1	0.4
SEP—median nerve (*wrist stimulation*)		
Absolute latency		
Erb's point	9.7	12.0
P/N 13 (cervicomedullary)	13.5	16.3
N 19/P 21 (cortical)	19.0	22.1
Interwave latency		
Erb's-P/N 13	3.8	5.2
P/N 13–N 19	5.5	6.8
Interside difference		
P/N 13–N 19	0.3	1.1
SEP—tibial nerve (*ankle stimulation; Fz-Cz recording; 165-cm height; absolute latencies are shorter for stimulation at the knee*)		
Absolute latency		
Lumbar point (cauda equina)	20	25
N/P 37 (cortex)	36	42.5
Interwave latency		
Lumbar–N/P 37	16.4	21.6
Interside difference		
Lumbar–N/P 37	0.7	1.9

BAER, brainstem auditory evoked response; PSVER, pattern shift visual evoked response; SSEP, somatosensory evoked response.

[a]Norms must be verified in each laboratory; in most instances they are sensitive to the technique and stimulus used and height of the patient in the cases of limb stimulation.

Visual Evoked Potentials

For many years it had been known that a light stimulus flashing on the retina evokes a discernible waveform over the occipital lobes. In the EEG, such responses to fast rates of stimulation are referred to as the occipital driving response (Fig. 2-7*C*). It is also appreciated that a visual evoked response is produced by the sudden change of a viewed checkerboard pattern. These responses, produced by rapidly reversing the pattern of black and white squares, are easier to detect and to measure than are flash responses and are more consistent in waveform from one individual to another. The pattern shift stimulus, applied first to one eye and then to the other, can demonstrate conduction delays in the visual pathways of patients who have had disease of the optic nerve—even when there are no residual signs of reduced visual acuity, visual field abnormalities, alterations of the optic nerve head, or changes in pupillary reflexes. Furthermore, the presence of a normal visual evoked response suggests that blindness is not due to a lesion in the anterior visual pathways and their projections to the occipital cortex, for example, in hysterical blindness. Figure 2-8 illustrates the normal pattern shift visual evoked response (PSVER) and two types of delayed responses. Reductions in the amplitude and duration of PSVER usually accompany prolonged latencies but are difficult to quantify. By presenting the pattern-shift stimulus to one hemifield, it is possible to isolate a lesion to an optic tract or radiation or one occipital lobe, but with much less precision than that provided by the usual monocular testing.

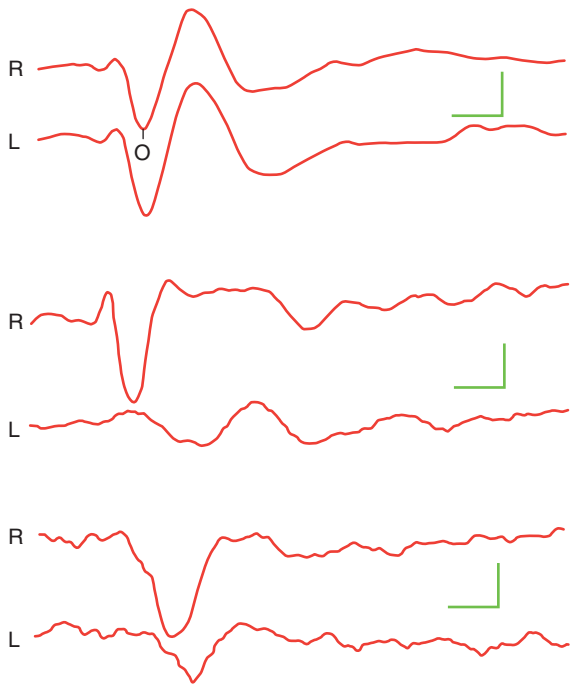

Figure 2-8. Pattern-shift visual evoked responses (PSVERs). Latency is measured to the first major positive peak (termed P100 because of its latency from the stimulus of approximate 100 ms) and marked by "o." Upper two tracings: These, from the right and left eyes, are normal. Middle tracings: PSVER from the right eye is normal, but the latency of the response from the left eye is prolonged and its duration is increased. Lower tracings: PSVER from both eyes show abnormally prolonged latencies, somewhat greater on the left than on the right. Calibration: 50 ms, 2.5 mV.

The expected latency for the positive wave, by convention a downward deflection, is near 100 ms (thus the term P100 has also been used to designate the waveform); an absolute latency from the stimulus longer than 118 ms or a difference in latencies of greater than 9 ms between the two eyes signifies involvement of one optic nerve (see Table 2-4). Bilateral prolongation of latencies, demonstrated by separate stimulation of each eye, can be caused by lesions in both optic nerves, the optic chiasm, or the visual pathways posterior to the chiasm.

As indicated above, PSVER is especially valuable in proving the existence of active or residual disease of an optic nerve. Patients with previous optic neuritis almost invariably have prolonged latencies. Furthermore, prolongations of PSVER are found in about one-third of multiple sclerosis patients who have had no history or clinical evidence of optic nerve involvement. This acquires significance in that the finding of abnormal PSVER in a patient with a clinically apparent demyelinating lesion elsewhere in the CNS may usually be taken as evidence of multiple sclerosis, as discussed in Chap. 37.

A compressive lesion of an optic nerve will have the same effect as a primarily demyelinating one. Many other diseases of the optic nerves—including toxic and nutritional amblyopias, ischemic optic neuropathy, and the Leber type of hereditary optic neuropathy—show abnormalities of the PSVER. Glaucoma and other diseases of the eye, if severe enough to affect the optic nerve, may also produce increased latencies. Impaired visual acuity has little effect on the latency but does correlate well with the amplitude of the PSVER (a property that is exploited in some computerized testing for visual acuity).

Brainstem Auditory Evoked Potentials

The effects of auditory stimuli can be studied in the same way as visual ones by a procedure called brainstem auditory evoked responses or potentials (BAERs or BAEPs). Between 1,000 and 2,000 clicks, delivered first to one ear and then to the other, are recorded through scalp electrodes and superimposed on each other by computer and thereby maximized. A series of seven waves appear at the scalp within 10 ms after each stimulus. On the basis of depth recordings and the study of lesions produced in cats, as well as pathologic studies of the brainstem in disease, it has been established that each of the first five waves is generated by a specific brainstem structure, as indicated in Fig. 2-9. The generators of waves VI and VII, in particular, are uncertain. The presence of wave I and its absolute latency test the integrity of the auditory nerve.

Clinical interpretations of BAERs are based mainly on latency measurements from the stimulus and interwave latencies. The most important is the interwave latencies between I and III, and III and V (see Table 2-4). A lesion that affects one of the auditory nuclear relay stations or its immediate connections manifests itself by a delay in the appearance or an absence of all subsequent waves; in other

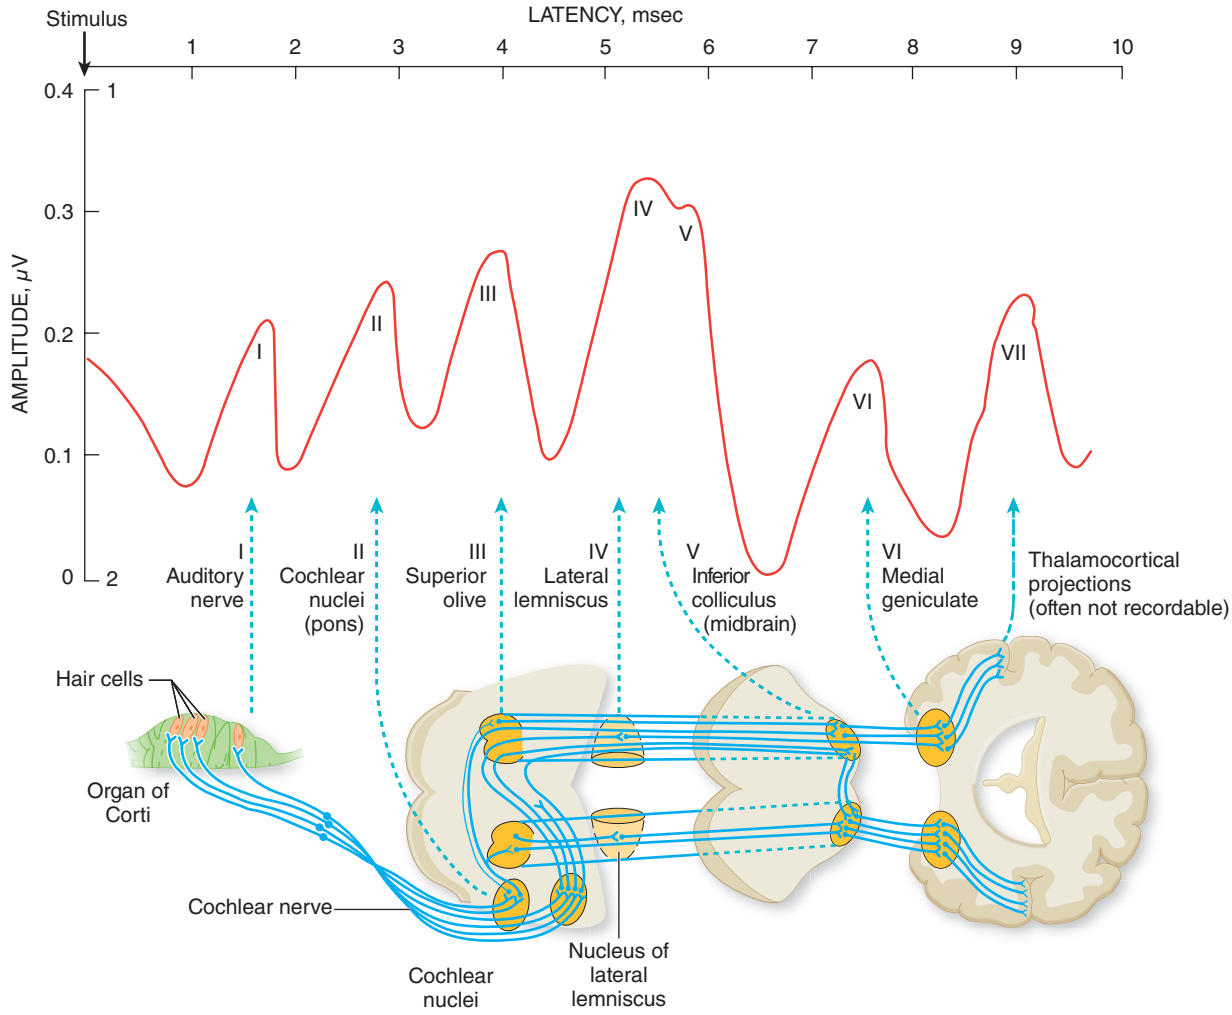

Figure 2-9. Short-latency brainstem auditory evoked responses (BAERs). Diagram of the proposed electrophysiologic–anatomic correlations in human subjects. Waves I through V are the ones measured in clinical practice.

words, the nuclei behave as if they are connected in series. These effects are more pronounced on the side of the stimulated ear than contralaterally. This is difficult to understand, as a majority of the cochlear-superior olivary-lateral lemniscal-medial geniculate fibers cross to the opposite side. It is also surprising that a lesion of one relay station would allow impulses, even though delayed, to continue their ascent and be recordable in the cerebral cortex.

BAERs are a particularly sensitive means of detecting lesions of the eighth cranial nerve (vestibular schwannoma and other tumors of the cerebellopontine angle) and of the auditory pathways of the brainstem. Almost one-half of patients with definite multiple sclerosis and a lesser number with a possible or probable diagnosis of this disease will show abnormalities of the BAERs (usually a prolongation of interwave latencies I to III or III to V), even in the absence of clinical symptoms and signs of brainstem disease. The BAERs are also useful in assessing hearing in infants who have been exposed to ototoxic drugs, in young children who cannot cooperate with audiometry, and in those with psychogenic or feigned deafness.

Somatosensory Evoked Potentials

The technique consists of applying 5-per-second painless transcutaneous electrical stimuli to the median, peroneal, or tibial nerves and recording the evoked potentials (for the upper limb) sequentially as they pass the brachial plexus over the Erb point above the clavicle, over the C2 vertebra, and over the opposite parietal cortex, and (for the lower limb) over the lumbar roots of the cauda equina, the nuclei over the cervical spine, and the opposite parietal cortex. The impulses generated in large touch fibers by 500 or more stimuli and averaged by computer can be traced through the corresponding peripheral nerves, spinal roots, and posterior columns to the cuneate and gracile nuclei in the lower medulla, through the medial lemniscus to the contralateral thalamus, and thence to the sensory cortex of the parietal lobe. Delay between the stimulus site and the Erb point or the lumbar spine indicates peripheral nerve disease; delay from the Erb point (or lumbar spine) to C2 implies an abnormality in the appropriate nerve roots or, more frequently, in the posterior columns; the presence of lesions in the medial lemniscus and thalamoparietal

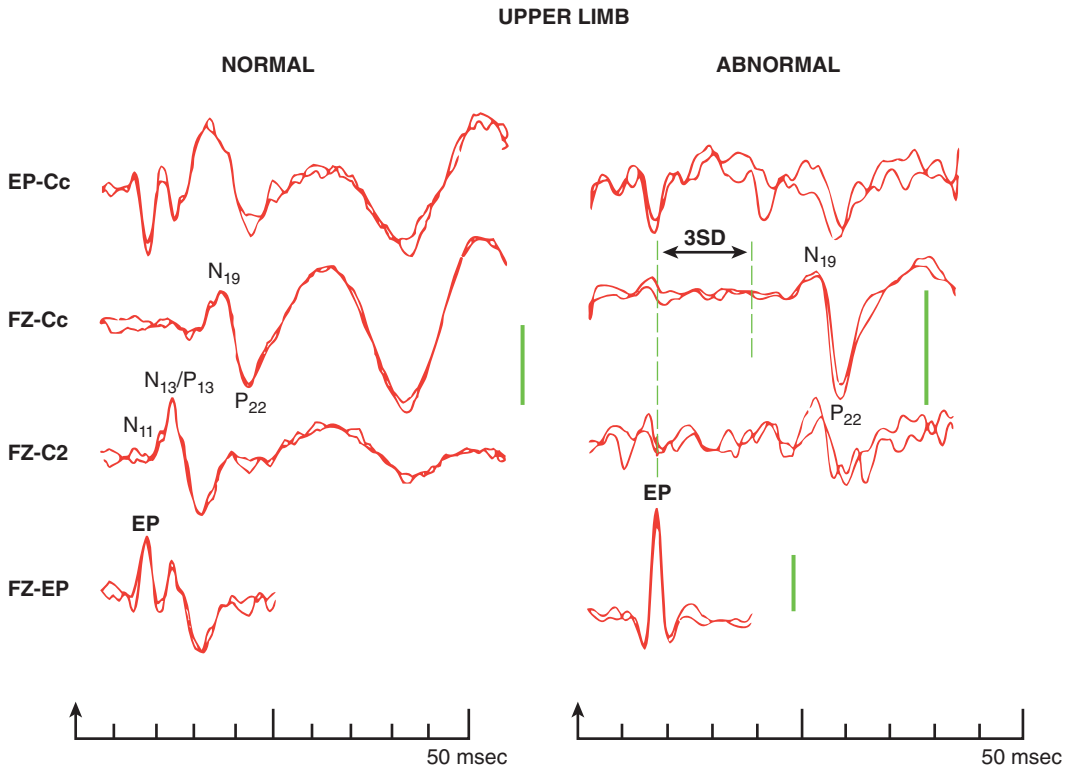

Figure 2-10. Short-latency SEPs produced by stimulation of the median nerve at the wrist. The set of responses shown at the left is from a normal subject; the set at the right is from a patient with multiple sclerosis who had no sensory symptoms or signs. In the patient tracing, note the preservation of the brachial–plexus component (EP), the absence of the cervical cord (N11) and lower-medullary components (N/P13), and the latency of the thalamocortical components (N_{19} and P_{22}), prolonged above the normal mean +3 SD for the interval from the brachial plexus potential. Unilateral stimulation occurred at a frequency of 5 per second. Recording electrode locations are as follows: FZ, midfrontal; EP, the Erb point (the shoulder); C2, the middle back of the neck over the C2 cervical vertebra; and Cc, the scalp overlying the sensoriparietal cortex contralateral to the stimulated limb. Relative negativity at the second electrode caused an upward trace deflection. Amplitude calibration marks denote 2 mV. (From The New England Journal of Medicine, Chiappa KH, Ropper AH, Evoked potentials in clinical medicine, 306:1140-1211. Copyright © 1982 *Massachusetts Medical Society*. Reprinted with permission.)

pathway can be inferred from delays of subsequent waves recorded from the parietal cortex (Fig. 2-10).

The normal waveforms are designated by the symbols P (positive) and N (negative), with a number indicating the interval of time in milliseconds from stimulus to recording (e.g., N11, N_{13}, P_{13}, P_{22}, etc.). As shorthand for the polarity and approximate latency, the summated wave that is recorded at the cervicomedullary junction is termed N/P13, and the cortical potential from median nerve stimulation seen in two contiguous waves of opposite polarity is called N_{19}–P_{22}. The corresponding cortical wave after tibial or peroneal nerve stimulation is called N/P_{37}. Each trace is the averaged response to 1,024 stimuli; the superimposed trace represents a repetition to demonstrate waveform consistency.

For purposes of clinical interpretation, the generators of the SEP waves are assumed to be linked in series so that an interwave prolongation in latency indicates a conduction defect between the generators of the two peaks involved (Chiappa and Ropper). Normal values are shown in Table 2-4. This test has been most helpful in establishing the existence of lesions in spinal roots, posterior columns, and brainstem in disorders such as ruptured lumbar and cervical discs, multiple sclerosis, and lumbar and cervical spondylosis when the clinical data are uncertain. The cerebral counterpart also pertains—namely, that obliteration of the cortical waves (assuming that all preceding waves are unaltered) reflects profound damage to the somatosensory pathways in the hemisphere or to the cortex itself. For example, the bilateral absence of cortical somatosensory waves after cardiac arrest is a powerful predictor of a poor clinical outcome; the persistent absence of a cortical potential on one side after stroke usually indicates such profound damage that only a limited clinical recovery is to be expected.

Evoked potential techniques have also been used in the experimental study of olfactory and trigeminal sensation (see Chap. 11).

Magnetic Stimulation of the Motor System

It is possible, by using single-pulse high-amplitude magnetic stimulation, to directly activate the motor cortex (transcranial magnetic stimulation) and cervical spine segments, and to detect delays or lack of conduction in descending motor pathways. This technique, introduced by Marsden and associates, painlessly stimulates only the largest motor neurons (presumably Betz cells) and the fastest-conducting axons. Cervical magnetic stimulation is believed to activate the anterior roots. The difference in

time between the motor cortical and cervical activation of hand or forearm muscles reflects the conduction velocity of the cortical–cervical cord motor neurons. The technique has been used to understand the organization, function, and recovery of the motor cortex and the pathophysiology of stroke, multiple sclerosis, and amyotrophic lateral sclerosis. Although the degree of functional deficit does not precisely correlate with the degree of electrophysiologic change, one expects that refinements of this technique may be useful in evaluating the status of the corticospinal motor system as well as other cortically based functions.

It is also possible to activate the motor (anterior) roots by magnetic stimulation and to measure the time required to elicit a muscle contraction (Cros and Chiappa). These root stimulation tests can be quite uncomfortable for the patient as a result of the contraction of muscles surrounding the stimulation site. This technique finds its main use in diseases of the motor neuron, roots, and plexus.

Endogenous Event-Related Evoked Potentials

Among the very late brain electrical potentials (>100-ms latency) that can be extracted from background activity by computer methods are a group that cannot be classified as sensory or motor but rather as psychophysical responses to environmental stimuli. These responses are of very low voltage, often fleeting and inconsistent, and of unknown anatomic origin. The most studied types occur approximately 300 ms (P300) after an attentive subject identifies an unexpected or novel stimulus that has been inserted into a regular train of stimuli. Almost any stimulus modality can be used, and the potential occurs even when a stimulus has been omitted from a regular pattern. The amplitude of the response depends on the difficulty of the task and has an inverse relationship to the frequency of the unexpected or "odd" event; the latency depends on the task difficulty and other features of testing. There is, therefore, no single P300; instead, there are numerous types, depending on the experimental paradigm. Prolongation of the latency is found with aging and in dementia as well as with degenerative diseases such as Parkinson disease, progressive supranuclear palsy, and Huntington chorea. The amplitude is reduced in schizophrenia and depression. The potential has been interpreted by some as a reflection of the subject's orienting behavior or attention and by others, including Donchin, who discovered the phenomenon as related to an updating of the brain's representation of the environment. The P300 remains a curiosity for the clinical neurologist because abnormalities are detected only when large groups are compared to normal individuals, and the technique is not as standardized as the conventional evoked potentials.

NERVE CONDUCTION STUDIES AND ELECTROMYOGRAPHY

It was long ago discovered that muscle would contract when a pulse of electric current was applied to the skin, near the point of entrance of the muscular nerve (*the motor point*). The electrical pulse required is brief, less than a millisecond, and is most effectively induced by rapidly alternating (faradic) current. If there has been muscle *denervation*, an electrical pulse of several milliseconds induced by a constant electrical (galvanic) stimulus is required to produce the same response. For decades, this was the standard electrical method for evaluating denervation of muscle. Although still valid, it was replaced by nerve conduction studies and by the needle electrode examination. The latter test, based on the Sherringtonian concept of the "motor unit" described in Chap. 3, is accomplished by the insertion into muscle of needle electrodes to measure spontaneous and voluntarily evoked muscle fiber activity. The terms *electromyography* and *electromyogram* were used originally to describe the needle electrode examination but are now a common shorthand designation for the entire electrodiagnostic evaluation, including *nerve conduction studies*.

Nerve Conduction Studies

The main laboratory technique for the study of peripheral nerve function involves the transcutaneous stimulation of motor or sensory nerves and recording of the elicited action potentials in the muscle (compound muscle action potential [CMAP]) and the sensory nerve action potential (SNAP). The results of these *motor and sensory nerve conduction studies* expressed as amplitudes, conduction velocities, and distal latencies, yield certain quantitative information and additional qualitative observations regarding the waveform of electrical neural and muscular impulses.

Hodes and coworkers, in 1948, were the first to describe nerve conduction studies in patients, and the techniques used currently are not much changed. An accessible nerve is stimulated through the skin by surface electrodes, using a stimulus that is large enough to recruit (cause a discharge in) all the available nerve fibers. The resulting action potential is recorded by electrodes on the skin (1) over the muscle distally in the case of motor fibers stimulated in a mixed or motor nerve (CMAP), (2) over the nerve more distally, using antidromic techniques for sensory nerve conduction studies (this has technical advantages over orthodromic techniques), and (3) over the nerve more proximally for mixed (sensory and motor) nerve conduction studies. These techniques are the ones used most often in clinical work. An alternative but much more demanding experimental technique uses "near-nerve" needle electrodes to record action potentials as they course through the nerve. The main characteristics of the conventional nerve conduction studies are described below.

Compound Muscle Action Potential Amplitude

The peak amplitude of the evoked muscle action potential to a maximal stimulus (CMAP) yields valuable information about peripheral nerve function. The amplitude, usually in the order of millivolts, reflects the summated electrical potential generated by the depolarization of a muscle innervated by the motor nerve (Fig. 2-11). In instances of disease, the amplitude is a semiquantitative measure of the number of remaining normal nerve fibers and of the innervated volume of muscle. It is usually possible to obtain a

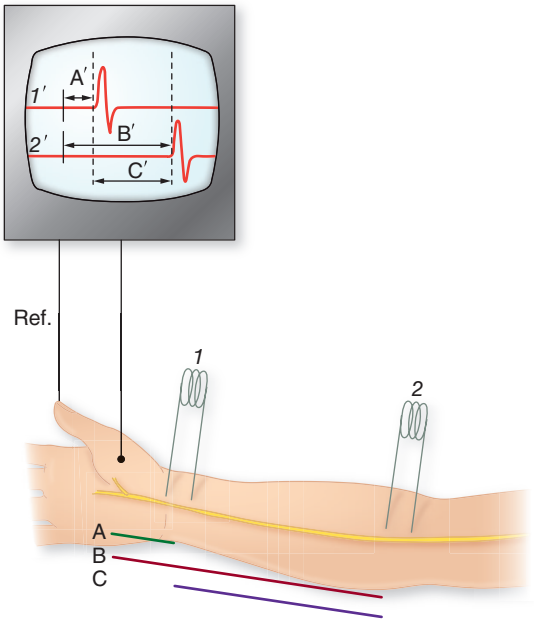

Figure 2-11. The median nerve is stimulated percutaneously (1) at the wrist and (2) in the antecubital fossa with the resultant CMAP recorded over the abductor pollicis brevis. The motor waveform is recorded as the voltage between the surface electrode and a reference electrode (*Ref.*) more distally. Sweep 1′ on display depicts the stimulus artifact followed by the CMAP. The distal latency, A′, is the time from the stimulus artifact to the onset of the CMAP and corresponds to conduction over distance A. The same is true for sweep 2′, where stimulation is at site 2 and the time from the artifact to the response is B′. The maximum motor conduction velocity over segment C is calculated by dividing the distance between the two stimulating electrodes, C, by the time C′.

reliable motor conduction study as long as some functioning nerve fibers remain intact, although the compound muscle potential recorded may be very low. The latency to the CMAP waveform is the basis for calculations of motor nerve conduction velocity. Reduction in motor amplitudes is a specific and sensitive indicator of axonal loss. Demyelinative lesions affecting the large, fast-conducting fibers also reduce the peak summated amplitude of the CMAP but are the result of differential arrival times of the electrical potentials from each axon at the muscle. Table 2-5 shows the range of normal amplitudes for the CMAPs that are elicited by stimulation of the main motor nerves.

Motor Distal Latencies and Conduction Velocities

The conduction times that are utilized in clinical work are the latency from the stimulus artifact to the onset of the CMAP, the *distal* (or terminal) latency; and from the stimulus to the peak of the CMAP, *peak* motor latency (see Fig. 2-11). A stimulus is then applied to the nerve at a second site more proximally, and a conduction time can be measured over a longer segment of the nerve. When the distance (in millimeters) between the two sites of stimulation is divided by the difference in the distal latencies (in milliseconds), one obtains a *conduction velocity* (in meters per second). This method isolates the conduction time across a segment of a peripheral nerve by eliminating the transmission time across the neuromuscular junction and the duration of muscle depolarization. Motor nerve conduction velocity represents the maximal velocity of propagation of the action potentials in the largest diameter and fastest conducting nerve fibers. These velocities in normal subjects vary from a minimum of 40 or 45 m/s to a maximum of 65 to 75 m/s, depending upon which nerve is studied (e.g., slower in the legs than in the arms; see Table 2-5). Values are lower in infants, reaching the adult range by the age of 2 to 4 years, and declining again slightly with advancing age. Conduction velocity also is diminished with exposure to cold, a potentially important factor if these recordings are taken when the patient's skin is cool; consequently, measurement of skin temperature is routinely done prior to performing the nerve conduction tests.

Normal values have been established for distal latencies from the usual sites of stimulation on various mixed nerves to the appropriate muscles. Stimulating the median nerve at the wrist, for example (see electrode 1 and segment A in Fig. 2-11), has a latency for motor conduction through the carpal tunnel to the median-innervated thenar muscles of less than approximately 4.5 ms in healthy adults. Similar normal values have been compiled for orthodromic and antidromic sensory conduction velocities and for distal latencies in all the main peripheral nerves (see Table 2-5).

The main effect of disease processes that preferentially injure axons, as mentioned above, is a reduction in the CMAP amplitude (Fig. 2-12*B*). However, some processes affect the fastest-conducting, large-diameter fibers and also usually reduce the conduction velocity because the remaining thinner fibers conduct more slowly. In most neuropathies, all the axons are affected either by a fairly uniform "dying-back" phenomenon or by Wallerian degeneration, as described in Chap. 43, and nerve conduction velocities are then less affected. This is true, for example, in typical alcoholic-nutritional, carcinomatous, uremic, diabetic, and other metabolic neuropathies, in which conduction velocities range from the low-normal range to mildly slowed. By contrast, demyelinating neuropathies (see Chap. 46) show marked slowing of conduction, and, in the case of acquired demyelinating diseases, there is also temporal dispersion of the motor action potential (Fig. 2-12*C*).

Sensory Nerve Action Potentials

The SNAP is far lower in amplitude than the CMAP. It directly represents the action potentials in a group of sensory nerve axons. When one attempts to measure SNAPs, the summation of electrical activity provided by many motor units discharging at the muscle is not available and electronic amplification is required. In contrast to motor conduction measurements, the nerve is typically stimulated at one site, and recordings are performed at two distal sites (therefore antidromically for sensory conduction) in order to obtain both the amplitude (at the more proximal site) and conduction velocity by the subtraction method (Fig. 2-13). Sensory potentials, measured in microvolts, are sometimes very small or absent and sensory conduction measurements may then be difficult to determine. Table 2-5 gives the range of normal values for SNAP amplitudes and velocities.

Table 2-5

NORMAL VALUES FOR REPRESENTATIVE NERVE CONDUCTION VALUES AT VARIOUS SITES OF STIMULATION (MEAN VALUES ± 2 SD FOR ADULTS 16 TO 65 YEARS OF AGE)

MOTOR NERVE CONDUCTION STUDIES

NERVE	DISTAL STIMULATION SITE	OTHER STIMULATION SITES	RECORDING SITE	ONSET LATENCY (ms)	AMP (mV)	CV (m/s)	DISTANCE (cm)	F-WAVE LATENCY (ms)
Median	Wrist	Elbow	APB	<4.2	>4.4	>49	6–8	<31
Ulnar	Wrist	BG, AG	ADM	<3.4	>6.0	>49	5.5–7.5	<32

SENSORY NERVE CONDUCTION STUDIES[b]

NERVE	DISTAL STIMULATION SITES	RECORDING SITE	ONSET LATENCY (ms)	PEAK LATENCY (ms)	AMP (μV)	CV (m/s)	DISTANCE (cm)
Median	Wrist	Index finger	<2.5	<3.5	>20	>52	13
Ulnar	Wrist	Fifth finger	<2.1	<3.0	>15	>52	11
Radial	Forearm	Wrist	<1.9	<2.8	>20	>48	10
Sural	Calf	Ankle	<3.2	<4.4	>6	>42	14

LATE RESPONSE (F WAVE)

NERVE	DISTAL STIMULATION SITES	RECORDING SITE	UPPER LIMIT LATENCY (ms)
Median	Wrist	Abductor pollicis brevis	32
Ulnar	Wrist	Abductor digiti minimi	32
Peroneal	Fibular head	Extensor digitorum brevis	57
Tibial	Behind knee	Abductor hallucis	58

ADM, adductor digiti minimi; AFH, above fibular head; AG, above ulnar groove; AH, abductor hallucis; APB, abductor pollicis brevis; BFH, below fibular head; BG, below ulnar groove; EDB, extensor digitalis brevis; EIP, extensor indicis proprius; PF, popliteal fossa; SG, spiral groove; TA, anterior tibialis.

[a]Tibial H reflexes: latency < 35 ms; side-to-side difference < 1.4 ms.

[b]Sensory studies are performed antidromically; amplitudes are measured from baseline to negative peak of nerve potential.

Conduction Block

By stimulating a motor nerve at multiple sites along its course, it is possible to demonstrate segments in which conduction is partially "blocked" or is differentially slowed. From such data, one infers the presence of a multifocal demyelinative process in motor nerves. This contrasts with the findings in certain of the inherited and metabolic demyelinating neuropathies, in which all parts of the nerve fiber are altered to more or less the same degree, that is, there is uniform slowing and reduction in amplitude and no conduction block.

As a technical matter, conduction block is demonstrated by a reduction in the amplitude of the CMAP elicited from the proximal site along the motor nerve compared to stimulation at a distal site. Generally, a 40 percent reduction in amplitude over a short distance of nerve, or 50 percent over a longer distance, qualifies as a block, one possible exception being along the tibial nerve, in which there is some degree of physiologic dispersion; therefore, a slight drop in amplitude over the length of the nerve is normally expected. It is important to be sure that any reduction in amplitude along the course of the nerve is not solely a result of dispersion of the waveform, as mentioned previously. The presence of a conduction block can also be inferred from the finding of poor recruitment of muscle action potentials and the concurrent absence of active denervation (see further on). The finding of conduction block is the main feature of a number of acquired immune demyelinating neuropathies, including Guillain-Barré syndrome, chronic inflammatory demyelinating neuropathy, and multifocal conduction block associated with the G_{M1} antibody, which are discussed in Chap. 46.

Focal conduction block may be caused simply by nerve compression at certain common sites (fibular head, across the elbow, flexor retinaculum at the wrist, etc.) rather than to an intrinsic disease of the peripheral nerves. Focal compression of nerve, as occurs in these entrapment syndromes, produces localized slowing or blocks in conduction, perhaps because of segmental demyelination at the site of compression. The demonstration of such localized changes of conduction affords ready confirmation of nerve entrapment; for example, if the distal latency of the median nerve (Fig. 2-11*A*) exceeds 4.5 ms while that of the ulnar nerve remains normal, compression of the median nerve in the carpal tunnel is likely. Similar focal slowing or partial block of conduction may be recorded from the

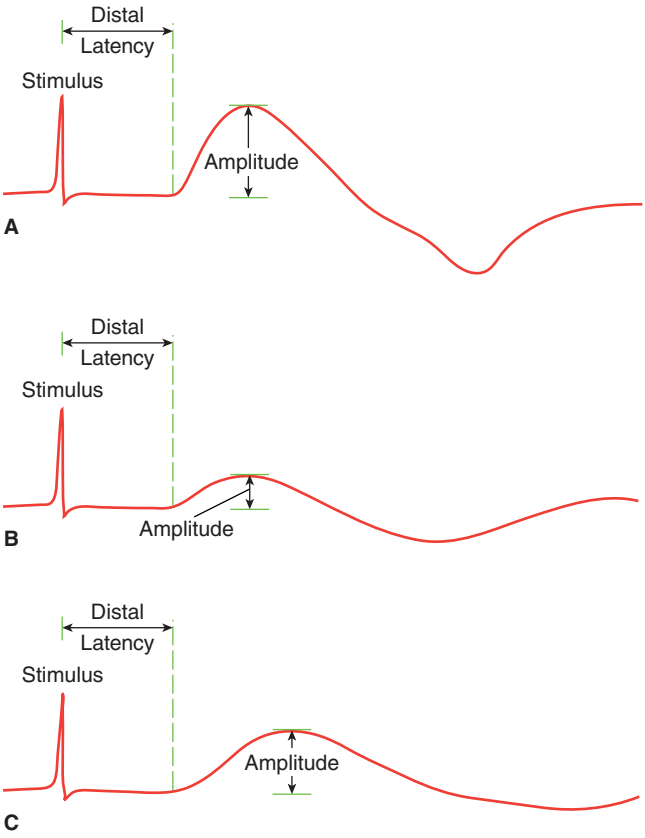

Figure 2-12. The principal pathologic alterations of CMAP. *A.* The normal CMAP, representing the summed discharges from a group of motor units activated by a supramaximal stimulus, measured over the muscle. *B.* With the loss of motor axons, fewer motor units are activated and the CMAP has reduced amplitude. *C.* With demyelination of motor axons, the same number of motor units activate, but over a prolonged duration; thus, the CMAP has reduced amplitude because there is temporal dispersion of the waveform.

ulnar nerve at the elbow and from the peroneal nerve at the fibular head.

The examiner should also be aware of a normal variant, the Martin-Gruber anastomosis that exists in close to 20 percent of individuals; in this configuration, axons from the median nerve cross into the ulnar nerve in the midforearm to innervate normally ulnar associated muscles in hand. Distal stimulation of the ulnar nerve then gives higher amplitude ulnar CMAP than proximal stimulation, simulating conduction block, but without weakness or atrophy. The anastomosis can be demonstrated by obtaining a normal CMAP when stimulating the proximal median nerve and recording over ulnar innervated muscles.

Late Responses

Information about the conduction of impulses through the proximal segments of a nerve, including the spinal roots, is provided by the study of the H reflex and the F wave (Fig. 2-14).

H reflex In 1918, Hoffmann, after whom the H reflex was named, showed that submaximal stimulation of mixed motor–sensory nerves induces a muscle contraction (H wave, Fig. 2-14*A*) after a latency that is far longer than that of the direct motor response. This reflex, the electrical representation of the ankle jerk, is based on the activation of afferent fibers from muscle spindles (the same axons that conduct the afferent volley of the tendon reflex). Thus the long delay, typically 28 to 35 ms after the stimulus (adjusted for height and age), reflects the cumulative time required for the impulses to reach the spinal cord via the sensory fibers, synapse with anterior horn cells, and to be transmitted along motor fibers to the muscle (see Fig. 3-1). The H reflex is a useful measure because the impulse traverses both the posterior and anterior spinal roots. The H reflex is particularly helpful in the diagnosis of S1 radiculopathy and of polyradiculopathies. It is difficult to obtain an H reflex from nerves other than the tibial. Stimuli of increasing frequency but low intensity cause a progressive depression and finally obliteration of H waves. In parallel with the Achilles tendon reflex, the H-reflex is transiently obliterated in spinal shock (see Chap. 42).

F response (wave) The F response, so named because it was initially elicited in the feet, was first described by Magladery and McDougal in 1950. It is evoked by a

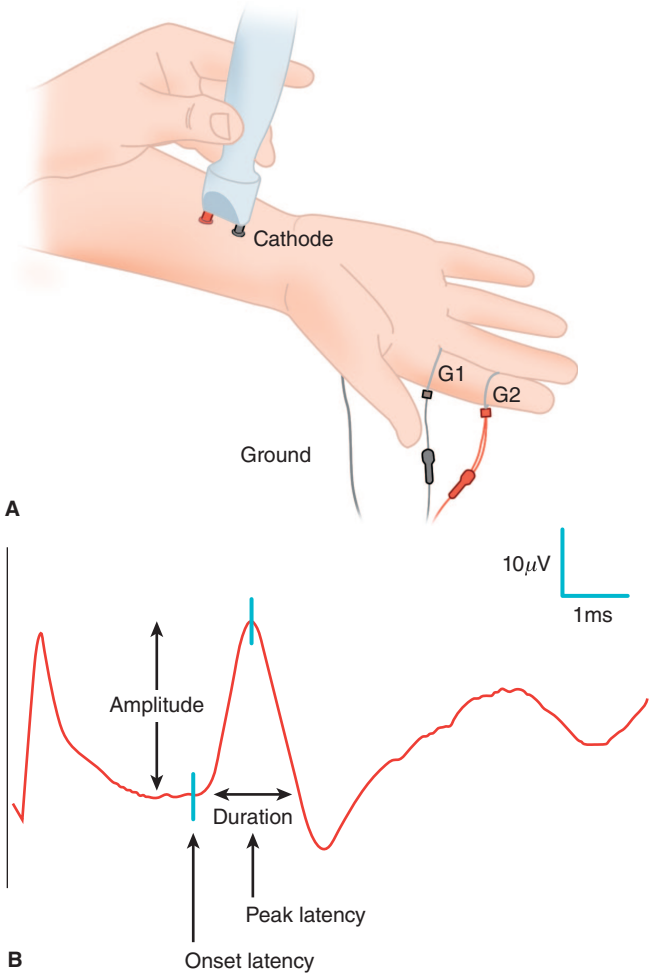

Figure 2-13. SNAP recording. *A.* Electrical stimulation of the median nerve at the wrist with recording of sensory action potentials at two sites in the second digit. The responses are generated by antidromic propagation of action potentials from the site of stimulation. *B.* An SNAP recorded from G1. Sensory nerve conduction velocity can be calculated by dividing the distance between G1 and G2 by the difference in onset latencies from these two sites.

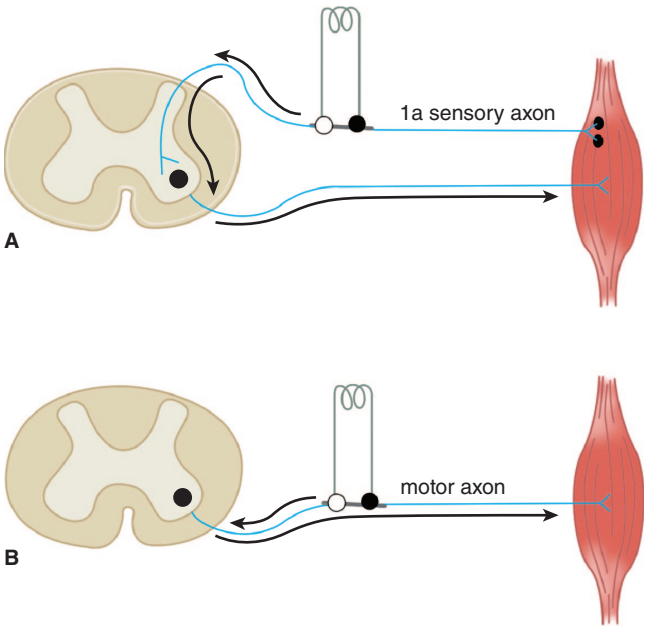

Figure 2-14. Late responses. *A*. The H reflex is elicited by stimulating a sensory nerve. The action potentials travel in an orthodromic fashion through the dorsal root into the spinal cord, where synapses occur with motor neurons. The motor axons innervate a muscle (the gastrocnemius) from which the late CMAP response is recorded. *B*. The F response is elicited by stimulating a motor nerve. Some of the action potentials that have traveled in an antidromic fashion through the anterior horn are volleyed back in an orthodromic fashion along the same motor neurons. The late CMAP response is recorded from the muscle innervated by these axons.

supramaximal stimulus of a mixed motor–sensory or pure motor nerve (Fig. 2-14*B*). After a latency substantially longer than for the CMAP, a second small muscle action potential is normally recorded at 28 to 32 ms in arms and 40 to 58 ms in legs. This F wave is the result of impulses that travel antidromically in motor fibers to the anterior horn cells, a small number of which are activated and produce an orthodromic response that is recorded in a distal muscle. The F response is representative of proximal motor nerve and root conduction in that it traverses only the ventral root and can be elicited from a number of muscles.

Both responses are lost or delayed in some severe and generalized polyneuropathies (see Chap. 43). The combination of a normal F response and an absent H reflex is found in diseases of sensory nerves and roots. As with the H reflex, the F wave may be absent in the state of spinal shock or destructive diseases of the spinal cord (see Chap. 42). Both of these "late responses" find their main use as corroborative tests that are interpreted in the context of the entire nerve conduction examination.

Blink responses This special nerve conduction test is not in frequent clinical use, but it serves a purpose in the diagnosis of certain demyelinating neuropathies and in any process that affects the trigeminal or facial nerve. The supraorbital (or infraorbital) nerve is stimulated transcutaneously and the reflex closure of both orbicularis oculi muscles is recorded with surface electrodes. Two CMAP bursts generated by facial motor neurons are observed: the first (R1) appears ipsilaterally 10 ms after the stimulus and the second (R2), ipsilaterally at 30 ms and contralaterally up to 5 ms later. The amplitudes of the responses vary considerably and are not in themselves clinically important. The first response is not visible as a muscular contraction but may serve some preparatory function by shortening the blink reflex delay. R1 is mediated by an oligosynaptic pontine circuit consisting of one to three neurons located in the vicinity of the principal sensory nucleus of the trigeminal nerve; R2 uses a broader and less well-defined reflex pathway in the pons and medulla.

The pattern of abnormalities of the R1 and R2 responses assists in localizing a lesion to the afferent trigeminal nerve, the efferent facial nerve, or the interneurons in the pons. In Bell palsy, there is a delay or absence of R1 and R2 responses only on the affected side. Large acoustic neuromas (vestibular schwannomas) also may interfere with the efferent portion of the response. The test may be helpful in identifying a demyelinating neuropathy when the facial and oropharyngeal muscles are affected. Diseases of the brainstem have yielded inconsistent responses. It is noteworthy that the test is normal in patients with trigeminal neuralgia.

Repetitive Motor Nerve Stimulation (See Also Chap. 46)

This test of the neuromuscular junction is based on Jolly's observation in 1895 that in myasthenia gravis, the strength of muscular contractions progressively declines in response to a train of stimuli. By adjusting the amplitude of a stimulus over a nerve to the supramaximal range, a maximal CMAP may be obtained for each stimulus. With repeated stimuli, each response will have the same waveform and amplitude. In a healthy individual, a muscular response follows each stimulus with rates of stimulation up to 25 per second for periods of 60 s or more before a decrement of the CMAP appears. A decrement of 10 percent or more denotes a failure of a proportion of the neuromuscular junctions.

In certain disorders, notably myasthenia gravis, a train of 4 to 10 stimuli at rates optimally 2 to 3 per second results in a decrease or *decrement* in the amplitude of each successive motor response (Fig. 2-15*A*). A progressive reduction in amplitude is most likely to be found in proximal

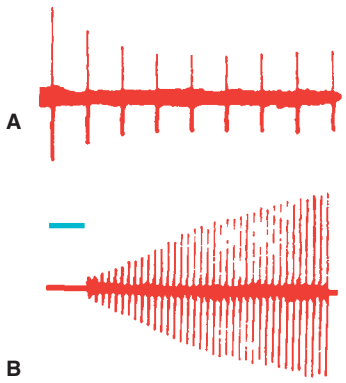

Figure 2-15. Repetitive stimulation of the hypothenar muscles. *A*. Patient with myasthenia gravis—typical pattern of decrement in first four responses followed by slight increment. At this rate of stimulation (3 per second), the decrement in response does not continue to zero. *B*. Patient with Lambert-Eaton syndrome and oat cell carcinoma—marked increase from low toward normal amplitude with rapid repetitive stimulation (20 per second). Horizontal calibration: 250 ms.

muscles, but these are not easily stimulated for which reason the locations most commonly used for clinical testing are the accessory nerve in the posterior triangle of the neck (trapezius), the ulnar nerve (hypothenar muscle), the median nerve at the wrist (thenar muscle), and the facial nerve (orbicularis oculi muscle).

The sensitivity of the procedure is improved by first exercising the tested muscle for 30 to 60 s; a form of post-tetanic potentiation. The full procedure consists of testing the muscle with a train of stimuli before and immediately after exercise (or maximal voluntary contraction) and at 30-s intervals for several minutes. The post-tetanic potentiation at first partially compensates for the depletion of ACh during slow rates of stimulation; this is followed by an exaggerated decrease in the transmission through the neuromuscular junction during the approximately 2 to 4 min after exercise. The induced failure of neuromuscular transmission in myasthenia is similar to the one produced by curare and other nondepolarizing neuromuscular blocking agents, and the electrical features of both can be partially corrected with anticholinesterase drugs such as neostigmine and edrophonium. Similar but lesser decremental responses may occur in poliomyelitis, ALS, and certain other diseases of the motor unit or motor nerve, particularly those resulting in the growth of reinnervating nerve twigs.

The Lambert-Eaton myasthenic syndrome, sometimes associated with small cell carcinoma of the lung, as discussed in Chap. 46, is characterized by a presynaptic blockage of acetylcholine release and, with rapid rates of stimulation, produces the opposite effect on neuromuscular transmission to the one recorded in myasthenia gravis. There is instead an increment in the amplitude of the CMAP with continued stimulation. During very rapid repetitive stimulation (20- to 50-per-second), the muscle action potentials, which are small or practically absent with the first stimulus, increase in voltage with each successive response until a more nearly normal amplitude is attained (see Fig. 2-15*B*). Exercising the muscle for 10 s before stimulation will cause a post-tetanic facilitation in patients with the Lambert-Eaton syndrome (200-fold increases are not uncommon). A less important decremental response to slow stimulation may occur, but it is difficult to discern because of the greatly diminished amplitude of the initial responses. The effects of botulinum toxin and of aminoglycoside antibiotics are similar, that is, being active at the presynaptic membrane; they produce an incremental response at high rates of stimulation.

The single-fiber EMG, discussed in a later section, is an even more sensitive method of detecting the failure of the neuromuscular junction.

Needle Examination of Muscle (Electromyography)

In the usual EMG examination, a plan for the study is made based on detailed knowledge of muscular innervation and focusing on the regions affected by weakness. In some patients, as in those with motor neuron diseases or polymyositis, a wider sampling of muscles is required to detect changes in asymptomatic regions. This technique requires the use of monopolar or concentric bipolar needle electrodes, which are inserted into the body of the muscle to record the electrical activity generated by contraction. With concentric electrodes, the tip of the wire that runs in the hollow of the needle is in proximity to many muscle fibers belonging to several different overlapping motor units; this is the active recording electrode. The shaft of the needle, in contact over most of its length with intercellular fluid and many other muscle fibers, serves as the reference electrode. Monopolar electrodes use the uninsulated needle tip as the active electrode, while the reference electrode may be another monopolar needle electrode placed elsewhere in subcutaneous tissue or a surface electrode on the skin overlying the muscle. Patients almost invariably find this portion of the test uncomfortable and should be prepared by a description of the procedure. Rapid and brief needle insertion by the skilled examiner makes the test more tolerable.

As the electrical impulse travels along the surface of the muscle toward the recording electrode, a positive potential is recorded on the oscilloscope, that is, the recorded signal is deflected downward by convention (at A in Fig. 2-16). When the depolarized zone moves under the recording electrode, it becomes relatively negative and the recorded signal is deflected upward (at B). As the depolarized zone continues to move along the sarcolemma, away from the recording electrode, the current begins to flow outward through the membrane toward the distant depolarized region, and the recording electrode becomes relatively positive again (at C). There is then a return to the resting isopotential position. The net result is a triphasic action potential, as in Fig. 2-16. This configuration is typical of the firing of a single fiber.

The electrical activity of various muscles is recorded both at rest and during active contraction by the patient. Muscle fibers do not normally discharge until activated

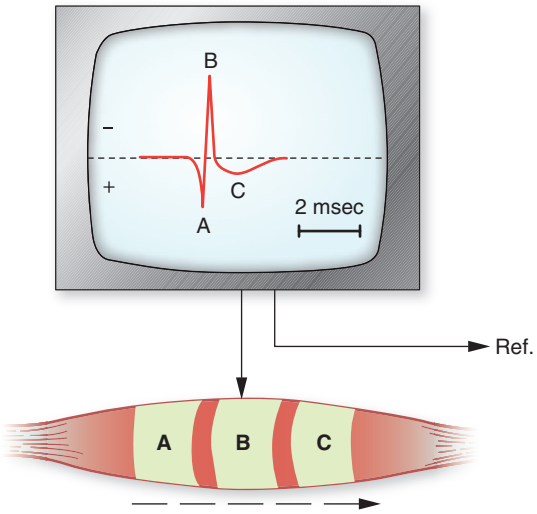

Figure 2-16. The shaded areas on the muscle (A, B, and C) represent zones of the propagating action potential depicted by the dashed arrow. The correspondingly lettered portions of the triphasic muscle action potential displayed on the screen reflect the potential difference between the active (*vertical arrow*) and reference (*Ref.*) electrodes. Polarity in this and subsequent figures is negative upward as depicted.

together in motor unit activity. This involves the almost simultaneous contraction of all the muscle fibers innervated by a single anterior horn cell. Although the typical configuration of a motor unit potential (MUP) is triphasic, up to 10 percent of normal MUPs consist of four or more phases (*polyphasic potentials*); however, an excess of polyphasic potentials beyond this is pathologic.

Normal muscle in the resting state should be electrically silent; the small tension spoken of as muscle tone has no EMG equivalent. There are, however, two closely related types of normal spontaneous activities and another that is induced by the insertion of the needle itself. One is a low-amplitude, 10- to 20-μV monophasic (negative) potential of very brief (0.5 to 1 ms) duration. These represent single or synchronized miniature end-plate potentials (MEPPs) because of the small number of ACh quanta that are being released all the time. They are normally sparse but are most evident when the recording needle electrode is placed near a motor endplate ("endplate noise"). Fortuitous placement of the needle electrode very close to or in contact with the endplate gives rise to a second type of normal spontaneous activity that is characterized by irregularly discharging high-frequency (50- to 100-Hz) biphasic spike discharges, 100 to 300 μV in amplitude (i.e., large enough to cause an isolated muscle action potential). These potentials have been termed *endplate spikes* and represent discharges of single muscle fibers excited by spontaneous activity in nerve terminals. They must be distinguished from fibrillation potentials (see later). Finally, insertion of the needle electrode into the muscle injures and mechanically stimulates a number of fibers, causing a burst of potentials of short duration (300 ms). This is referred to as normal *insertional activity*, but the extent of this activity is greatly raised in certain pathologic states as noted below.

When a muscle is voluntarily contracted, the depolarization potentials of motor units begin to appear. One can observe a pattern of force buildup by watching the progressive recruitment of MUPs; the initial ones, representing smaller motor units, firing at rates of 5 to 10 per second. With the increased force of contraction, there is an increased rate of firing (40 to 50 per second as well as a recruitment of larger, previously inactive motor units; Fig. 2-17*A*). Because individual MUPs can no longer be distinguished during maximal voluntary contraction, this activity is referred to as a *complete interference pattern* (Fig. 2-17*A*, *right*). This is seen not only as a summated signal pattern but is also heard as a mixed high-frequency clicking when the electrical activity is made audible. As muscles relax, an increasing number of units drop out. If a muscle is weakened by denervation or if electrical conduction is blocked, there will be fewer MUPs, but the remaining ones will still show a rapid firing rate (*reduced recruitment*; see Fig. 2-17*B*). In contrast, with poor voluntary effort and with upper motor neuron lesions, the MUPs fire in decreased numbers, at slower rates, and often in an irregular pattern (termed *poor activation*).

The Abnormal Electromyogram

Clinically important deviations from the normal EMG include (1) increased or decreased activity upon insertion of the needle; (2) the occurrence of abnormal "spontaneous" activity during the relaxed state (fibrillation potentials, positive sharp waves, fasciculation potentials, cramp potentials, myotonic discharges, myokymic potentials); (3) abnormalities in the amplitude, duration, and shape of single MUPs; (4) a decrease in the number of MUPs and changes in their firing pattern such as recruitment discussed above; (5) variation in amplitude and number of phases of MUPs during voluntary contraction; and (6) the demonstration of special phenomena such as in states of continuous muscle fiber activity or electrical silence during shortening of the muscle (physiologic contracture). The underlying physiology of these changes is discussed in Chap. 45, in relation to diseases of the muscle.

Insertional activity At the moment the needle is inserted into muscle, there is a normally brief burst of action potentials that ceases once the needle is stable, provided that it is not in a position to irritate a nerve terminal. Increased insertional activity, however, is an abnormal finding seen in most instances of denervation as well as in many forms of primary muscle disease and in disorders that dispose to muscle cramps. In cases of advanced denervation or advanced myopathy, in which muscle fibers have been largely replaced by connective tissue and fat, insertional activity may be decreased and there is a palpable increase in the mechanical resistance to the insertion of the needle.

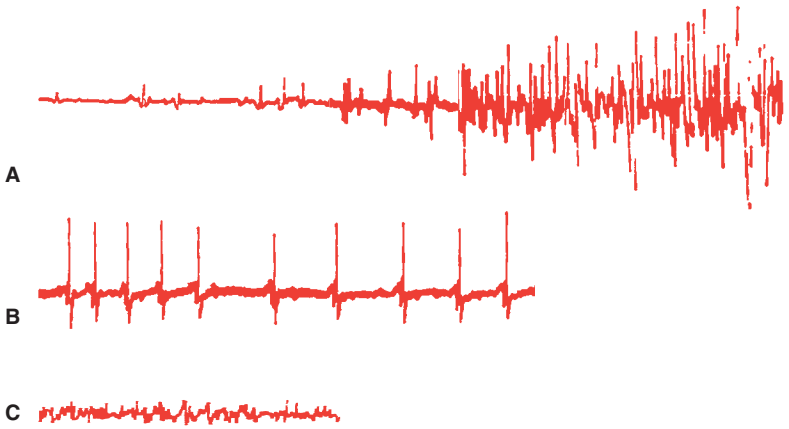

Figure 2-17. Patterns of motor unit recruitment. *A*. Normal. With each increment of voluntary effort, more and larger units are brought into play until, with full effort at the extreme right, a complete "interference pattern" is seen in which single units are no longer recognizable. *B*. After denervation, only a single motor unit is recorded despite maximal effort. It is seen to fire repetitively. *C*. With myopathic diseases, a normal number of units are recruited on minimal effort, though the amplitude of the pattern is reduced. Calibration: 50 ms (horizontal) and 1 mV (vertical).

Abnormal spontaneous activity With the muscle at rest, spontaneous activity of single muscle fibers and of motor units, known as *fibrillation* potentials and *fasciculation* potentials, is abnormal. The two phenomena may be confused. *Fibrillation* is the spontaneous contraction of a *single muscle fiber*. It occurs when the muscle fiber has lost its nerve supply and is ordinarily not visible through the skin (but may be visible on the tongue). *Fasciculation* represents the spontaneous firing of an entire motor unit, causing contraction of a group of muscle fibers, and may be visible through the skin. The irregular firing of a number of motor units, seen as a rippling of the skin, is called *myokymia*.

Fibrillation potentials Destruction of a motor neuron or interruption of its axon causes the distal part of the axon to degenerate, a process that takes several days or more. The muscle fibers formerly innervated by the branches of the dead axon—that is, the motor unit—are thereby disconnected from the nervous system. By mechanisms that are still obscure, the chemosensitive region of the sarcolemma at the motor endplate "spreads" after denervation to involve the entire surface of the muscle fiber. Then, 10 to 25 days after interruption of the axon, the denervated fibers develop spontaneous activity; each fiber contracts at its own rate and without relation to the activity of neighboring fibers. This spontaneous activity, fibrillation, is associated with a random conglomeration of brief di- or tri-phasic fibrillation potentials (Fig. 2-18*A*) having a duration of 1 to 5 ms and rarely exceeding 300 μV in amplitude. When brief spontaneous fibrillation potentials of this sort are observed firing at two or three different locations (outside the endplate zone) of a resting muscle, one may conclude that the fibers are denervated. In addition, fibrillation potentials may take the form of *positive sharp waves*, that is, spontaneous, initially positive diphasic potentials of longer duration and slightly greater amplitude than the spikes of fibrillation potentials. Usually, fibrillation potentials discharge at an almost regular rate but after 6 to 8 weeks, irregularly firing fibrillation potentials may be observed.

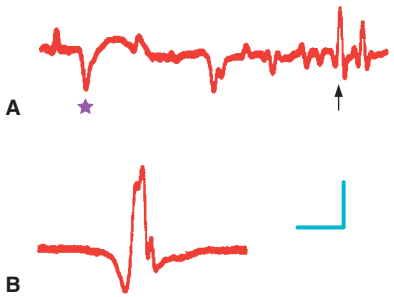

Figure 2-18. Abnormal spontaneous activity. *A*. Positive sharp waves and fibrillations recorded from a paralyzed, denervated muscle. A typical positive sharp wave is seen above the star. The fibrillations (*arrow*) are 1 to 2 ms in duration, 100 to 300 mV in amplitude, and largely negative (*upward*) in polarity following an initial positive deflection. *B*. Fasciculation. This spontaneous MUP was recorded from a patient with amyotrophic lateral sclerosis. It has a serrated configuration and it fired once every second or two. Calibrations: 5 ms (*horizontal*) and 200 μV in *A*; 1 mV in *B* (*vertical*).

Fibrillation potentials continue until the muscle fiber is affected by one of several processes: reinnervation by regeneration of the interrupted nerve fiber, by outgrowth of nearby remaining nerve fibers (collateral sprouting), or replacement of the atrophied fibers by connective tissue, a process that may take years. Diseases such as poliomyelitis, which damage spinal motor neurons, or injuries of the peripheral nerves or anterior spinal roots, frequently produce only partial denervation of the involved muscles. In such muscles, one electrode placement may record fibrillation potentials at rest from denervated fibers and normal potentials during voluntary contraction from nearby healthy fibers.

Fibrillation potentials, while characteristic of neurogenic denervation, are not altogether specific; for example, they are seen in muscle diseases such as polymyositis and inclusion body myopathy, which presumably damage the muscle fiber and make its membrane electrically unstable.

Fasciculation potentials A fasciculation is the spontaneous or involuntary contraction of the muscle fibers of a single motor unit or part of a unit. Fasciculation potentials are evidence of motor nerve fiber irritability and are generally markers of denervation and reinnervation of muscle. Such contractions cause a visible dimpling or twitching under the skin, and infrequently they are of sufficient force to move a small distal joint. They occur irregularly and may be infrequent so that prolonged inspection of the skin overlying a muscle may be necessary to detect them. The accompanying electrical form of any individual fasciculation potential is relatively constant. Typically, a fasciculation potential will have three to five phases ("polyphasic" as described later, in contrast to normal biphasic muscle activity), a duration of 5 to 15 ms (far longer than fibrillation potentials and more dispersed than a typical CMAP), and an amplitude of several millivolts (see Fig. 2-18*B*). The combination of fibrillations and fasciculations indicates active denervation combined with more chronic reinnervation of muscle.

The precise mechanism of fasciculation is still contested. Forster and colleagues challenged the original belief that the discharge originated in anterior horn cells by demonstrating that in disease of the anterior horn cell, fasciculations persisted after nerve block. These observations favored a distal axonal site of generation. It seems that several regions of the axon are capable of spontaneous impulse generation, depending on the underlying disease. Most of the diseases that produce fasciculations involve the anterior horn cell or the motor root, but more distal sites in the motor axon may become spontaneously active in cases of nerve compression.

Occasional fasciculation potentials, particularly in the calves, hands, and periocular or paranasal muscles, occur in many normal persons. They can be almost constant for days or weeks on end, or even for years in some individuals, without weakness or wasting; therefore, they need not be taken as evidence of disease ("benign fasciculations"). Certain quantitative features of fasciculations, such as brief duration and a consistent pattern and location of firing on the needle EMG examination, favor benign over pathologic discharges. Shivering induced by low temperature and twitchings associated with low serum calcium levels

are other forms of fasciculatory activity. The main diseases that cause fasciculations are discussed in Chap. 45 and other related sections of the book.

Other types of spontaneous and elicited electrical activity (See also Chaps. 45 and 46) These various phenomena can be classified according to their generating source. The muscle fibers themselves are the source of fibrillations, positive sharp waves, and complex repetitive discharges (CRDs). The motor axons produce fasciculation potentials, myokymic discharges, neuromyotonia, and cramp syndromes; and the CNS is the source of complex ensembles of continuous motor activity such as occur in the stiff man syndrome, all described just below.

The common phenomenon of CRDs, referred to in the past as bizarre high-frequency discharges, consists of repetitive spontaneous potentials created by numerous single muscle fibers that fire in near synchrony; there is often an erratic configuration and abrupt starting and stopping of the discharges. They are seen in some myopathies, in hypothyroidism, and in certain denervating disorders, and are a mark of chronicity (lesions > 6 months old). High-frequency coupling of action potentials into doublets, triplets, or higher multiples of single units, indicating instability in repolarization of the nerve fiber to a muscle, occurs in tetany and in the early stages of myokymia.

Myokymia is a persistent quivering and rippling of muscles at rest. The EMG picture is distinctive. The spontaneously firing MUPs are called *myokymic potentials*, or *discharges* and consist of groups of repetitive discharging units, each firing at its own rate, quasirhythmically, usually several times per second, followed by a briefer period of silence. The small motor unit discharges may occur singly or as doublets, triplets, or multiplets.

The phenomenon of *myotonia* or neuromyotonia denotes a failure of voluntary relaxation of muscle because of sustained firing of the muscle membrane (see Chaps. 45 and 46) and is characterized by high-frequency repetitive discharges generally having a positive sharp waveform. These myotonic discharges wax and wane in amplitude and frequency, producing a "dive-bomber" sound on the audio monitor. The discharges can be elicited mechanically by percussion of the muscle or movement of the needle electrode and are also seen following voluntary contraction or electrical stimulation of the muscle via its motor nerve. The MUPs may appear normal during voluntary contraction, but they are not followed by the silence that normally occurs on relaxation; instead, there is a "prolonged afterdischarge" consisting of long trains of fibrillation-like potentials that may take as long as several minutes to subside (Fig. 2-19*A*). These EMG findings can be seen with any myotonic disorder. If the muscle is activated repeatedly at short intervals, the late discharge becomes briefer and briefer and eventually disappears (see Fig. 2-19*B*), as the patient becomes able to relax the exercised muscle ("warmup" effect).

In *paradoxical myotonia* the myotonia worsens after each of a succession of voluntary contractions. This is the converse of what happens in *myotonia congenita* (Thomsen disease). As shown by single-fiber EMG studies, myotonia is generated by single muscle fibers and the mechanism of the membrane instability, at least in some forms, seems to involve changes in the chloride conductance. These disorders are discussed in subsequent chapters.

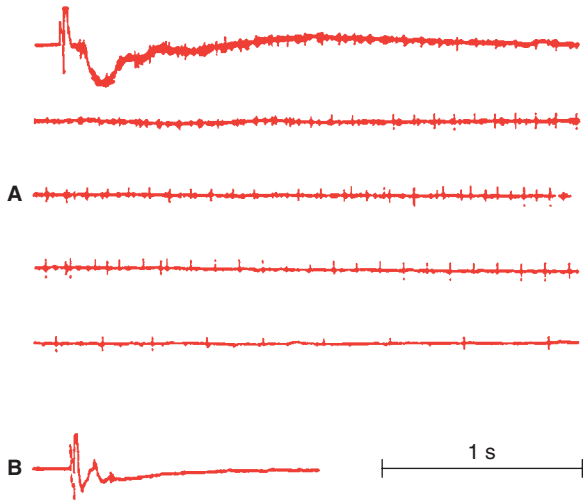

Figure 2-19. *A*. Myotonia congenita (Thomsen disease). The five lines are a continuous record of activity in the biceps brachii following a tap on the tendon. The initial response is within normal limits, but it is followed by a prolonged burst of rapid activity, gradually subsiding over a period of many seconds or minutes. *B*. Same electrode placement as in *A*. Response to the fifth of a series of tendon taps. "Warmup" has occurred, and the characteristic prolonged myotonic activity is no longer evident. (See Chap. 46 for a description of the disease.)

The *cramp-like contracture* of McArdle disease and phosphofructokinase deficiency is associated with electrical silence of contracting muscle. This feature is an important part of the definition of true physiologic muscle contracture (as distinguished from chronic shortening of a muscle and its tendon, which, strictly speaking, is a pseudocontracture).

In the *syndrome of continuous muscle fiber activity or Isaacs syndrome* (see Chap. 46), which is a generalized form of myokymia, the EMG discloses high-frequency (up to 300-Hz) repetitive discharges of varying waveforms. In the *stiff person syndrome*, painful muscle spasms and stiffness are generated by a spinal mechanism; the EMG potentials resemble normal motor units but are abnormal by virtue of continuous firing at rest.

Abnormalities in Amplitude, Duration, and Shape of Motor Unit Potentials

Figure 2-20 depicts the ways in which disease processes affect the motor unit and the appearance of the MUP in the EMG.

Motor unit potentials in denervation Early in the course of denervation of muscle by disease of the nerve, many motor units with functional connections to the spinal cord are unaffected, and although the number of MUPs appearing during contraction is reduced, the configurations of the remaining ones are quite normal. In time, the remaining MUPs often increase in size and in electrical amplitude, perhaps two to three times normal, and become longer in duration and sometimes *polyphasic* (more than four phases).

Such large and sometimes *giant polyphasic potentials* (Fig. 2-20*C*) arise from motor units containing more than

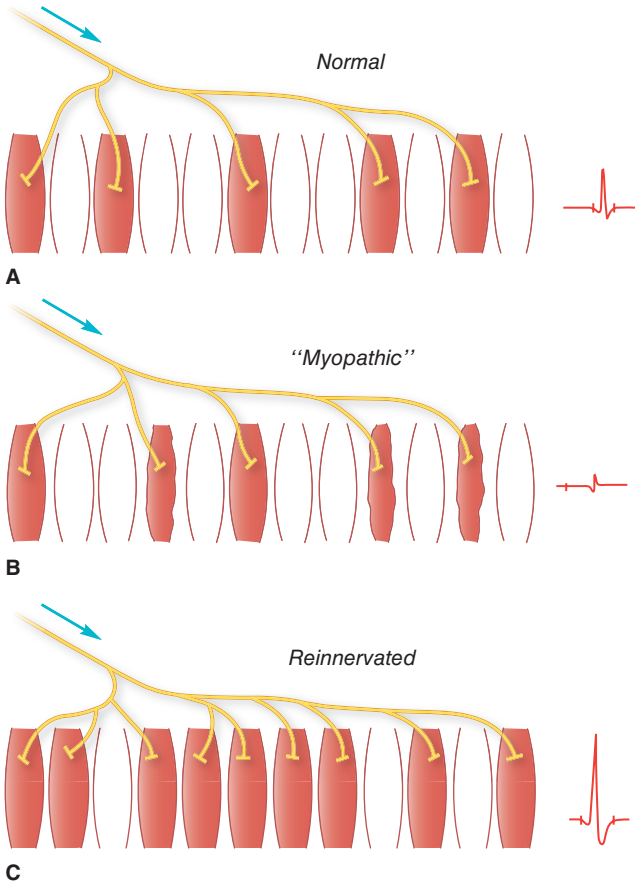

Figure 2-20. Normal, myopathic, and reinnervated motor units. The *colored* muscle fibers are functional members of one motor unit whose axon enters from the upper left and branches terminally to innervate the appropriate muscle fibers. The action potential produced by each motor unit is seen to the right: its duration is measured between the two vertical lines. The normal-appearing but *uncolored* fibers belong to other motor units. *A*. There are five muscle fibers illustrated in the active unit. *B*. In this myopathic unit, only two fibers remain active; the other three (*shrunken*) were affected by one of the primary muscle diseases. *C*. Four fibers that originally belonged to other motor units and had been denervated are now reinnervated by terminal sprouting from an undamaged axon. Both the motor unit and its action potential are now larger than normal. Note that only under these abnormal circumstances do fibers in the same unit lie next to one another.

the usual number of muscle fibers that are spread out over a greatly enlarged territory within the muscle. Presumably, new nerve twigs have sprouted from nodal points and terminals of undamaged axons and have reinnervated previously denervated muscle fibers, thus adding them to their own motor units. Soon after reinnervation, the MUPs generated will be low in amplitude, extremely prolonged, and polyphasic, findings that constitute a transitional configuration of early reinnervation. These amplitudes disappear as the motor unit is reestablished. Increased amplitude is usually associated with very chronic, proximal axon loss, for example, with remote poliomyelitis and chronic radiculopathy. These MUPs are to be differentiated from (1) polyphasic potentials of normal duration, which, as has been mentioned, make up as much as 10 percent of the total number of MUPs in normal muscle and (2) polyphasic MUPs of short duration and low amplitude, which are characteristic of most myopathies and of myasthenia gravis and other disorders of neuromuscular transmission.

The motor unit potential in myopathy As Fig. 2-20*B* shows, diseases such as polymyositis, muscular dystrophies, and other myopathies that randomly destroy muscle fibers or render them nonfunctional, and obviously reduce the population of muscle fibers per motor unit. Therefore, when such a unit is activated, its potential is of lower voltage and shorter duration than normal, and it may also appear polyphasic as the compound MUP becomes fragmented into its constituent single-fiber potentials. Slowing of the propagated muscle fiber action potential in affected muscle fibers also contributes to the changes in the "myopathic" MUP. When most of the muscle fibers are affected, the MUPs are very small and of short duration and are recruited out of proportion to the tension generated, the so-called *early recruitment*. Both types of alterations produce a characteristic high-pitched crackling sound from the audio monitor that has been likened to rain falling on a tin roof. They occur in all forms of chronic myopathies. Identical MUP changes are seen occasionally with other processes that cause disintegration of the motor unit, for example, early Guillain-Barré syndrome (because of conduction block along some of the terminal nerve fibers), and rarely with disorders of neuromuscular transmission (myasthenia gravis, other myasthenic syndromes), but they are most characteristic of primary muscle disease.

Abnormalities of the interference pattern Diseases that reduce the population of functional motor neurons or axons within the peripheral nerve decrease the number of motor units that can be recruited in the affected muscles. The decreased number of motor units available for activation produces a low-amplitude interference pattern with only a few remaining units firing at a moderate to rapid rate. A severe reduction in the interference pattern may result in the recruitment of only a single unit (see Fig. 2-17*B*). Structural damage to nerve, as well as demyelinating block, can produce this pattern of reduced recruitment; indeed, a reduced recruitment pattern coupled with the absence of denervation usually indicates a conduction block.

If muscle power is reduced in diseases such as polymyositis or muscular dystrophy, in which individual muscle fibers are affected, there may be little or no reduction in the number of motor units available for recruitment until the process is far advanced and entire MUPs have been lost as a result of random loss of all their constituent muscle fibers. Nonetheless, each motor unit will consist of fewer muscle fibers than normal, so more motor units must be activated to reach a certain degree of force. A modest effort can thus produce a full interference pattern despite marked weakness (increased recruitment). Because fewer muscle fibers are firing, the amplitude of the pattern will be reduced from normal. This type of full, highly complex interference pattern of less-than-usual amplitude in the face of dramatic weakness is the hallmark of myopathy (see Fig. 2-17*C*).

Single-Fiber Electromyography

This is a special technique for the recording of single muscle-fiber action potentials that has found utility in

measuring muscle fiber density and in detecting the so-called jitter in disease of the neuromuscular junction, particularly myasthenia gravis. *Jitter* is the variability of the interpotential interval of successive discharges of two single muscle fibers belonging to the same motor unit. This phenomenon is largely a result of the very slight variability of delay at the branch points in the distal axon and by synaptic delay at the neuromuscular junction, especially in myasthenia gravis where it has found its main clinical use. Fiber density and jitter may, however, also be increased in neuropathic disorders that cause denervation with reinnervation. Both are usually normal or only slightly increased in myopathic disorders.

Testing for jitter is carried out by having the patient voluntarily contract a muscle to the slightest degree possible so as to activate only one motor unit (requiring a great deal of cooperation by the patient) or by stimulating an intramuscular nerve twig (requiring great patience on the part of the examiner). The EMG needle is advanced until two muscle fibers from the same motor unit are recorded. If the oscilloscope sweep is triggered by the firing of the first fiber, a fluctuating latency of the second fiber potential can be seen on the screen as a movement (jitter) of the second peak. The degree of jitter can be quantitated by measuring the interval between the activation of the two muscle fibers (the result of slightly differing lengths of the terminal axons) from which a mean interpeak interval is determined. Approximately 20 fiber pairs are sampled, and an average of the mean intervals can be derived. In a muscle such as the extensor digitorum communis, the average variation should be no more than 34 ms. The acceptable average is lower for large proximal muscles. Also, in disease of the neuromuscular junction, one muscle fiber in a pair may fail to fire intermittently as a result of a blocking of conduction.

Imaging of Muscle and Nerve

Imaging techniques—CT, MRI, and ultrasonography—enable one to measure muscle volume and to recognize qualitative changes in muscle structure. Such methods are finding some clinical and research use in the diagnosis of disorders of muscle and in gauging the effects of treatment. CT of dystrophic muscle shows foci of decreased attenuation, representing masses of fat cells. The fatty masses spread gradually from multiple foci and eventually replace muscle fibers. The original shape of the muscle is retained; indeed, an enlarged weak muscle containing mostly fat confirms the clinical impression of pseudohypertrophy. In denervative atrophy, the muscles are obviously small and contain multiple punctate areas of decreased attenuation, which represent interstitial fat. Eventually, large portions of chronically denervated muscle may be replaced by fat. Blood, blood products, and calcium deposits are expressed by increased attenuation on CT. This may be helpful in the diagnosis of muscle trauma, myositis ossificans, and dermato- and polymyositis.

Fat and bone marrow have a high-signal intensity in MR images, whereas fascia, ligaments, and cortical bone lack signal intensity. In T1-weighted images, normal muscle has a low signal and dystrophic muscle, a slightly increased signal; in T2-weighted images, dystrophic muscle has a slightly increased (brighter) signal. Given its sensitivity to these dystrophic changes in muscle, MRI is particularly effective in determining the topographic distribution of muscle involvement in a dystrophy (see Chap. 45). Spectroscopic MRI in metabolically determined myopathies has the capacity to quantitate levels of selected biochemical constituents of muscle, including intracellular pH and levels of metabolic intermediates such as phosphocreatine. This technique is particularly effective in demonstrating subnormal generation of intracellular acidosis after a limb is exercised in disorders of glycogenolysis and of glycolysis. Some individuals with mitochondrial disease of muscle will demonstrate rapid depletion of energy supplies and profound delays in recovery that can be quantified and used as an end point for treatments.

Magnetic resonance techniques and sequences have been developed that allow visualization of nerves. This may be an aid in assessing traumatic nerve injury and in demonstrating neuromas and other tumors, hypertrophy or atrophy of a nerve trunk or plexus, or in visualizing the root, plexus, and nerve inflammation that may occur in the inflammatory demyelinating polyneuropathies.

NEUROPSYCHOLOGICAL TESTS, PERIMETRY, AUDIOMETRY, AND VESTIBULAR TESTING

These methods are used in defining and quantitating the nature of the psychologic or sensory deficits produced by disease of the nervous system. They are performed most often to obtain confirmation of a disorder of function in particular parts of the nervous system or to quantitate, by subsequent examinations, the progression of the underlying illness such as dementia. A description of these methods and their clinical uses is found in the chapters dealing with localized cerebral function (Chap. 21), developmental disorders of the cerebrum (Chaps. 27 and 37), dementia (Chaps. 20 and 38), and disorders of vision (Chap. 12) and of hearing and equilibrium (Chap. 14).

GENETIC TESTING

Numerous genetic markers of inherited and sporadic disease have become available to the clinician and have greatly advanced both diagnosis and categorization of neurologic disease. The main examples are analyses of DNA extracted from blood or other cells for the identification of mutations (e.g., muscular dystrophy, spinocerebellar atrophies, and genetically determined polyneuropathies, and the quantification of abnormally long repetitions of certain trinucleotide sequences, most often used for the diagnosis of Huntington chorea). The use of these tests is elaborated in Chap. 38. The study of mitochondrial genetics has allowed the detection of an entire category of diseases that affect this subcellular structure, as detailed in Chap. 37.

BIOPSY OF BRAIN, NERVE, MUSCLE, AND OTHER TISSUE

The application of light, phase, and electron microscopy to the study of these tissues may be highly informative. The findings are discussed in Chaps. 36 (skin and conjunctivum in the diagnosis of metabolic storage diseases), 45 (muscle), and 46 (nerve). Temporal artery biopsy is indicated when giant cell arteritis is suspected (Chap. 33). Brain biopsy, aside from its main use in the direct sampling of a suspected neoplasm, may be diagnostic in cases of granulomatous angiitis, some forms of encephalitis, and infectious abscesses. Biopsy of the pachymeninges or leptomeninges may disclose vasculitis, sarcoidosis, other granulomatous infiltrations, or an obscure infection, but its sensitivity is low. This is usually performed in concert with a biopsy of the underlying brain. Biopsy is avoided in cases of suspected prion disease because of the risk of transmitting the causative agent. Abdominal fat pad biopsy is used in the diagnosis of amyloidosis. In choosing to perform a biopsy in any of these clinical situations, the paramount issue is the likelihood of establishing a definitive diagnosis—one that would permit successful treatment or otherwise enhance the management of the disease.

PART 2

CARDINAL MANIFESTATIONS OF NEUROLOGIC DISEASE

The cardinal manifestations of neurologic disease are described in this second part of the book. To understand the signs and symptoms created by the disordered function of the nervous system, it is necessary to first describe normal anatomy and physiology. Each chapter, therefore, begins with a consideration of these basic facts, followed by the manner in which they are affected by disease states and give rise to observable changes such as weakness, incoordination, abnormal movements, sensory loss, and pain.

SECTION 1

Disorders of Motility

CHAPTER 3 **Paralysis and Weakness**
CHAPTER 4 **Disorders of Movement and Posture**
CHAPTER 5 **Ataxia and Disorders of Cerebellar Function**
CHAPTER 6 **Disorders of Stance and Gait**

The complexity of motor activity is almost beyond imagination. Scratching one's shoulder has been estimated to recruit about 75 muscles. And what must be involved in playing a piano concerto? Over a century ago Hughlings Jackson commented that "There are, we shall say, over thirty muscles in the hand; these are represented in the nervous centers in thousands of different combinations, that is, as very many movements; it is just as many chords, musical expressions, and tunes can be made out of a few notes." Based on clinical observations, Jackson surmised that the motor system is organized hierarchically in three levels. According to his framework, the spinal and brainstem neurons represent the lowest, simplest, and most organized motor centers; the motor neurons of the posterior frontal region represent a more complex and less closely organized second motor center; and the prefrontal parts of the cerebrum are the third and highest motor center. This scheme is still regarded as being essentially correct, although since Jackson's time the importance of the parietal lobe and basal ganglia in motor control has also been recognized.

More recently, functional imaging has analyzed motor organization and found it to be remarkably complex. The cooperative activities of motor and sensory cortices, under the critical influence of the basal ganglia, cerebellum, and reticular formation of the brainstem, are continuously integrated and modulated by feedback mechanisms from the sensory and spinal motor neurons (Faglioni and Basso). Motor and sensory systems, although separated for practical clinical purposes, are not independent entities; without sensory feedback, motor control is ineffective. Furthermore, at the higher cortical levels of motor control, motivation, planning, and other frontal lobe activities that subserve volitional movement are preceded and modulated by activity in the parietal sensory cortex.

Physiologic studies, cast in their simplest terms, indicate that the following parts of the nervous system are engaged primarily in the control of movement, yielding characteristic derangements in the course of the disease. The large motor neurons in the anterior horns of the spinal cord and the motor nuclei of the brainstem innervate the skeletal muscles. These nerve cells and their axons constitute the *lower motor neurons*, constituting the final common pathway by which all neural impulses are transmitted to muscle. The motor neurons in the precentral gyrus of the frontal cortex connect with the spinal motor neurons by a system of fibers known as the *corticospinal tract*, or, alternatively, as the *upper motor neurons.* The portion of these fibers that travel through the ventral medulla is designated the *pyramidal tract,* because of the shape of the fasciculus in that location. In addition, several brainstem nuclei that govern motor control project to the spinal cord, notably the pontine and medullary reticular nuclei, vestibular nuclei, and red nuclei. These nuclei and their descending fibers primarily subserve movement is highly automatic and repetitive, particularly posture and gait. Two subcortical systems modulate the activity of all movement; these are the *basal ganglia* (striatum, pallidum, and related structures, including the substantia nigra and subthalamic nucleus) and the *cerebellum*. Each of these systems plays an important role in the control of muscle tone, posture, and coordination.

These structures and their disorders are the subjects of the following four chapters.

3

Paralysis and Weakness

Definitions

Paralysis refers to loss of voluntary movement as a result of interruption of the motor pathways at any point from the cerebrum to the muscle fiber. The term *plegia* refers to severe weakness, coming from a Greek word meaning "to strike," and the word *palsy* stems from a French word that has the same meaning as paralysis. A lesser degree of weakness is described as *paresis*.

THE LOWER MOTOR NEURON

Anatomic and Physiologic Considerations

Each motor neuron, through extensive arborization of the terminal part of its efferent fiber, comes into contact with a variable number of muscle fibers, ranging from only a few to 1,000 or more. Together, the motor neuron, its axon, and the muscle fibers they innervate constitute the *motor unit*. All variations in the force, range, rate, and type of movement are determined by the number and size of motor units called into action and the frequency and sequence of firing of each motor unit. Smaller movements involve relatively few motor units; powerful movements recruit many more units that accumulate to an increasing size.

The motor nerve fibers emanating from a group of anterior horn cells in one segment of the spinal cord constitute a ventral spinal root, which joins a dorsal sensory root to form the spinal nerves that intermingle to form plexuses and then form the peripheral nerves. A *myotome* refers to the group of muscles that receive innervation from a single spinal nerve root, though most large muscles are usually supplied by two or more roots that have contributed to a given peripheral nerve. In contrast, a single peripheral nerve usually provides the complete motor innervation of a muscle. For this reason, paralysis caused by disease of the anterior horn cells or ventral roots has a different topographic pattern than paralysis following the interruption of a peripheral nerve (see Table 43-1). For example, a lesion of the L5 root causes weakness of foot dorsiflexion and inversion, whereas a lesion of the peroneal nerve causes weakness of foot dorsiflexion but spares foot inversion, since the invertors of the foot are supplied by L5 but via the tibial nerve.

All motor activity, even the most elementary reflex, requires the synchronous activity of many muscles. Analysis of a relatively simple movement, such as clenching the fist, conveys some idea of the complexity of the underlying neuromuscular arrangements. In this act, the primary movement is a contraction of the flexor muscles of the fingers, the flexor digitorum sublimis and profundus, the flexor pollicis longus and brevis, and the abductor pollicis brevis. In the terminology of Beevor, these muscles act as *agonists*, or prime movers. For flexion to be smooth and forceful, the extensor muscles (*antagonists*) must relax at the same rate as the flexors contract (*reciprocal innervation*, or Sherrington's law). The muscles that flex the fingers also flex the wrist. If it is desired that only the fingers flex, the extensors of the wrist must be brought into play to prevent its flexion; the extensors are *synergists*. During this action of the hand, appropriate flexor and extensor muscles stabilize the wrist, elbow, and shoulder; muscles that accomplish this serve as *fixators*. A complex interplay of neurons at each segmental level engages the coordination of agonists, antagonists, synergists, and fixators once stimulated by afferent proprioceptive sensory impulses. In general, the more delicate the movement, the more precision is required in the coordination of agonist and antagonist muscles.

Motor activities include not only those that alter the position of a limb or other part of the body (isotonic contraction) but also those that stabilize posture (isometric contraction). Movements that are performed slowly are called *ramp movements*. Very rapid movements, which are too fast for sensory control, are called *ballistic* or *phasic*.

Voluntary ballistic movements toward a target are accomplished by the activation of ensembles of motor neurons. Large motor units participate mainly in triphasic movement, which is characterized by an initial burst of activity in the agonist muscles, then a burst in the antagonists, followed by a third smaller burst in the agonists. The strength of the initial agonist burst determines the speed and distance of the movement, but the same triphasic pattern of agonist, antagonist, and agonist activity always occurs (Hallett et al). Smaller motor units are more efficiently activated by sensory afferents from muscle spindles and more readily recruited in reflex activities, postural maintenance, walking, and running. The basal ganglia and cerebellum set the pattern and timing of the muscle action

in any projected motor performance. These points are discussed further in Chaps. 4 and 5.

Unlike the phasic movements just described, certain basic motor activities do not involve reciprocal innervation. In support of the body in an upright posture, the agonists and antagonists of the legs contract simultaneously. Locomotion requires that the extensor pattern of reflex standing be inhibited and that the coordinated pattern of alternating stepping movements be substituted; the latter is accomplished by the so-called locomotor centers that comprise multisegmental spinal and brainstem reflexes. Suprasegmental control of the axial and proximal limb musculature (antigravity postural mechanisms) is mediated primarily by the reticulospinal and vestibulospinal tracts. These aspects of motor function are elaborated further on.

Muscle stretch (tendon) reflex activity and muscle tone depend on the status of the large anterior horn motor neurons (the alpha motor neurons), the muscle spindles and their afferent fibers, and the small anterior horn cells (gamma neurons), whose axons terminate on the specialized intrafusal muscle fibers (nuclear chain fibers) within the spindles (Burke and Lance; Davidoff). Some gamma motor neurons are tonically active at rest, keeping the intrafusal muscle fibers taut and more sensitive to active and passive changes in muscle length. Each anterior horn cell has on its surface membrane approximately 10,000 receptive synaptic terminals. Some of these terminals are excitatory, others inhibitory; in combination, they determine the activity of the neuron.

A tap on a tendon causes stretch of the spindle that activates its nuclear bag fibers. Afferent projections from these fibers synapse directly with alpha motor neurons in the same and adjacent spinal segments; these neurons, in turn, send impulses to the skeletal muscle fibers, resulting in the monosynaptic muscle contraction commonly referred to as the *tendon reflex*, more correctly called the muscle stretch or proprioceptive reflex (Fig. 3-1). All this occurs within 25 ms of the sudden stretch. The alpha neurons of antagonist muscles are simultaneously inhibited but through disynaptic rather than monosynaptic connections. This is accomplished in part by inhibitory interneurons (*reciprocal inhibition*) that also receive input from descending pathways. Renshaw cells also participate by providing negative feedback through inhibitory synapses of alpha motor neurons (*recurrent inhibition*). Reflexive muscle contraction can also be produced when vibration is applied to a tendon; this *tonic vibration reflex* is characterized by a long latency, implying a polysynaptic pathway, and it can be suppressed voluntarily (Brodal).

The tension in the spindle fibers and the state of excitability of the alpha and gamma neurons (influenced

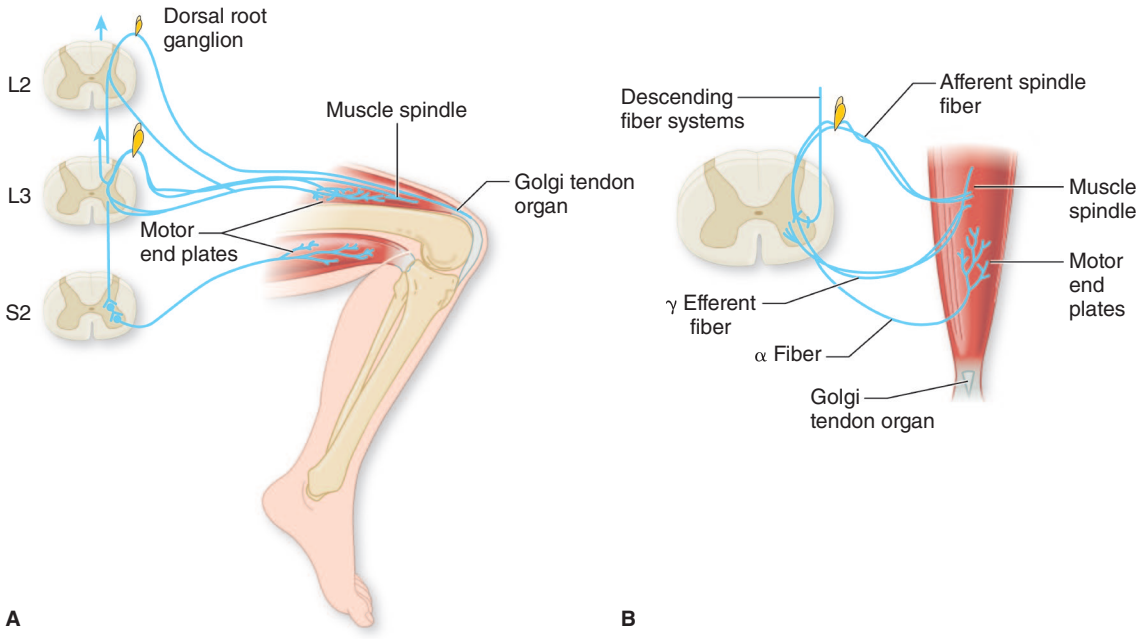

Figure 3-1. *A*. Patellar tendon reflex. Sensory fibers of the femoral nerve (spinal segments L2 and L3) mediate this myotatic reflex. The principal receptors are the muscle spindles, which respond to brisk stretching of the muscle affected by tapping the patellar tendon. Afferent fibers from muscle spindles are shown entering only the L3 spinal segment, while afferent fibers from the Golgi tendon organ are shown entering only the L2 spinal segment. In this monosynaptic reflex, afferent fibers entering spinal segments L2 and L3 and efferent fibers issuing from the anterior horn cells of these and lower levels complete the reflex arc. Motor fibers shown leaving the S2 spinal segment and passing to the hamstring muscles demonstrate the disynaptic pathway by which inhibitory influences are exerted upon an antagonistic muscle group during the reflex. *B*. The gamma loop is illustrated. Gamma efferent fibers (γ) pass to the polar portions of the muscle spindle. Contractions of the intrafusal fibers in the polar parts of the spindle stretch the nuclear bag region and thus cause an afferent impulse to be conducted centrally. The afferent fibers from the spindle synapse with many alpha motor neurons. Because the alpha motor neurons innervate extrafusal muscle fibers, excitation of the alpha motor neurons by spindle afferents causes a cocontraction of the muscle. In this way, both gamma and alpha fibers can simultaneously activate muscle contraction. Both alpha and gamma motor neurons are influenced by descending fiber systems from supraspinal levels. (Reproduced with permission from Carpenter MB, Sutin J. *Human Neuroanatomy*, 8th ed. Baltimore: Williams & Wilkins; 1983.)

greatly by descending fiber systems) determines the level of activity of the tendon reflexes and muscle tone (the responsiveness of muscle to stretch). Other mechanisms, of an inhibitory nature, involve the Golgi tendon organs, which detect the tension produced by active contraction of muscle. These encapsulated receptors, which lie in the tendinous portions of muscle, activate afferent fibers that end on internuncial cells, which project to alpha motor neurons, thus forming a disynaptic reflex arc. Golgi tendon receptors are silent in relaxed muscle and during passive stretch; they serve, together with muscle spindles, to monitor or calibrate the length and force of muscle contraction under different conditions. They also play a role in naturally occurring limb movements, particularly in locomotion.

The alpha motor neurons are located in the anterior gray matter (anterior horn) of the spinal cord. The medial parts of the anterior horn supply trunk or axial muscles, and neurons of the lateral parts supply the appendicular muscles. The largest neurons innervate large muscles with large motor units. Smaller anterior horn cells innervate small muscles and control more delicate movements, particularly those in the fingers and hand. Both groups of alpha neurons receive projections from propriospinal neurons via the large fasciculi proprii from adjacent spinal segments. All the facilitatory and inhibitory influences supplied by cutaneous and proprioceptive afferent and descending suprasegmental neurons are coordinated at segmental levels.

Alpha motor neurons use acetylcholine as their transmitter at the neuromuscular junction. The main neurotransmitters of the descending corticospinal tract are aspartate and glutamate. Glycine is the neurotransmitter released by Renshaw cells, which are responsible for recurrent inhibition, and by interneurons that mediate reciprocal inhibition during reflex action. Gamma-aminobutyric acid (GABA) serves as the inhibitory neurotransmitter of interneurons in the posterior horn. There are also descending cholinergic, adrenergic, and dopaminergic axons, which play a less well-defined role in reflex functions.

Paralysis due to Lesions of the Lower Motor Neurons

If all the peripheral motor fibers supplying a muscle are interrupted, the voluntary, postural, and reflex movements of that muscle are abolished. The muscle becomes lax and soft and does not resist passive stretching, a condition known as flaccidity. Muscle tone—the slight resistance that normal relaxed muscle offers to passive movement—is reduced (referred to as hypotonia or atonia). The denervated muscle undergoes significant atrophy, being reduced to 20 or 30 percent of its original bulk within 3 to 4 months. Areflexia occurs, with loss of reaction of the muscle to sudden stretch. Damage restricted to only a portion of the motor fibers supplying the muscle results in partial paralysis, or paresis, and a proportionate diminution in the force and speed of contraction. The atrophy will be less and the tendon reflex reduced instead of lost. The electrodiagnostic findings that demonstrate denervation of muscle include fibrillations, fasciculations, and other abnormalities as mentioned in the previous chapter. However, some of these abnormalities do not appear until several days or a week or two after nerve injury.

In any case, where lower motor neuron weakness is present, an important clinical question is whether sensory changes coexist. The combination of flaccid, areflexic paralysis with sensory changes usually indicates the involvement of mixed motor and sensory nerves or of both anterior and posterior roots. If sensory changes are absent, the lesion must be situated in the anterior gray matter of the spinal cord, in the anterior roots, in a purely motor branch of a peripheral nerve, or in motor axons alone (or in the muscle itself).

Reduced tendon reflexes and muscle tone also occur with acute and profound spinal cord lesions and, to a lesser extent, corticospinal lesions in the brainstem and cerebrum, ("spinal shock"; see Chap. 42). This phenomenon is probably caused by interruption of descending tonic excitatory impulses that normally maintain a level of excitation in spinal motor neurons required for peripheral activation of segmental reflexes. The attenuation of spinal shock by opiate antagonists, such as naloxone, suggests that the phenomenon is in part mediated by the release of endogenous opiates from the distal terminals of neurons in the periaqueductal gray matter. Once the stored opiates are depleted, the presynaptic inhibition of motor neurons ceases, heralding the end of spinal shock and the transition to muscle spasticity.

THE UPPER MOTOR NEURON

Anatomic and Physiologic Considerations

The corticospinal tract descends from the cerebral cortex; traverses the subcortical white matter (corona radiata), internal capsule, cerebral peduncle, basis pontis (ventral pons), and pyramid of the upper medulla; decussates in the lower medulla; and continues its caudal course in the lateral funiculus (column) of the spinal cord (Fig. 3-2). This is the only direct long-fiber connection between the cerebral cortex and the spinal cord. The portion of the corticospinal tract that travels through the medullary pyramid may also be referred to as the *pyramidal* tract. Indirect pathways through which the cortex influences spinal motor neurons are the rubrospinal, reticulospinal, vestibulospinal, and tectospinal; these tracts do not run in the pyramid. All these pathways, direct and indirect, are embraced by the broader term *upper motor neuron*. It is best to recognize the specific definitions of the terms corticospinal, pyramidal, and upper motor neuron, and avoid using them interchangeably.

A frequent point of confusion about the pyramidal tract stems from the traditional view, formulated at the turn of the twentieth century, that it originates entirely from the Betz cells of the primary motor cortex (Brodmann area 4) (Figs. 3-3 and 21-2). However, there are only some 25,000 to 35,000 Betz cells, whereas the medullary pyramid contains about 1 million axons (Lassek). Thus, most of the fibers of the pyramidal tract arise from cortical neurons

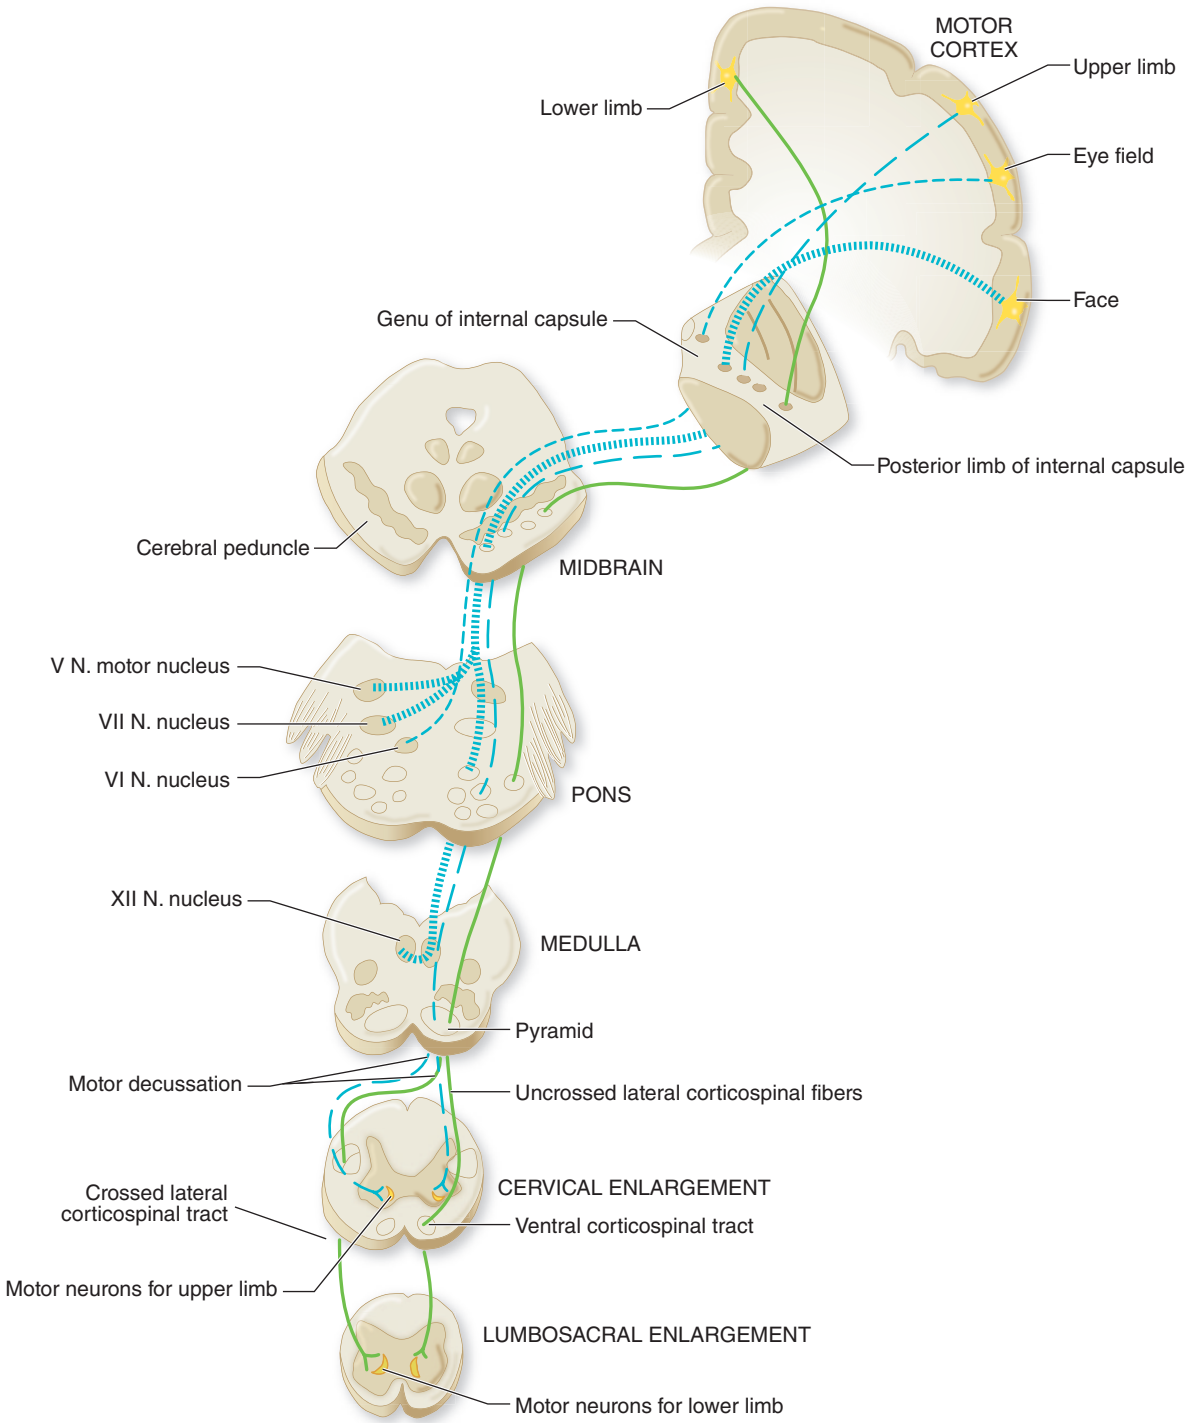

Figure 3-2. Corticospinal and corticobulbar tracts. The various lines indicate the trajectories of these pathways, from their origin in particular parts of the cerebral cortex to their nuclei of termination.

other than Betz cells, particularly from the supplementary motor of the frontal cortex (Brodmann area 6); the primary somatosensory cortex (areas 3, 1, and 2); and the superior parietal lobule (areas 5 and 7). In the monkey, by counting the pyramidal axons that remained after cortical excisions and long survival periods, Russell and DeMyer found that 40 percent of the descending axons arose from portions of parietal cortex (areas 1, 3, 5, and 7), and roughly 30 percent each from motor area 4 and from premotor area 6. Data concerning the origin of the pyramidal tract in humans are less robust.

The fibers that comprise the corticospinal tract converge in the corona radiata and then descend through the posterior limb of the internal capsule, basis pedunculi,

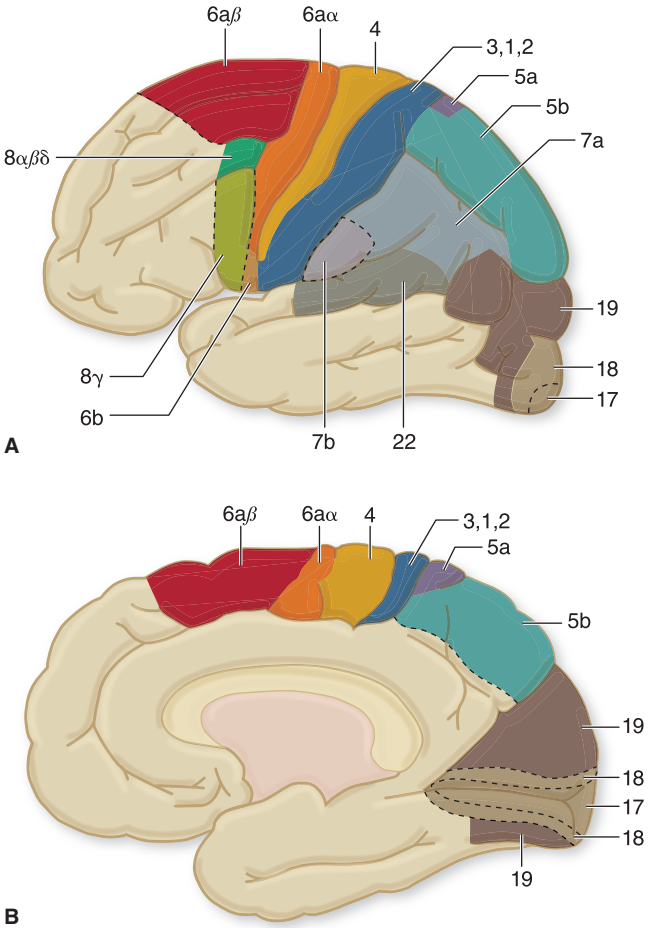

Figure 3-3. Lateral (*A*) and medial (*B*) surfaces of the human cerebral hemispheres, showing the areas of excitable cortex, numbered to the scheme of Brodmann. (Reproduced with permission from House EL, Pansky B: *A Functional Approach to Neuroanatomy*. 2nd ed. New York: McGraw-Hill; 1967.

basis pontis, and medulla. As the corticospinal tracts descend in the cerebrum and brainstem, they send collaterals to the striatum, thalamus, red nucleus, cerebellum, and reticular formations. Accompanying the corticospinal tracts in the brainstem are the corticobulbar tracts, which are distributed to motor nuclei of the cranial nerves ipsilaterally and contralaterally (see Fig. 3-2). Direct projection of axons of cortical neurons can be traced to the trigeminal, facial, ambiguus, and hypoglossal nuclei (Iwatsubo et al), but no axons terminate directly in the oculomotor, trochlear, abducens, or vagal nuclei. The term upper motor neuron may be used to describe both corticobulbar and corticospinal fibers.

The somatotopic organization of the corticospinal system is of importance in clinical work, especially in relation to certain stroke syndromes. As the descending axons subserving limb and facial movements emerge from the cortical motor strip, they maintain the anatomic organization of the overlying cortex; therefore, a discrete cortical–subcortical lesion can result in weakness restricted to the hand and arm or the foot and leg. More caudally, the descending motor fibers converge in the posterior limb of the internal capsule, so that even a small lesion there will cause pure motor hemiplegia in which the face, arm, hand, leg, and foot are affected to approximately same degree (see Lacunar syndromes in Chap. 33). The axons subserving facial movement are situated anterior in the posterior limb of the capsule, those for hand and arm in the central portion, and those for the foot and leg in the posterior portion (Brodal).

This topographic distribution is maintained in the cerebral peduncle, where the corticospinal fibers occupy approximately the middle of the peduncle. The fibers destined to innervate the facial nuclei lie most medially. More caudally, in the basis pontis (ventral part of the pons), the descending motor tracts separate into bundles that are interspersed with masses of pontocerebellar neurons. Restricted pontine lesions may cause a pure motor hemiplegia that is indistinguishable from the paralysis caused by lesions in the internal capsule. Anatomic studies in nonhuman primates indicate that arm–leg distribution of fibers in the rostral pons is much the same as in the cerebral peduncle; in the caudal pons, this distinction is less well-defined. MRI mapping techniques of patients with hemiplegia due to brainstem lesions also suggest that the usual somatotopic organization breaks down in the base of the pons, but fibers innervating proximal muscles lie more dorsally and those exciting distal parts of the limbs lie more ventrally (Marx and colleagues).

The corticobulbar fibers that innervate the facial nuclei can take several paths. Most often, the decussation occurs in the ventromedial pons, whereas in some individuals these fibers descend through the upper medulla and then ascend to innervate the opposite facial motor nucleus (Pick bundle). The existence of the latter configuration explains occasional instances of facial palsy from brainstem lesions caudal to the midpons (Terao and colleagues). Electrophysiologic studies in patients with facial weakness resulting from lower brainstem infarctions have supported the existence of these various configurations (Urban and colleagues).

The descending fibers of the corticospinal tracts, now devoid of their corticopontine projections, reunite to form the medullary pyramid. About 75 to 80 percent of the corticospinal fibers cross, while the remaining fibers descend ipsilaterally, mostly in the ventral corticospinal tract. Most of the crossing fibers decussate at the lower end of the medulla, although some cross above this level. The fibers destined for the upper limb neurons cross first (more rostrally). Uncrossed fibers in the corticospinal tract account for mirror movements that are seen during fine motor tasks, particularly in children and in conditions such as Klippel-Feil syndrome and Kallmann syndrome.

The proportion of crossed and uncrossed fibers varies to some extent from one person to another (Nyberg). The corticospinal tract is phylogenetically relatively new, being found only in mammals, which probably accounts for its variability between individuals as compared to the older vestibulospinal, rubrospinal, and reticulospinal systems, which are invariant among persons. In very rare cases, the corticospinal tracts in an individual cross completely or remain completely uncrossed. These variations are probably of functional significance in determining the

amount of neurologic deficit that results from a unilateral cerebral lesion such as capsular infarction (Vulliemoz et al). A few well-studied cases describe acute stroke of the cerebral hemisphere causing hemiplegia on the same side (Terakawa and colleagues). Yakovlev found instances of completely uncrossed pyramids among autopsies of developmentally delayed neonates, but this finding may not be generalizable.

The different upper motor neuron pathways occupy distinct locations in the spinal cord. After their decussation, the corticospinal pathways descend in the anterior and posterolateral white matter columns (funiculi) (see Fig. 3-2). The lateral vestibulospinal tract lies in the most anterolateral portion of the anterior funiculus (Nathan and colleagues). The medial vestibulospinal fibers mingle with those of the medial longitudinal fasciculus. Reticulospinal fibers are less compact; they descend bilaterally, and most of them come to lie just anterior to the lateral corticospinal tract. The propriospinal (also called spinal-spinal) pathway consists of a series of short fibers (one or two segments long) next to the gray matter.

The corticospinal tracts and other upper motor neurons terminate mainly upon neurons in the intermediate zone of spinal gray matter (internuncial neurons), which then relay impulses to the anterior horn cells. Only 10 to 20 percent of corticospinal fibers (predominantly the thick, rapidly conducting axons derived from Betz cells) establish direct synaptic connections with the large motor neurons of the anterior horns.

Motor, Premotor, and Supplementary Motor Cortices and Cerebral Control of Movement

The motor area of the cerebral cortex is defined physiologically as the region from which isolated movements can be evoked by electrical stimulation of minimal intensity. The muscle groups of the contralateral face, arm, trunk, and leg are represented in the primary motor cortex (area 4 in Fig. 3-3), those of the face being in the most inferior part of the precentral gyrus on the lateral surface of the cerebral hemisphere and those of the leg in the paracentral lobule on the medial surface of the cerebral hemisphere. The parts of the body capable of the most delicate movements have the largest cortical representation, as displayed in the motor homunculus ("little man," a term first suggested by Wilder Penfield) shown in Fig. 3-4.

Area 6α, the *premotor area*, can also evoke movements with electrical stimulation, but the threshold is much higher than for area 4. Stimulation of the caudal aspect of the premotor area produces responses that are similar to those elicited from area 4, but these responses are probably produced by direct propagation of impulses to area 4 (as they cannot be obtained after ablation of area 4). Stimulation of the rostral premotor area elicits more general movement patterns, predominantly of proximal limb musculature, which are affected via pathways other than those derived from area 4. In general, the motor–premotor cortex synthesizes agonist actions into an almost infinite variety of finely graded, highly differentiated patterns.

The *supplementary motor area* is the most anterior portion of area 6 on the medial surface of the frontal lobe (area 6β in Fig. 3-3*B*). Stimulation of this area can induce gross ipsilateral or contralateral movements, bilateral tonic contractions of the limbs, contraversive movements of the head and eyes with tonic contraction of the contralateral arm, and sometimes inhibition of voluntary motor activity and vocal arrest.

Precisely how the motor cortex controls movements remains a complex matter. The traditional view, based on the interpretations of Hughlings Jackson and Sherrington, and elaborated by Denny-Brown, has been that the motor cortex is organized not in terms of individual muscles

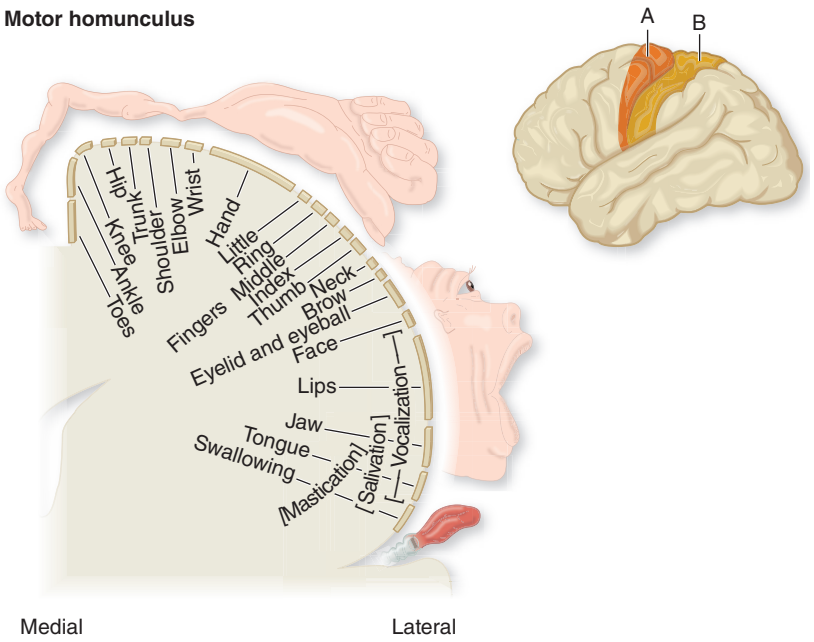

Figure 3-4. The representation of body parts in the motor cortex, commonly called the motor homunculus. The large area of cortex devoted to motor control of the hand, lips, and face is evident. A in the smaller diagram represents the motor cortex; B is the sensory cortex.

but of movements, that is, the coordinated contraction of groups of muscles. Jackson visualized a widely overlapping representation of muscle groups in the cerebral cortex based on his observation that a patient could recover the use of a limb following damage to the area controlling that limb as defined by cortical stimulation. This view was supported by Sherrington's observations that stimulation of the cortical surface activated not solitary muscles but a combination of muscles, and always in a reciprocal fashion—that is, in a manner that maintained the expected relationship between agonists and antagonists. He also noted the inconstancy of stimulatory effects; the stimulation of a given cortical point that initiated flexion of a part on one occasion might initiate extension on another.

These interpretations must be viewed with circumspection, as must all observations based on the electrical stimulation of the surface of the cortex. It has been shown that to stimulate motor cells from the surface, the electric current must penetrate the cortex to layer V, where these neurons are located, inevitably activating on a large number of other cortical neurons. More precise stimulation of the depths of the cortex with microelectrodes demonstrates the existence of discrete zones of neurons that control the contraction of individual muscles (Asanuma and Evarts et al). Neurons that project to a particular set of spinal motor neurons are arranged in radially aligned columns, and they receive afferent impulses from the particular muscles to which they project.

The columnar arrangement of cells in the sensorimotor cortex had been appreciated for many years; the wealth of radial interconnections between the cells in these columns led Lorente de Nó to suggest that these "vertical chains" of cells were the elementary functional units of the cortex. This notion received strong support from Mountcastle's observations that the neurons in a column receive impulses of the same sensory modality, from the same part of the body. It is still not entirely clear whether the columns contribute to a movement as units or whether individual cells within many columns are selectively activated (Henneman and Asanuma).

Pyramidal (area 4) motor neurons are prepared for sensory-evoked or planned movements mediated by inputs from the parietal, prefrontal, premotor, and auditory and visual areas of the cortex. Single-cell recording techniques show that pyramidal cells fire about 60 ms prior to the onset of a movement, in a sequence determined by the ultimate pattern and force of the movement (Evarts and colleagues). Electrographic activity in the supplementary motor cortex leading up to voluntary muscle movement has been named the Bereitschaft "readiness" potential (Kornhuber and Deecke). This potential is 1 to 2 orders of magnitude smaller than the α-rhythm of the EEG; its detection requires averaging multiple measurements prior to the onset of movement. Motor cortex also receives inputs from the posterior parietal cortex for movements initiated by sensory inputs, and from limbic areas that subserve motivation and attention. Functional cerebral blood flow measurements have shown the ensembles of neural events leading to activation of motor cortex (Roland).

Thus the prefrontal cortex, supplementary motor cortex, premotor cortex, and motor cortex are all responsive to afferent stimuli and are involved prior to, and in coordinated fashion with, a complex movement (Thach and Montgomery). As remarked later on, the basal ganglia and cerebellum also project to these cortical areas, are activated prior to or concurrently with the discharge of corticospinal neurons, and make critical contributions to the production of coordinated movement.

Paralysis Caused by Lesions of the Upper Motor Neurons

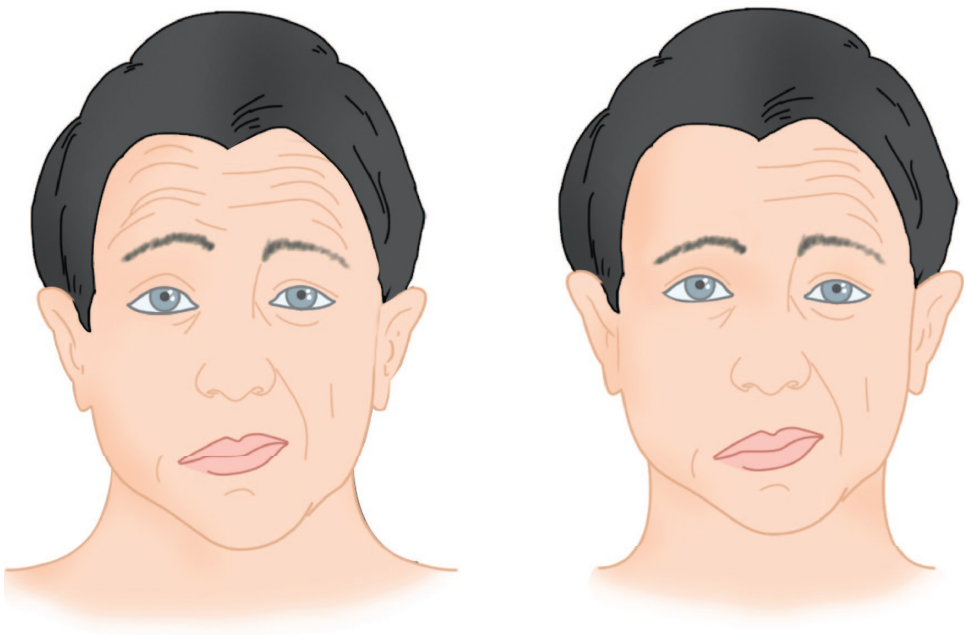
The corticospinal pathway may be interrupted by a lesion at any point along its course—at the level of the cerebral cortex, subcortical white matter, internal capsule, brainstem, or spinal cord. Usually, hemiplegia that is severe and permanent requires a lesion that affects more than the corticospinal pathway alone. In the cerebral white matter (corona radiata) and internal capsule, the corticospinal fibers are intermingled with corticostriate, corticothalamic, corticorubral, corticopontine, cortico-olivary, and corticoreticular fibers. It is noteworthy that thalamocortical fibers, which are a vital link in an ascending fiber system from the basal ganglia and cerebellum, also pass through the internal capsule and cerebral white matter. Thus, lesions in these parts can simultaneously affect both corticospinal and extrapyramidal systems, and attribution of a capsular hemiplegia solely to a lesion of the corticospinal or pyramidal pathway is not entirely correct. The term *upper motor neuron paralysis*, which recognizes the involvement of several descending fiber systems in addition to the corticospinal tract that influence and modify the lower motor neuron, is more appropriate.

In primates, lesions limited to Brodmann area 4, the motor cortex, cause mainly hypotonia and weakness of the distal limb muscles. Lesions of the premotor cortex (area 6) result in weakness, spasticity, and increased stretch reflexes (Fulton). Resection of cortical areas 4 and 6 and subcortical white matter in monkeys causes complete and permanent paralysis and spasticity (Laplane et al). Lesions of the supplementary motor cortex lead to involuntary grasping. These clinical effects have not been as clearly defined in humans.

The one place where corticospinal fibers are entirely isolated is the pyramidal tract in the medulla. In humans, there are a few documented cases of a lesion confined to this location. The result of such lesions has been an initial flaccid hemiplegia (with sparing of the face), from which there is considerable recovery. In monkeys, interruption of the pyramidal tracts initially produces a hypotonic paralysis which then yields to the recovery of a wide range of movements, although loss of dexterity remains permanent (Tower; Lawrence and Kuypers; Gilman and Marco). Also, the cerebral peduncle had in the past been sectioned in patients in an effort to abolish involuntary movements, resulting in a slight degree of weakness but no spasticity (Bucy et al). These observations indicate that a pure pyramidal tract lesion, though rare in clinical practice, does not result in spasticity. Animal experiments suggest that the

corticoreticulospinal pathways, whose fibers are arranged somatotopically and influence stretch reflexes, are particularly important in the genesis of spasticity.

The distribution of the paralysis caused by upper motor neuron lesions varies with the locale of the lesion, but certain features are characteristic of all of them. A group of muscles is always involved, never individual muscles. If any movement is possible, the proper relationships between agonists, antagonists, synergists, and fixators are preserved. On careful inspection, the paralysis never involves all the muscles on one side of the body, even in the severest forms of hemiplegia. Movements that are invariably bilateral—such as those of the eyes, jaw, pharynx, upper face, larynx, neck, thorax, diaphragm, and abdomen—are affected little or not at all. This occurs because these muscles are bilaterally innervated; that is, stimulation of either the right or left motor cortex results in contraction of these muscles on both sides of the body. Upper motor neuron paralysis is rarely complete for any long period of time; in this respect it differs from the absolute paralysis that results from the destruction of anterior horn cells or their axons.



Upper motor neuron lesions are characterized further by certain peculiarities of retained movement. There is decreased voluntary drive on spinal motor neurons (fewer motor units are recruitable and their firing rates are slower), resulting in a slowness of movement. There is also increased cocontraction of antagonistic muscles, reflected in a decreased rate of rapid alternating movements. These abnormalities probably account for the greater sense of effort and the manifest fatigability in effecting voluntary movement of the weakened muscles. Another phenomenon is the activation of paralyzed muscles as parts of certain automatisms, such as a paralyzed arm that moves during yawning and stretching. Attempts by the patient to move the hemiplegic limbs may also result in a variety of associated movements. Thus, attempted flexion of the arm may result in involuntary pronation and flexion of the leg or in dorsiflexion and eversion of the foot. Also, volitional movements of the paretic limb often evoke imitative (mirror) movements in the normal one. In some patients, as they recover from hemiplegia, a variety of movement disorders emerge, such as tremor, athetosis, and chorea on the affected side. These are expressions of damage to basal ganglionic and thalamic structures and are discussed in Chap. 4.

If the upper motor neurons are interrupted above the level of the facial nucleus in the pons, hand and arm muscles are affected most severely and the leg muscles to a lesser extent. Of the cranial musculature, only muscles of the lower part of the face are involved to any significant degree (Fig. 3-5). Because Broadbent was the first to call attention to this distribution of facial paralysis that spares the forehead muscles, it has been referred to as "Broadbent's law."

At lower levels, such as the cervical cord, complete, acute lesions of the upper motor neurons not only cause paralysis of voluntary movement but also temporarily abolish the spinal reflexes of segments below the lesion. This is the condition referred to earlier as *spinal shock*, a state of acute flaccid paralysis that is replaced later by spasticity. To a lesser degree, a similar state of areflexia and hypotonia may occur with acute cerebral lesions. With some acute cerebral lesions, spasticity and paralysis develop together; in others, especially with parietal lesions, the limbs remain flaccid but reflexes are retained.

Spasticity, Hyperreflexia, and the Babinski Sign

The identifying characteristics of paralysis from an upper motor neuron lesion are a predilection for involvement of certain muscle groups, a pattern of resistance that increases linearly in relation to velocity of passive stretch,

A B

Figure 3-5. *A.* Supranuclear facial palsy. There is lower facial weakness contralateral to the lesion, but the upper face is spared due to its bilateral cortical innervation. *B.* Nuclear and infranuclear facial palsy. Both upper and lower portions of the face are weak.

and a manifest exaggeration of tendon reflexes. The antigravity muscles—the flexors of the arms and the extensors of the legs—are predominantly affected. Thus, the arm tends to assume a flexed and pronated position and the leg an extended and adducted one.

Velocity-dependent tone known as the "clasp-knife" phenomenon is a characteristic feature of spasticity. When the muscles are stretched briskly, the limb moves freely for a very short distance, after which there is an abrupt catch with rapidly increasing muscular resistance; then, as passive extension of the arm or flexion of the leg continues, the resistance reduces. By contrast, if the arm is extended or the leg flexed slowly, there may be little or no change in muscle tone. While a clasp-knife relaxation following peak resistance is highly characteristic of cerebral hemiplegia, it is by no means found consistently. At times, a form of velocity-independent hypertonia, termed rigidity, is observed.

The degree of spasticity and weakness present in a patient do not bear a constant relationship. Severe weakness may be associated with only the mildest signs of spasticity; in contrast, the most extreme degrees of spasticity, for example, observed in cervical spinal cord disease, may seem disproportionate to the extent of weakness, signifying that these two states depend on separate mechanisms. Indeed, the selective blocking of small gamma neurons abolishes spasticity as well as hyperactive segmental tendon reflexes but leaves power unchanged.

The pathophysiology of spasticity further depends on two more refined descending tracts: (1) the dorsal reticulospinal tract, which has inhibitory effects on stretch reflexes; and (2) the medial reticulospinal and vestibulospinal tracts, which together facilitate extensor tone. In cerebral and capsular lesions, cortical inhibition from these pathways is reduced, resulting in spastic hemiplegia. In spinal cord lesions that involve the corticospinal tract, the dorsal reticulospinal tract is usually involved as well. If the latter tract is spared, only paresis, loss of support reflexes, and possibly release of flexor reflexes (Babinski phenomenon) occur. In some instances, flaccidity persists after hemiplegic stroke, possibly as a result of primary involvement of the lenticular nucleus of the basal ganglia and the thalamus (Pantano and colleagues).

The heightened stretch reflexes (tendon jerks) of the spastic state may be a "release" phenomenon—the result of interruption of descending inhibitory pathways. Animal experiments have demonstrated that this aspect of the spastic state is mediated through disinhibition of spindle efferents (increased tonic activity of gamma motor neurons) and through loss of the influence of reticulospinal and vestibulospinal pathways that act on alpha motor neurons.

The most reliable indications of an upper motor neuron lesion are the signs described by Babinski in 1896 (the great toe sign) and 1903 (the toe abduction, or fan sign) (Fig. 3-6). In modern parlance, the toe and fan signs have generally been conflated and termed the Babinski sign (van Gijn; Fulton and Keller; Phillipon and Poirer). In its essential form, the sign consists of an extension of the large

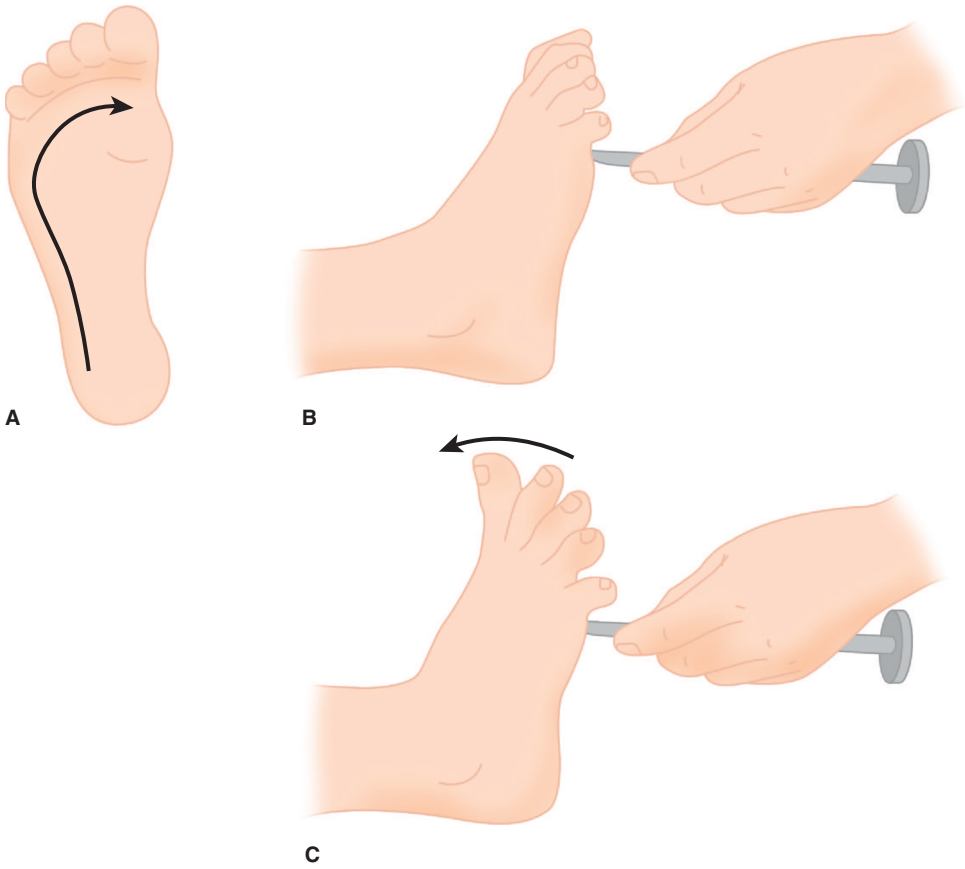


Figure 3-6. *A.* The plantar response is elicited by stroking from the heel to the ball of the foot. *B.* The normal plantar response consists of flexion of the toes. *C.* The extensor plantar response (Babinski sign) consists of an extension of the great toe coupled with fanning of the remaining digits.

toe and extension and fanning of the other toes triggered by stroking the lateral plantar surface of the foot. The stimulus is applied along the dorsum of the foot from the lateral heel, sweeping upward and across the ball of the foot. The stimulus must be firm but not necessarily painful. Several dozen surrogate responses (with numerous eponyms) have been described over the years, most utilizing alternative sites and types of stimulation, but all have the same significance as the Babinski response.

As Babinski himself indicated, a movement resembling the Babinski sign is present in normal infants (see Phillipon and Poirer), but it disappears and its persistence or emergence in late infancy and childhood or later in life is an indicator of a lesion at some level of the corticospinal tract. There has been considerable discussion regarding the form and meaning of the sign in infants; some studies indicate that the first movement of the great toe is flexor (Hogan and Milligan), others, that the four toes fan outward but do not extend.

Clinical and electrophysiologic observations indicate that the extension movement of the great toe is a component of a larger synergistic flexion or shortening reflex of the leg—that is, toe extension when viewed from a physiologic perspective is a protective (nocifensive, or defensive) response. The most characteristic of these is the "triple flexion response," in which the hip, thigh, and ankle flex (dorsiflex) slowly, following an appropriate stimulus. These *spinal flexion reflexes*, of which the Babinski sign is the most characteristic, are common accompaniments to—but not essential components of—spasticity. They are present because of disinhibition or release of motor programs of spinal origin. Important characteristics of these responses are their capacity to be induced by weak superficial stimuli (such as a series of pinpricks) and their tendency to persist for a few moments after the stimulation ceases. With incomplete suprasegmental lesions, the response may be fractionated; for example, the hip and knee may flex but the foot may not dorsiflex, or vice versa.

The hyperreflexic state that characterizes spasticity may take the form of *clonus*, a series of rhythmic involuntary muscular contractions occurring at a frequency of 5 to 7 Hz in response to an abruptly applied and sustained stretch stimulus. It is usually designated in terms of the part of the limb to which the stimulus is applied (e.g., patella, ankle). The frequency is constant within 1 Hz and is not appreciably modified by altering peripheral or central nervous system activities. Clonus requires an appropriate degree of muscle relaxation, integrity of the spinal stretch reflex mechanisms, sustained hyperexcitability of alpha and gamma motor neurons (suprasegmental effects), and synchronization of the contraction–relaxation cycle of muscle spindles.

The cutaneomuscular abdominal and cremasteric reflexes ("cutaneous or superficial reflexes") are elicited by rapid, gentle stroking of the skin overlying these muscles, and are usually abolished when the upper motor neuron is damaged acutely. They are difficult to interpret because they are absent in some normal individuals and may disappear after acute spinal injury, only to reappear at a later time.

Spread, or radiation of reflexes, is regularly associated with spasticity, although it may be observed to a lesser degree in normal persons with brisk tendon reflexes. Tapping of the radial periosteum, for example, may elicit a reflex contraction not only of the brachioradialis but also of the biceps, triceps, or finger flexors. This spread of reflex activity is probably not the result of radiation of impulses in the spinal cord, but a result of the propagation of a vibration wave from bone to muscle, stimulating the excitable muscle spindles in its path (Lance). Other manifestations of the hyperreflexic state are the Hoffmann sign and the crossed adductor reflex of the thigh muscles. Also, reflexes may be "inverted," as in the case of a lesion of the cervical myelopathy at the C5 or C6 level. Here the biceps and brachioradialis reflexes are abolished, but a tap over the distal radius or the biceps tendon produces triceps and finger flexor reflexes owing to hyperreflexia evident at those levels.

With bilateral cerebral lesions, exaggerated stretch reflexes may be elicited in cranial as well as limb and trunk muscles because of interruption of the corticobulbar pathways. These are seen as easily triggered masseter contractions in response to a brisk downward tap on the chin ("jaw jerk") and brisk contractions of the orbicularis oris muscles in response to tapping the philtrum or corners of the mouth. In advanced cases, weakness or paralysis or slowness of voluntary movements of the face, tongue, larynx, and pharynx are added (bulbar spasticity or "pseudobulbar" palsy; see also Chap. 24).

Knowledge of the biochemical changes that underlie spasticity helps understand the mechanisms of action of antispasticity drugs (Davidoff). Baclofen, a derivative of GABA, reduces the release of excitatory transmitters from the presynaptic terminals of primary afferent terminals. Diazepam and other benzodiazepines have a similar effect but by a different mechanism of potentiating postsynaptic GABA receptors. For severe spasticity, the intrathecal administration of baclofen often has more beneficial effect than the oral administration of these agents. The antispasticity agent tizanidine acts by yet another mechanism as an alpha-2 adrenergic agonist, which increases presynaptic inhibition. Glycine is the transmitter released by inhibitory interneurons and is measurably reduced in quantity, uptake, and turnover in spasticity. There is some evidence that the oral administration of glycine reduces experimentally induced spasticity. Interruption of descending noradrenergic, dopaminergic, and serotonergic fibers is also undoubtedly involved in the genesis of spasticity, although the exact mode of action of these neurotransmitters on the various components of spinal reflex arcs remains to be defined.

Table 3-1 summarizes the main attributes of upper motor neuron lesions and contrasts them with those of the lower motor neuron lesions discussed earlier.

Motor Disturbances Caused by Lesions of the Parietal Lobe

As indicated earlier in this section, a significant portion of the pyramidal tract originates in neurons of the parietal cortex. Also, the parietal lobes are important sources of visual and tactile information necessary for the control of movement. Motor disturbances caused by lesions of the parietal cortex include the inability to exert a steady contraction

Table 3-1

DIFFERENCES BETWEEN UPPER AND LOWER MOTOR NEURON PARALYSIS

UPPER MOTOR NEURON OR SUPRANUCLEAR PARALYSIS	LOWER MOTOR NEURON OR NUCLEAR-INFRANUCLEAR PARALYSIS
Muscles affected in groups; never individual muscles	Individual muscles may be affected
Atrophy slight and the result of disuse	Atrophy pronounced; up to 70% of total bulk
Spasticity with hyperactivity of the tendon reflexes and extensor plantar reflex (Babinski sign)	Flaccidity and hypotonia of affected muscles with loss of tendon reflexes
Fasciculations absent	Plantar reflex, if present, is of normal flexor type
Normal nerve conduction studies; no denervation potentials in EMG	Fasciculations may be present Abnormal nerve conduction studies; denervation potentials fibrillations, (fasciculations, positive sharp waves) in EMG

or to maintain stable postures of the outstretched hand when his eyes are closed (Pause and colleagues). Exploratory movements and manipulation of small objects are impaired, and the speed of tapping is diminished. Posterior parietal lesions (involving areas 5 and 7 in Fig. 3-3) are more detrimental in this respect than anterior ones (areas 1, 3, and 5), but both regions are affected in patients with the most severe deficits.

APRAXIA AND OTHER NONPARALYTIC DISORDERS OF MOTOR FUNCTION

All that has been said in this chapter about the cortical and spinal control of the motor system gives one only a limited idea of human motility. Viewed objectively, the conscious and sentient human organism is continuously active—adjusting posture and position, walking, speaking, manipulating tools, or performing intricate sequences of movements such as those involved in athletic or musical skills. Some of these activities are relatively simple, automatic, and stereotyped. Others have been learned and mastered through intense conscious effort and with long practice have become habitual—that is, reduced to an automatic level. Still others are complex and voluntary, parts of a carefully formulated plan, and demand continuous attention and thought. What is more remarkable, one can be occupied in several of these variably conscious and habitual activities simultaneously, such as driving through heavy traffic while adjusting the radio and engaging in animated conversation. Moreover, when an obstacle prevents a particular sequence of movements from accomplishing its goal, a new sequence can be undertaken automatically for the same purpose.

The term *apraxia* denotes a disorder in which an attentive patient loses the ability to efficiently execute previously learned activities, in the absence of weakness, ataxia, sensory loss, or extrapyramidal derangement that would be adequate to explain the deficit (Heilman and Gonzalez-Rothi). This was the meaning given to apraxia by Liepmann, who introduced the term in 1900, and was discussed further by Denny-Brown in 1958. Clinical and functional imaging data indicate that the organization of motor sequences required for planned or commanded action is formulated in the parietal lobe of the language-dominant hemisphere, where visual, auditory, and somesthetic information is integrated. The formation of ensembles of skilled movements, which Liepmann called a "space-time plan," depends on the integrity of the dominant parietal lobe; if this part of the brain is damaged, complex patterns of movement become awkward and inappropriate, or cannot be activated at all.

Apraxia has been traditionally divided into three types: ideomotor, ideational, and limb-kinetic (described in greater detail in Chap. 21). *Ideomotor apraxia* is the fundamental type, in which the patient conceptually knows what action is intended, but cannot actually execute the sequence of motor movements in a coordinated way. While the most common localization of a lesion giving rise to apraxia is the supramarginal gyrus or the superior parietal lobe (areas 5 and 7) of the dominant parietal lobe, there is variability across individuals. Other lesion locations can disrupt relevant networks underlying praxis and give rise to variations in the clinical presentation of apraxia. Geschwind supported Liepmann's proposition that a lesion of a subcortical tract (presumably the arcuate fasciculus) can disconnect the parietal from the left frontal cortex, accounting for the ideomotor apraxia of the right limbs. A lesion of the anterior corpus callosum can disconnect motor program inputs to the supplemental motor areas of the right frontal lobe, giving rise to apraxia of the left hand (Heilman).

Ideational apraxia refers to a more general failure to even conceive or formulate an action, and is believed to result from lesions more broadly affecting networks that include sensory areas 5 and 7 in the dominant parietal lobe, the supplementary and premotor cortices of both cerebral hemispheres, and their integral connections. Certain tasks are said to differentiate ideomotor from ideational apraxia, as discussed further on, but in many cases the distinction can be subtle. Nonetheless, ideational apraxia has been said to be characterized by difficulty in "what to do," whereas ideomotor apraxia is a block in "how to do it."

A third type of apraxia, less well established than the first two, is referred to as *limb-kinetic apraxia*. As described by Kleist, it refers to a clumsiness and maladroitness that results from an inability to fluidly connect or isolate individual movements of the hand and arm. The hand displays awkwardness that is disproportionate to weakness or sensory loss, yet gestures and complex movements can be accomplished, unlike the case in ideomotor apraxia. Because a breakdown of fine fractionated finger movements is central to the disorder, the differentiation between limb-kinetic apraxia and a mild corticospinal disorder is often elusive, calling into question whether it is a true apraxia. The term limb-kinetic apraxia has also been applied to cases of a frontal lesion causing contralateral paralysis with an associated ipsilateral impairment of fine finger movements. This is more properly termed "*sympathetic apraxia.*"

Testing for apraxia is carried out in several ways, recognizing that it cannot be fully assessed in the presence of other cognitive disorders such as confusion, abulia, and aphasia. The patient can be asked to carry out familiar symbolic acts, such as waving goodbye, saluting a flag, or blowing a kiss. The patient can also be asked to perform simulated tasks such as brushing the hair, brushing the teeth, or using scissors. Finally, the patient can be asked to perform more complex activities, requiring a sequence of actions, such as hanging a picture, cutting a loaf of bread, or opening a bottle of soda, pouring some into a glass, and drinking it. These latter actions are said to be tests of both ideational and ideomotor apraxia, whereas the simpler, familiar acts are considered tests of ideomotor apraxia. To imitate the performance of tasks in the absence of the tool or utensil is always more demanding because the patient must mentally formulate a plan of action rather than engage in a habitual motor sequence. If these actions cannot be performed, it can be helpful to assess the performance of an activity with the relevant tool. In addition, the examiner can act and ask the patient to imitate it.

Oral-buccal-lingual apraxia is a special subset of apraxia, which is probably the most commonly observed type in practice. Such patients have difficulty carrying out purposeful facial movements to command, such as licking the lips or showing how to blow out a match. As with other types of apraxia, they may do better when asked to imitate the examiner or when actually confronted with a lighted match. This form of apraxia typically localizes to the left inferior frontal cortex, deep frontal white matter, insula, or basal ganglia.

The so-called apraxia of gait is considered in Chap. 6, but strictly speaking, this is not an apraxia since walking is not truly a learned, skilled act. The terms dressing apraxia and constructional apraxia are used to describe special manifestations of nondominant parietal lobe disease. Although dressing apraxia in many ways resembles an ideomotor apraxia, it probably has a basis in visuospatial dysfunction and a loss of appreciation of extrapersonal space. These issues are discussed further in Chap. 21.

A related disorder of movement has been termed the *alien hand*. In the absence of volition, the hand and arm undertake complex and seemingly purposeful movements such as reaching into a pocket or handbag, placing the hand behind the head, tugging on the opposite hand or other body part, and rebuttoning the shirt immediately after it has been unbuttoned by the other hand. These activities may occur even during sleep. The patient is aware of the movements but there is often an impression that the hand is estranged, as if commanded by an external agent. Most instances arise from infarction in the right parietal lobe or the anterior cerebral artery including the corpus callosum. When the callosum is involved, there can be a conflict between the actions of the hands, the normal one sometimes even restraining the alien one (Feinberg).

Children with various cerebral diseases that delay development are often unable to learn the sequences of movement required in hopping, jumping over a barrier, hitting or kicking a ball, or dancing. They suffer *developmental motor apraxia*. Certain tests quantitate deficits in these age-linked motor skills (see Chap. 27).

CLINICAL PATTERNS OF PARALYSIS

The diagnostic considerations in cases of paralysis can be simplified by using the following scheme based on the location and distribution of the muscle weakness:

1. *Monoplegia* refers to weakness or paralysis of all the muscles of one leg or arm. This term is not applied to paralysis of isolated muscles or groups of muscles supplied by a single nerve or motor root.
2. *Hemiplegia*, the commonest form of paralysis, involves the arm, the leg, and sometimes the face on one side of the body. Hemiplegia is almost always attributable to a lesion of the corticospinal system on the side opposite to the paralysis.
3. *Paraplegia* indicates weakness or paralysis of both legs. It is most often the result of diseases of the thoracic spinal cord, cauda equina, or peripheral nerves, and rarely, both medial frontal cortices.
4. *Quadriplegia* (tetraplegia) denotes weakness or paralysis of all four extremities. It may result from disease of the peripheral nerves, muscles, or myoneural junctions; gray matter of the spinal cord; or the upper motor neurons bilaterally in the cervical cord, brainstem, or cerebrum. Diplegia is a special form of quadriplegia in which the legs are affected more than the arms. Triplegia occurs most often as a transitional condition in the development of, or partial recovery from, tetraplegia.
5. Isolated paralysis of one or more muscle groups due to disease of muscle, anterior horn cells, or nerve roots.
6. Nonparalytic disorders of movement (e.g., apraxia, ataxia, rigidity).
7. Hysterical (functional) paralysis.

Monoplegia

The examination of patients who complain of weakness of one limb often discloses an asymptomatic weakness of another, and the condition is actually a hemiparesis or paraparesis. In other cases, instead of weakness of most of the muscles in a limb, only isolated groups are found to be affected. Ataxia, sensory disturbances, or reluctance to move the limb because of pain should not be misinterpreted as weakness. Parkinsonism may give rise to the same error, as can other causes of rigidity or bradykinesia or a mechanical limitation resulting from arthritis and bursitis. The presence or absence of atrophy of muscles in a monoplegic limb is of particular diagnostic help.

Monoplegia Without Muscular Atrophy

This is most often caused by a lesion of the cerebral cortex or the spinal cord. A cerebral vascular lesion is the most common cause; a circumscribed tumor or abscess may have the same effect. Small cortical lesions in the motor strip may occasionally be so selective as to cause restricted regions of weakness, for example, of parts of the hand. Multiple sclerosis and spinal cord tumor, early in their course, may cause weakness of one limb, usually the leg. Monoplegia caused by a lesion affecting upper motor neurons is usually accompanied by spasticity, increased reflexes,

and an extensor plantar reflex (Babinski sign). In acute diseases of the lower motor neurons, the tendon reflexes are reduced or abolished, but atrophy may not appear for several weeks.

Monoplegia With Muscular Atrophy

This is more frequent than monoplegia without muscular atrophy. The location of the lesion (in nerves, spinal roots, or spinal cord) can usually be determined by the pattern of weakness, by the associated neurologic symptoms and signs, and by special tests—MRI of the spine, examination of the cerebrospinal fluid (CSF), and electrical studies of nerve and muscle. Prolonged disuse of one limb may lead to atrophy, but it is usually of lesser degree than atrophy caused by lower motor neuron disease (denervation atrophy). In disuse atrophy, the tendon reflexes are retained and nerve conduction studies are normal. With denervation of muscles, there may be visible fasciculations and reduced or abolished tendon reflexes in addition to paralysis. If the limb is partially denervated, the EMG shows reduced numbers of motor unit potentials (often of large size) as well as fasciculations and fibrillations.

A complete atrophic brachial monoplegia is uncommon; more often, only parts of a limb are affected. When present in an infant, it suggests brachial plexus trauma from birth; in a child, poliomyelitis or other viral infection of the spinal cord; and in an adult, syringomyelia, amyotrophic lateral sclerosis, or a brachial plexus lesion. Atrophic crural (leg) monoplegia is more frequent than atrophic brachial monoplegia and may be caused by any lesion of the lumbosacral spinal cord or plexus. The mode of onset and temporal course differentiate the various diseases that affect these structures.

Hemiplegia

This is the most frequent form of paralysis. With rare exceptions, this pattern of paralysis is a result of involvement of the corticospinal pathways. The site or level of the lesion—that is, cerebral cortex, corona radiata, capsule, brainstem, or spinal cord—can usually be deduced from the associated neurologic findings. Diseases localized to the cerebral cortex, cerebral white matter (corona radiata), and internal capsule usually manifest themselves by weakness or paralysis of the leg, arm, and lower face on the opposite side. The occurrence of seizures or the presence of a language disorder (aphasia), a loss of discriminative sensation (e.g., astereognosis, impairment of tactile localization), anosognosia, or a homonymous visual field defect suggests a contralateral cortical or subcortical location rather than at a lower level.

Damage to the corticospinal and corticobulbar tracts in the upper portion of the brainstem also causes paralysis of the face, arm, and leg of the opposite side (see Fig. 3-2). The lesion in the brainstem may be localized by the presence of a cranial nerve palsy or other segmental abnormality on the same side as the lesion (opposite the hemiplegia). These "crossed paralyses" are characteristic of brainstem lesions. With midbrain lesions there is a third nerve palsy (Weber syndrome); in low pontine lesions, an ipsilateral abducens or facial palsy is combined with a contralateral weakness or paralysis of the arm and leg (Millard-Gubler syndrome). Lesions in the medulla affect the tongue and sometimes the pharynx and larynx on one side and the arm and leg on the other. Even lower in the medulla, a unilateral infarct in the pyramid causes a flaccid paralysis of the contralateral arm and leg, with sparing of the face and tongue. The crossed brainstem syndromes are further described in Chaps. 33 and 44.

In some cases, an ipsilateral hemiplegia may be caused by a lesion in the corticospinal tract of the cervical spinal cord. In the spinal cord, however, the pathologic process is more often large enough to induce bilateral signs. A hemiparesis that spares the face, if combined with a loss of vibratory and position sense on the same side and a contralateral loss of pain and temperature, signifies disease of the spinal cord on the side of the hemiparesis (Brown-Séquard syndrome, as discussed in Chap. 42).

As indicated above, in general there is little or no muscle atrophy following upper motor neuron lesions, as there is in diseases of the lower motor neuron. The atrophy that accompanies upper motor neuron-induced weakness is mainly a consequence of disuse. In hemiplegia caused by spinal cord lesions, muscles at the level of the lesion may atrophy as a result of damage to anterior horn cells or ventral roots.

When the motor cortex and adjacent parts of the parietal lobe are damaged in infancy or childhood, normal development of the muscles, as well as the skeletal system in the affected limbs, may be impaired. The limbs and even the trunk are smaller on one side than on the other. This does not happen if the paralysis occurs after puberty, by which time the greater part of skeletal growth has been attained.

In the causation of hemiplegia, ischemic and hemorrhagic vascular diseases of the cerebrum and brainstem exceed all others in frequency. Trauma (brain contusion, epidural and subdural hemorrhage) ranks second. Other important causes, less acute in onset, are, in order of frequency, brain tumor, demyelinating disease, brain abscess, and the vascular complications of meningitis and encephalitis. Most of these diseases can be recognized by their mode of evolution and characteristic imaging, which are presented in the chapters on specific neurologic diseases. Alternating transitory hemiparesis may be the result of a special type of migraine (see discussion in Chap. 9). Hysteria (functional, formerly called conversion disorder) is another common cause of hemiplegia, as discussed further on.

Paraplegia

Paralysis of both lower extremities may occur with diseases of the spinal cord, nerve roots, or, less often, the peripheral nerves. If the onset is acute, it may be difficult to distinguish spinal paralysis, which results in flaccidity and abolition of reflexes from spinal shock, from that due to peripheral nerve disease. In acute spinal cord diseases with involvement of corticospinal tracts, the paralysis or weakness affects all muscles below a given level; if the white matter is extensively damaged, sensory loss below a circumferential level on the trunk is conjoined (loss of pain

and temperature sense because of spinothalamic tract damage, and loss of vibratory and position sense from posterior column involvement). Also in bilateral disease of the spinal cord, the bladder and bowel and their sphincters are usually affected. These abnormalities may be the result of an intrinsic lesion of the cord or an extrinsic mass that narrows the spinal canal and compresses the cord.

In peripheral nerve diseases, motor loss tends to involve the distal muscles of the legs more than the proximal ones (exceptions are certain varieties of the Guillain-Barré syndrome and some types of diabetic neuropathy and porphyria); sphincteric function is usually spared or impaired only transiently. Sensory loss, if present, is also more prominent in the distal segments of the limbs, and the degree of loss is often more for one modality than another.

For clinical purposes, it is helpful to separate the acute paraplegias from the chronic ones and to divide the latter into two groups: those beginning in adult life and those occurring in infancy. The most common cause of acute paraplegia (or quadriplegia if the cervical cord is involved) is spinal cord trauma, usually associated with fracture–dislocation of the spine. Less common causes are a vascular malformation or fistula of the cord or its overlying dura, which causes ischemia by a complex mechanism, and infarction of the cord resulting from occlusion of the anterior spinal artery or, more often, from occlusion of segmental branches of the aorta as a feature of dissecting aneurysm or atheroma, vasculitis, or nucleus pulposus embolism. Epidural or subdural hemorrhage from a hemorrhagic diathesis or warfarin therapy causes an acute or subacute paraplegia; in a few instances the bleeding follows a lumbar puncture.

Paraplegia or quadriplegia that develops more slowly, subacutely over a period of hours or days is caused by postinfectious myelitis, demyelinating or necrotizing myelopathy, or epidural abscess or tumor with spinal cord compression. Paralytic poliomyelitis and acute Guillain-Barré syndrome—the former a purely motor disorder with mild meningitis, the latter predominantly motor but often with sensory disturbances—must be distinguished from the acute and subacute myelopathies and from each other.

In adult life, multiple sclerosis and tumor account for most cases of chronic spinal paraplegia, but a wide variety of extrinsic and intrinsic processes may produce the same effect: protruded cervical disc and cervical spondylosis (often with a congenitally narrow canal), epidural abscess and other infections (tuberculous, fungal, and other granulomatous diseases, HIV and HTLV-1), syphilitic meningomyelitis, motor system disease, subacute combined degeneration (vitamin B_{12} deficiency and copper deficiency), syringomyelia, epidural lipomatosis, neuromyelitis optica, and degenerative disease of the lateral and posterior columns. (See Chap. 42 for discussion of these spinal cord diseases.)

In pediatric practice, delay in starting to walk and difficulty in walking are common problems. These conditions may indicate a systemic disease (such as rickets), mental retardation, or, more commonly, a muscular or neurologic process. Congenital cerebral disease because of periventricular leukomalacia accounts for a majority of cases of infantile diplegia (weakness predominantly of the legs, with minimal weakness of the arms). Present at birth, it becomes manifest in the first months of life and may appear to progress, but actually the progression is only apparent, being exposed as the motor system develops; later there may seem to be slow improvement as a result of the normal maturation processes of childhood. These disorders fall under the heading of cerebral palsy, as discussed in Chap. 38. Congenital malformation or birth injuries of the spinal cord are other possibilities. Friedreich ataxia and familial paraplegia, muscular dystrophy, tumor, and the chronic varieties of polyneuropathy tend to appear later, during childhood and adolescence, and are slowly progressive causes of leg weakness and walking disorder.

Quadriplegia (Tetraplegia)

All that has been said about the spinal causes of paraplegia applies to quadriplegia, the lesion being in the cervical rather than the thoracic or lumbar segments of the spinal cord. If the lesion is situated in the low cervical segments and involves the anterior half of the spinal cord, as occurs with occlusion of the anterior spinal artery, there is a level on the trunk below which pinprick and thermal sense is lost but there is retained vibration, deep sensation, and joint position sense.

A progressive syndrome of monoparesis, biparesis, usually of the arms, and then triparesis involving the leg on the side of the last affected arm ("around the clock" pattern) is caused by tumors and a variety of other compressive lesions in the region of the foramen magnum and high cervical cord. This is putatively explained by the pattern of corticospinal fiber decussation at the cervicomedullary junction. The fibers from the arms cross cephalad to those of the legs. Bilateral infarction of the medullary pyramids from occlusion of the vertebral arteries or their anterior spinal branches is a rare cause of quadriplegia. Repeated strokes affecting both hemispheres may lead to bilateral hemiplegia, usually accompanied by pseudobulbar palsy (see Chap. 22 on spastic dysarthria and Chap. 24 on pseudobulbar laughing and crying). In infants and young children, aside from developmental abnormalities and anoxia of birth, certain metabolic cerebral diseases (metachromatic and other forms of leukoencephalopathy, lipid storage disease) may be responsible for quadriparesis.

A rare pattern that may be considered is a fragment of quadriplegia occurs in instances of infarction of the motor cortex in the vascular border zones between the middle and anterior cerebral arteries. The syndrome is one of paralysis of the proximal arms and sometimes legs, with sparing of the face, hands, and feet, colorfully called "man in the barrel."

Triplegia

Paralysis that remains confined to three limbs is observed only rarely; more often the fourth limb is weak or hyperreflexic, and the syndrome is really an incomplete tetraplegia. As indicated earlier, this pattern of involvement is important, because it may signify an evolving lesion of the upper cervical cord or cervicomedullary junction. A meningioma of

the foramen magnum, for example, may begin with spastic weakness of one limb, followed by sequential involvement of the other limbs in the above-noted "around-the-clock" pattern. There are usually bilateral Babinski signs early in the process, but there may be few sensory findings. We have also seen this pattern in patients with multiple sclerosis and other intrinsic inflammatory and neoplastic lesions. These same diseases may produce triplegia (or triparesis) by a combination of paraplegia from a thoracic spinal cord lesion and a separate unilateral lesion in the cervical cord or higher that results in a hemiparesis.

Paralysis of Isolated Muscle Groups

This pattern usually indicates a lesion of one or more peripheral nerves or of several adjacent spinal roots. The diagnosis of an individual peripheral nerve lesion is made based on weakness or paralysis of a particular muscle or group of muscles and impairment or loss of sensation in the distribution of the nerve. Complete or extensive interruption of a peripheral nerve is followed by atrophy of the muscles it innervates and by loss of tendon reflexes of the involved muscles; abnormalities of vasomotor and sudomotor functions and trophic changes in the skin, nails, and subcutaneous tissue may occur if the condition has been chronic.

Detailed knowledge of the motor and sensory innervation of the peripheral nerve in question is needed for a diagnosis. It is impractical to memorize the precise sensorimotor distribution of each peripheral nerve and special manuals, such as *Aids to the Examination of the Peripheral Nervous System*, should be consulted (see also Table 43-1). Electromyography and nerve conduction studies are of great value for localization in cases where the clinical exam lacks precision, and to determine the extent to which the site of pathology is the axon or myelin of the peripheral nerves.

Psychogenic, Functional Paralysis

Psychogenic paralysis may involve one arm or leg, both legs, or all of one side of the body. Tendon reflexes are of normal amplitude, there is no Babinski sign, and atrophy is lacking, features that distinguish it from chronic lower motor neuron disease. Diagnostic difficulty arises only in certain acute cases of upper motor neuron disease that lack the usual changes in reflexes and muscle tone. Sometimes there is loss of sensation in the paralyzed parts and loss of sight, hearing, and smell on the paralyzed side—a pattern of sensory changes that cannot be explained based on organic disease of the nervous system. When the patient with a functional disorder is asked to move the affected limbs, the movements tend to be slow, hesitant, and jerky, often with contraction of agonist and antagonist muscles simultaneously and intermittently ("give-way" weakness). Lack of effort is usually obvious, despite facial and other expressions to the contrary. Power of contraction improves with encouragement and the weakness is inconsistent; some movements are performed tentatively and moments later another movement involving the same muscles is performed naturally.

The Hoover sign and the trunk–thigh sign of Babinski are helpful in distinguishing psychogenic from organic hemiplegia. The Hoover test is undertaken in the recumbent patient and is based on the downward pressure of one leg that is required to forcefully lift the opposite one. By placing the examiner's hand under the heel of the unaffected leg, the sign is elicited when downward pressure is absent as the patient attempts to raise the weak leg, thereby indicating a lack of voluntary effort. A second version of this test, also attributed to Hoover, is to detect downward pressure from the ostensibly paralyzed leg, as the good leg is raised. In a similar maneuver, the examiner tells the patient that the normal limb is being tested, while asking the patient to try to push the knees together. In psychogenic weakness, the paralyzed limb adducts with normal power. One can take advantage of midline motor actions in the upper extremity by asking the patient to push his hands together and telling him that the normal side is being tested. In hysterical weakness, there is adduction movement of the supposedly paralyzed limb.

To carry out the Babinski trunk–thigh test, the examiner asks the recumbent patient to sit up while keeping his arms crossed in front of his chest. In the patient with organic hemiplegia from an upper motor neuron lesion, there is an involuntary flexion of the paretic lower limb, but in hysterical hemiplegia, only the normal leg may be flexed. In organic paraplegia, both limbs are flexed as the trunk is flexed, while in hysterical paraplegia, neither leg is flexed. Patients with apparently paralyzed legs who are seated in a rolling chair may propel themselves by pedaling along the floor (a sign attributed to Blocq by Okun and colleagues).

Muscular Paralysis Unattended by Visible Changes in Nerve or Muscle

A discussion of motor paralysis would be incomplete without some reference to diseases in which muscle weakness may be profound but there are no overt structural changes in motor nerve cells or nerve fibers. Almost any disease of the neuromuscular junction and many diseases of muscle cause this combination. This group comprises myasthenia gravis, inflammatory myopathies, the muscular dystrophies, myotonia congenita (Thomsen disease), familial periodic paralysis, disorders of potassium, sodium, calcium, and magnesium metabolism, botulism, black widow spider bite, stiff-man syndrome, and the thyroid and other endocrine myopathies. In these diseases, each with a fairly distinctive clinical picture, the abnormality is essentially physiological or biochemical; their investigation requires EMG, special biochemical and histochemical tests, and electron microscopic study. These subjects are discussed in the sections on muscle disease later in this book.

Disorders of Movement and Posture

In this chapter, disorders of the automatic, static, postural, and other less voluntary motor activities of the nervous system are discussed. Many of them are an expression of what has come to be called the extrapyramidal motor system, meaning—according to S. A. K. Wilson, who introduced this term—the motor structures of the basal ganglia and certain related thalamic and brainstem nuclei. However, others such as myoclonus and various tremors have obscure or multiple causes. These are discussed together because they are often combined and because of their inclusion in the neurological subspecialty of movement disorders.

THE BASAL GANGLIA (STRIATOPALLIDONIGRAL SYSTEM)

The activities of the basal ganglia and the cerebellum are blended with and modulate the corticospinal system and the postural influence of the extrapyramidal system is indispensable to voluntary corticospinal movements. This close association of the basal ganglia and corticospinal systems becomes evident in the course of many forms of neurologic disease. In many aberrant motor patterns, one sees evidence not only of the activity of the basal ganglia but also of labyrinthine, tonic neck, and other postural reflexes that are mediated through parapyramidal brainstem motor systems, including the vestibulospinal, rubrospinal, and reticulospinal tracts. Observations such as these have blurred the original distinctions between pyramidal and extrapyramidal motor systems. Nevertheless, this division remains a useful concept in clinical work because it informs a distinction among several motor syndromes—one that is characterized by a loss of volitional movement accompanied by spasticity—the corticospinal syndrome; a second by bradykinesia, rigidity, and tremor without loss of paralysis—the hypokinetic basal ganglionic syndrome; a third by involuntary movements (choreoathetosis and dystonia)—the hyperkinetic basal ganglionic syndrome; and yet another by incoordination (ataxia)—the cerebellar syndrome. Table 4-1 summarizes the main clinical differences between corticospinal and extrapyramidal syndromes.

Anatomic Considerations

As an anatomic entity, the basal ganglia have no precise definition. Principally they include the caudate nucleus and the lentiform (lenticular, from its lens-like shape) nucleus with its two subdivisions—the putamen and globus pallidus. Insofar as the caudate nucleus and putamen are really a continuous structure (separated only incompletely by fibers of the internal capsule) and are cytologically and functionally distinct from the pallidum, it is more meaningful to divide these nuclear masses into the striatum (or neostriatum), comprising the caudate nucleus and putamen, and the paleostriatum or pallidum, which has a medial (internal) and a lateral (external) portion. The putamen and pallidum lie on the lateral aspect of the internal capsule, which separates them from the caudate nucleus, thalamus, subthalamic nucleus, and substantia nigra on its medial side (Figs. 4-1 and 4-2). By virtue of their close connections with the caudate and lenticular nuclei, the subthalamic nucleus (nucleus of Luys) and the substantia nigra are included as parts of the basal ganglia. The claustrum and amygdaloid nuclear complex, despite their largely different connections and functions, are sometimes included although they do not participate in any direct way in the modulation of movement.

For reasons indicated further on, some physiologists have expanded the list of basal ganglionic structures to include the red nucleus, the intralaminar thalamic nuclei, and the reticular formations of the upper brainstem. These structures receive direct cortical projections and give rise to rubrospinal and reticulospinal tracts that run parallel to the corticospinal (pyramidal) ones; hence they also were once referred to as extrapyramidal. However, these nonpyramidal linkages are structurally independent of the major extrapyramidal circuits and are better termed parapyramidal systems. As the final links in this circuit—the premotor and supplementary motor cortices—ultimately project onto the motor cortex, they are more aptly referred to as prepyramidal (Thach and Montgomery).

Earlier views of basal ganglionic organization emphasized serial connectivity and the funneling of efferent projections to the ventrolateral thalamus and from there to the motor cortex (Fig. 4-3). The most important basal ganglionic connections and circuitry are indicated in Figs. 4-1 to 4-3. The striatum, mainly the putamen, is the

Table 4-1

CLINICAL DIFFERENCES BETWEEN CORTICOSPINAL AND EXTRAPYRAMIDAL SYNDROMES

	CORTICOSPINAL	EXTRAPYRAMIDAL
Character of the alteration of muscle tone	Clasp-knife effect (spasticity)	Plastic, equal throughout passive movement (rigidity), or intermittent (cogwheel rigidity)
Distribution of hypertonus	Flexors of arms, extensors of legs	Generalized but predominates in flexors of limbs and of trunk
Involuntary movements	Absent	Presence of tremor, chorea, athetosis, dystonia
Tendon reflexes	Increased	Normal or slightly increased
Babinski sign	Present	Absent
Paralysis of voluntary movement	Present	Absent or slight

receptive part of the basal ganglia, receiving topographically organized fibers from all parts of the cerebral cortex and from the pars compacta (pigmented neurons) of the substantia nigra. The output nuclei of the basal ganglia consist of the medial (internal) pallidum and the pars reticulata (nonpigmented portion) of the substantia nigra (see Fig. 4-3). Further explication of basal ganglionic function can be found in the excellent book by Watts and Koller.

These concepts were based largely on the experimental work of Whittier and Mettler and of Carpenter, in the late 1940s. These investigators demonstrated, in monkeys, that a disorder, which they termed choreoid dyskinesia, could be brought about in the limbs of one side of the body by a lesion localized to the opposite subthalamic nucleus. They also showed that for such a lesion to provoke dyskinesia, the adjacent pallidum and pallidofugal fibers had to be preserved; that is, a second lesion—placed in the medial segment of the pallidum, in the fasciculus lenticularis, or in the ventrolateral thalamus—abolished the dyskinesia. This experimental hyperkinesia could also be abolished by interruption of the lateral corticospinal tract but not by sectioning of the other motor or sensory pathways in the spinal cord. These observations were interpreted to mean that the subthalamic nucleus exerts an inhibitory or regulating influence on the globus pallidus and ventral thalamus. Removal of this influence by selective destruction of the subthalamic nucleus is expressed physiologically by an irregular movement that is now identified as chorea, presumably arising from the intact pallidum and conveyed to the ventrolateral thalamic nuclei, and from there by thalamocortical fibers to the ipsilateral premotor cortex, and from there, to the motor cortex, all in a serial manner.

A general principle that has withstood the test of time is the central role of the ventrolateral and ventroanterior nuclei of the thalamus. Together, these nuclei form a nexus, not only from the basal ganglia but also from the

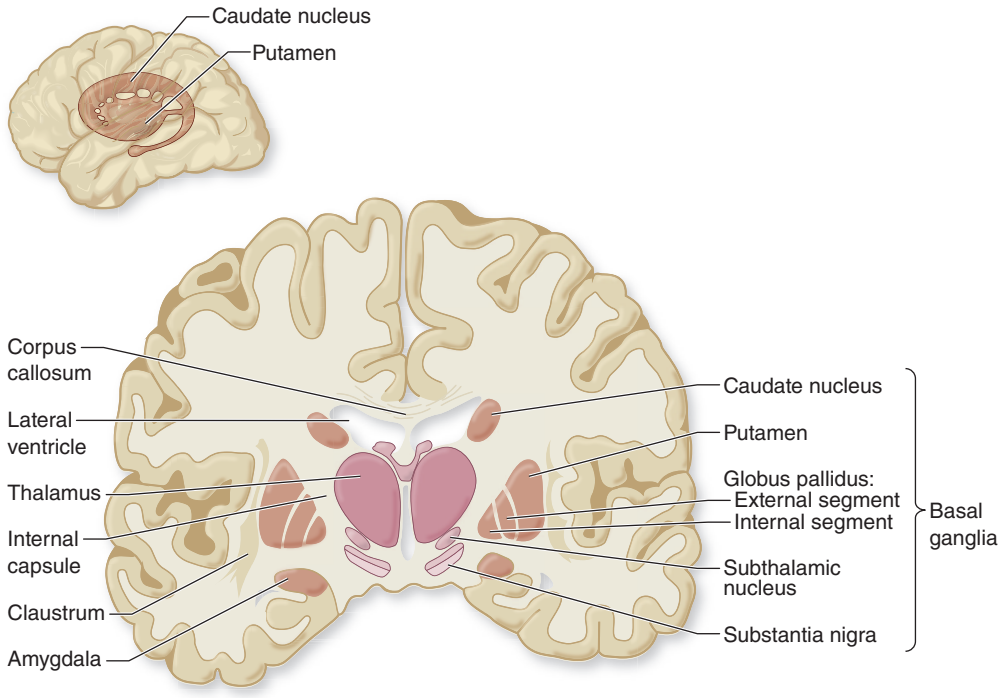

Figure 4-1. Overview of the components of the basal ganglia in coronal view. The main nuclei of the basal ganglia are represented in light brown, as labeled on the right.

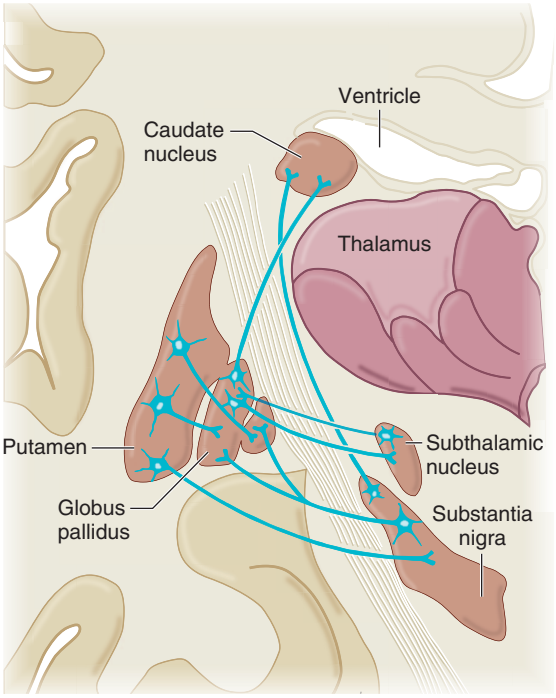

Figure 4-2. Diagram of the basal ganglia in the coronal plane, illustrating the main interconnections (see text for details). The pallidothalamic connections are illustrated in Fig. 4-3.

cerebellum, to the motor and premotor cortex. Thus, both basal ganglionic and cerebellar influences are brought to bear, via thalamocortical fibers, on the corticospinal system and on other descending pathways from the cortex. Direct descending pathways from the basal ganglia to the spinal cord are relatively insignificant.

It is currently proposed on the basis of physiologic, lesional, and pharmacologic studies that there are two main efferent projections from the putamen. There are reasons to conceptualize: (1) a *direct* efferent system from the putamen to the medial (internal) pallidum and then to the substantia nigra, particularly to the pars reticulata, and (2) an *indirect* system originating in the putamen that traverses the lateral (external) pallidum and continues to the subthalamic nucleus, with which it has strong reciprocal connection. To these, has been added (3) a *hyperdirect* pathway that activates the subthalamic nucleus directly from the motor cortex, without the necessity of the intervening striatum.

In most ways, the subthalamic nucleus and lateral pallidum operate as a single functional unit (at least in terms of the effects of lesions in those locations on parkinsonian symptoms and the neurotransmitters involved). The internal (medial) pallidum (GPi) and reticular part of the substantia nigra can be viewed in a similar unitary way, sharing the same input and output patterns. Within the indirect pathway, an internal loop is created by projections from the subthalamic nucleus to the medial segment of the pallidum and pars reticulata. A second offshoot of the indirect pathway consists of projections from the external (lateral) pallidum (GPe) to the medial pallidonigral output nuclei.

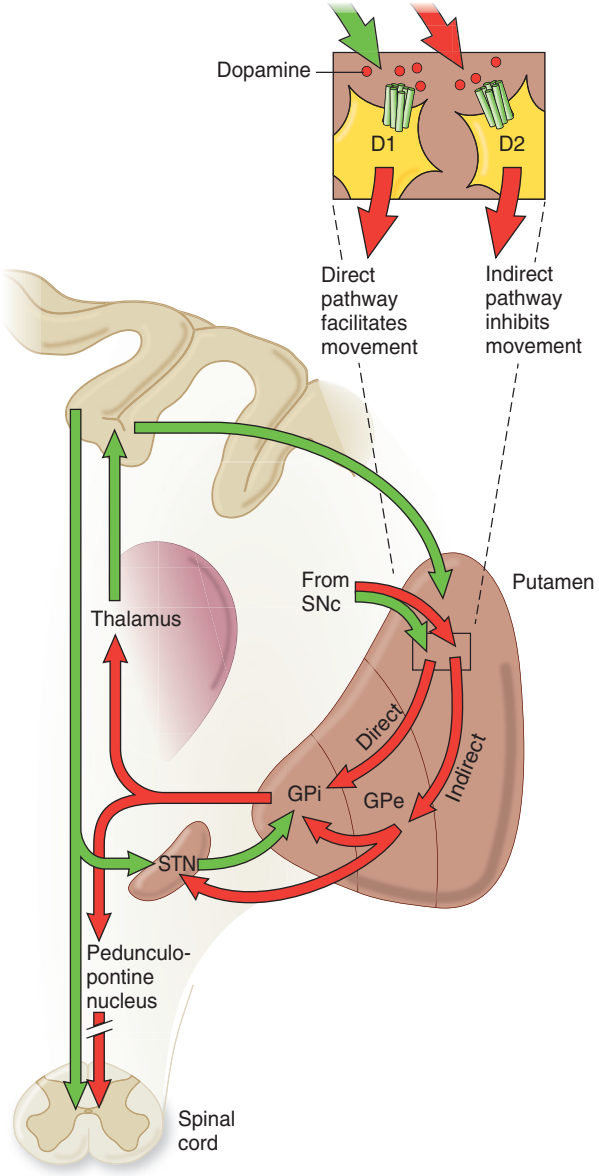

Figure 4-3. Schematic illustration of major efferent and afferent connections of the basal ganglia. The green lines indicate connections with excitatory effects, whereas the red lines indicate inhibitory influences. (See text for details and Fig. 4-2.) (Reproduced with permission from Kandel ER, Schwartz JH, Jessell TM: *Principles of Neural Science*, 5th ed. New York: McGraw-Hill, 2013.)

A complete account of this intricate connectivity cannot be given, but the main themes outlined here seem valid and are to be found in reviews (Obeso and colleagues).

From the internal pallidum, two bundles of fibers reach the thalamus—the ansa lenticularis and the fasciculus lenticularis. The ansa sweeps around the internal capsule; the fasciculus traverses the internal capsule in a number of small fascicles and then continues medially and caudally to join the ansa in the prerubral field. Both of these fiber bundles join the thalamic fasciculus, which then contains not only the pallidothalamic projections but also mesothalamic, rubrothalamic, and dentatothalamic ones.

These projections are directed to separate targets in the ventrolateral nucleus of the thalamus and to a lesser extent in the ventral anterior and intralaminar thalamic nuclei. The centromedian nucleus of the intralaminar group projects back to the putamen and, via the parafascicular nucleus, to the caudate. A major projection from the ventral thalamic nuclei to the ipsilateral premotor cortex completes the large cortical–striatal–pallidal–thalamic–cortical motor loop, with conservation of the somatotopic arrangement of motor fibers, again emphasizing the nexus of motor control at the thalamic nuclei.

Newer observations have made it apparent that there are a number of parallel basal ganglionic–cortical circuits. These circuits run parallel to the premotor pathway but remain separate anatomically and physiologically. At least five such anatomic connections have been described, each projecting to different portions of the frontal lobe: (1) the prototypical motor circuit, converging on the premotor cortex; (2) the ocular motor circuit, projecting onto the frontal eye fields; two prefrontal circuits; (3) one ending in the dorsolateral prefrontal; (4) the other on the lateral orbitofrontal cortex; and (5) a limbic circuit that projects to the anterior cingulate and medial orbitofrontal cortex.

An additional and essential feature of basal ganglionic structure is the nonequivalence of all parts of the striatum. Particular cell types and zones of cells within this structure appear to mediate different aspects of motor control and to utilize specific neurochemical transmitters, as detailed below under "Pharmacologic Considerations" (see also Albin et al. and DeLong). This specialization has taken on further importance with the observation that specific cell types are destroyed preferentially in degenerative diseases such as Huntington chorea.

Physiologic Considerations

In simplest physiologic terms, Denny-Brown and Yanagisawa, who studied the effects of ablation of individual extrapyramidal structures in monkeys, concluded that the basal ganglia function as a kind of clearinghouse where, during an intended or projected movement, one set of activities is facilitated and all other unnecessary ones are suppressed. They used the analogy of the basal ganglia as a brake or switch, the tonic inhibitory ("brake") action preventing target structures from generating unwanted motor activity and the "switch" function referring to the capacity of the basal ganglia to select which of many available motor programs will be active at any given time. Still other theoretical constructs focus on the role of the basal ganglia in the initiation, sequencing, and modulation of motor activity ("motor programming"). Also, it appears that the basal ganglia participate in the constant priming of the motor system, enabling the rapid execution of motor acts without premeditation—for example, hitting a baseball. In most ways, these conceptualizations restate the same notions of balance and selectivity imparted to all motor actions by the basal ganglia.

Physiologic evidence reflects this balanced architecture, one excitatory and the other inhibitory within the individual circuits. The *direct* striatomedial pallidonigral pathway is activated by glutaminergic projections from the sensorimotor cortex and by dopaminergic nigral (pars compacta)—striatal projections. Activation of this direct pathway inhibits the internal pallidum, which, in turn, disinhibits the ventrolateral and ventroanterior nuclei of the thalamus. As a consequence, thalamocortical drive is enhanced and cortically initiated movements are facilitated. The *indirect* circuit arises from putaminal neurons that contain gamma-aminobutyric acid (GABA) and smaller amounts of enkephalin. These striatal projections have an inhibitory effect on the medial pallidum, which, in turn, disinhibits the subthalamic nucleus through GABA release, providing subthalamic drive to the internal pallidum and substantia nigra pars reticulata. The net effect is thalamic inhibition, which reduces thalamocortical input to the precentral motor fields and impedes voluntary movement. These complex anatomic and physiologic relationships have been summarized in numerous schematic diagrams similar to Fig. 4-4 and those by Lang and Lozano and by Standaert and Young.

Restated, the current view is that enhanced conduction through the indirect pathway leads to hypokinesia by increasing pallidothalamic inhibition, whereas enhanced conduction through the direct pathway results in hyperkinesia by reducing pallidothalamic inhibition. The direct pathway has been conceived by Marsden and Obeso as facilitating cortically initiated movements and the indirect pathway as suppressing potentially conflicting and unwanted motor patterns. Dopamine released by the pars reticulata of the substantia nigra helps maintain the normal balance between the direct and indirect pathways. In Parkinson disease, a loss of dopaminergic input from the substantia nigra diminishes activity in the direct pathway and increases activity in the indirect pathway; the net effect is to increase inhibition of the thalamic nuclei and to reduce excitation of the cortical motor system.

Further insight into these systems and into the mechanism of Parkinson disease came from the discovery that the parkinsonian syndrome is largely reproduced in humans and primates by the toxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). This toxin was discovered when drug abusers self-administered an analogue of meperidine. The molecule binds with high affinity to monoamine oxidase (MAO), an extraneural enzyme that transforms it to pyridinium, a metabolite that is bound by melanin in the dopaminergic nigral neurons and destroys the cells, probably by interfering with mitochondrial function. In monkeys made parkinsonian by the administration of MPTP, electrophysiologic studies have shown increased activity in the internal globus pallidus and decreased activity in the external globus pallidus, as predicted from the above-described models. The end result is increased inhibition of thalamocortical neurons.

However, crude lesions of either or both parts of the pallidum, such as infarcts, hemorrhages, and tumors, even beyond their unilateral location, do not cause the full parkinsonian syndrome. Perhaps it is because the subtle imbalance is not reproduced between the internal and external pallidal circuits that exist in Parkinson disease. More specifically, the internal segment is part of the direct and indirect pathway, one excitatory and the other

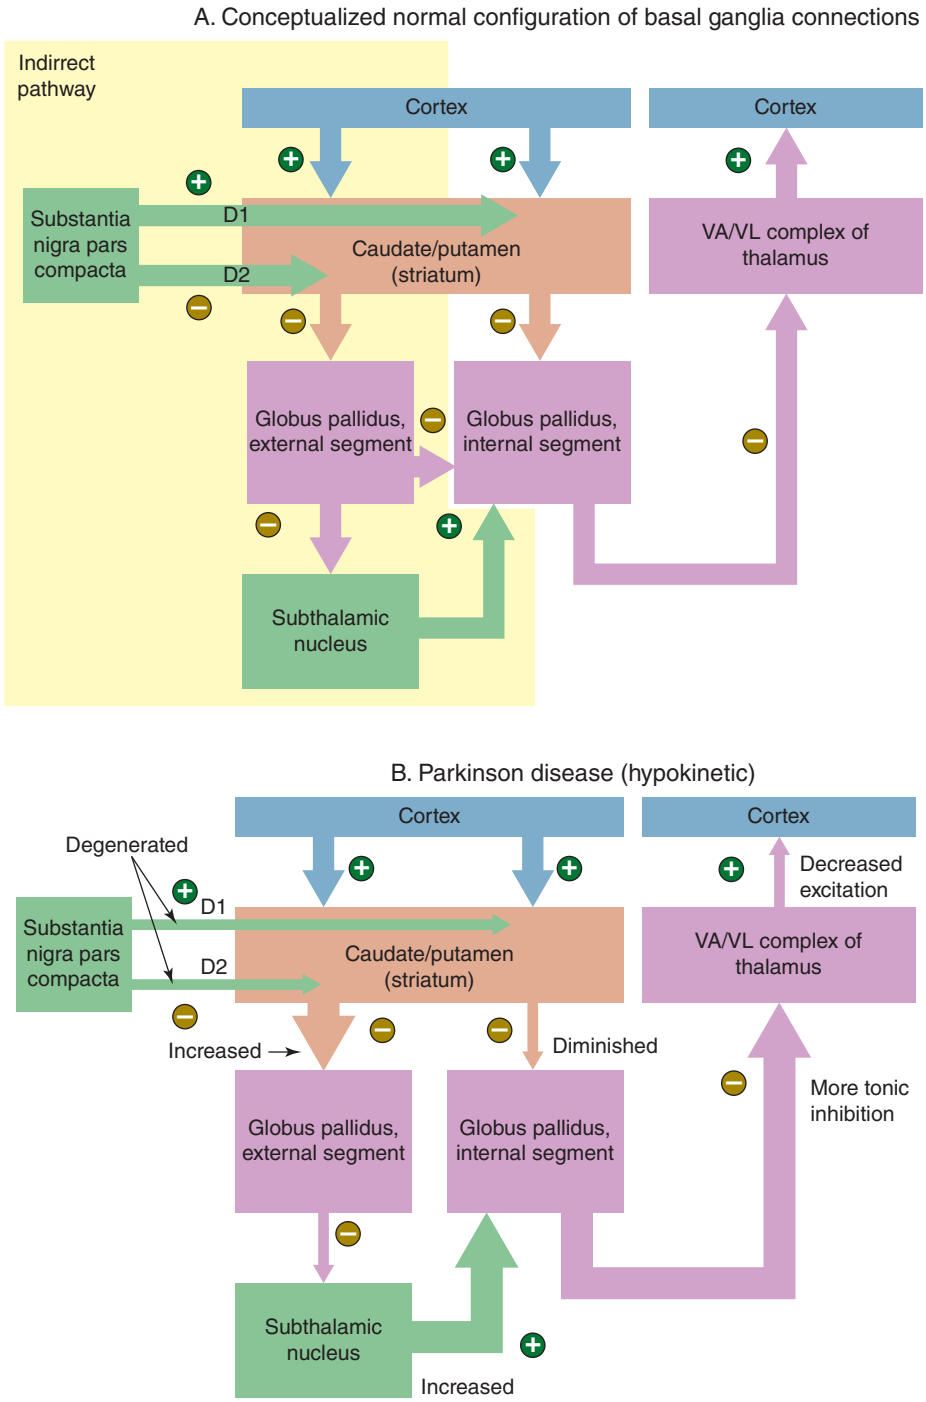

Figure 4-4. *A*. Schematic diagram of the cortical–basal ganglia–thalamic circuits showing the main neurotransmitter pathways and their effects. Dopaminergic neurons arising in the pars compacta of the substantia nigra have an excitatory influence on the direct pathway (via D1 receptors) and an inhibitory effect on the indirect pathway (via D2 receptors). *B*. In Parkinson disease, hypokinesia is thought to result from reduced dopamine input from the substantia nigra to the striatum. As a result, decreased inhibition of the globus pallidus interna by the direct pathway, and increased excitation of the globus pallidus interna by the indirect pathway, lead to increased inhibitory drive of the thalamus and therefore decreased excitation of the cortex. *C*. In Huntington disease, there is degeneration of the striatum. For the direct pathway, there is overall a net inhibition of the globus pallidus interna (due to decreased inhibition from the striatum, increased inhibition from the globus pallidus externa, and decreased excitation from the subthalamic nucleus). For the indirect pathway, there is less inhibition of the globus pallidus externa, leading to more inhibition of the subthalamic nucleus, less excitation of globus pallidus interna. In sum, there is less inhibition of the thalamus, and increased excitation of the cortex, leading to hyperkinetic movements.

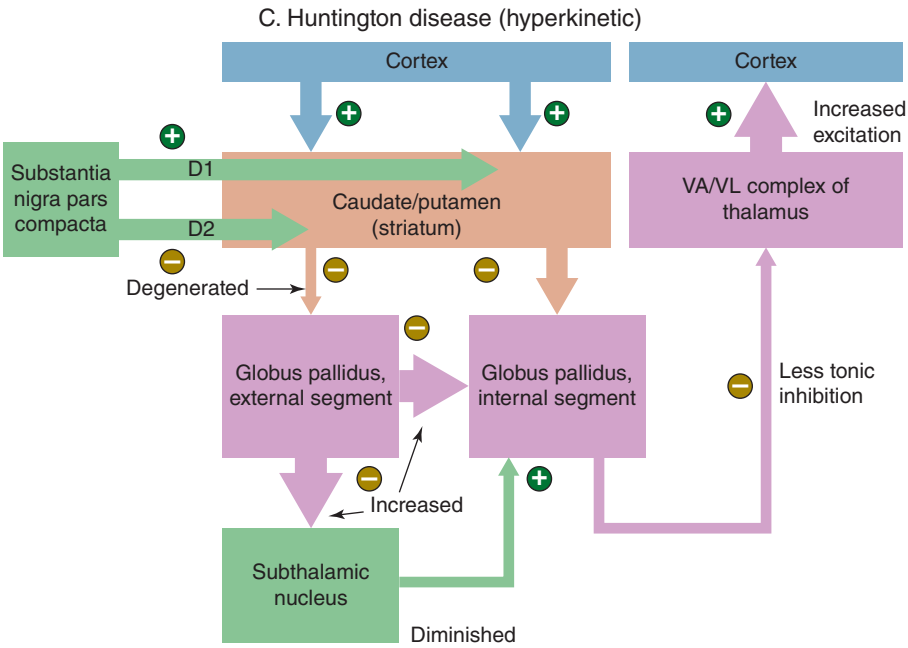

Figure 4-4. (*Continued*)

inhibitory, whereas the external segment is only influenced by the indirect pathway. Indeed, striking improvements in parkinsonian symptoms are obtained, paradoxically, by placing lesions in the internal pallidum (pallidotomy) as discussed in Chap. 38.

It is likely that the static model of inhibitory and excitatory pathways and the parsing of a direct and an indirect pathway, as useful as it is as a mnemonic, does not account very well for the dynamic activities of the basal ganglia. In particular, the electrical activity of the neurons in these systems oscillates and influences the frequency pattern of firing in other parts of the system, as well as bringing individual cells closer to firing. Another limitation of currently conceived models is that they do not account for the tremor of Parkinson disease. To further complicate matters, the various subtypes of dopamine receptors act in both excitatory and inhibitory ways under different circumstances depending on their location as discussed below.

The manner in which excessive or reduced activity of various components of the basal ganglia gives rise to hypokinetic and hyperkinetic movement disorders is discussed further on, under "Symptoms of Basal Ganglia Disease."

Pharmacologic Considerations

A series of pharmacologic observations have considerably enhanced our understanding of basal ganglionic function and led to a rational treatment of Parkinson disease and other extrapyramidal syndromes. Whereas physiologists had for years failed to discover the functions of the basal ganglia by stimulation and crude ablation experiments, clinicians became aware that certain drugs, such as reserpine and the phenothiazines, could produce extrapyramidal syndromes (e.g., parkinsonism, choreoathetosis, dystonia). These observations stimulated the study of central nervous system (CNS) transmitter substances in general. The current view is that the integrated basal ganglionic control of movement can be best understood by considering, in the context of the anatomy described above, the physiologic effects of neurotransmitters that convey the signals between cortex, striatum, globus pallidus, subthalamic nucleus, substantia nigra, and thalamus.

The most important neurotransmitter substances from the point of view of basal ganglionic function are glutamate, GABA, dopamine, acetylcholine, and serotonin. A more complete account of this subject may be found in the reviews of Penney and Young, of Alexander and Crutcher, and of Rao.

The following is what is known with a fair degree of certainty. Glutamate is the neurotransmitter of the excitatory projections from the cortex to the striatum and of the excitatory neurons of the subthalamic nucleus. GABA is the inhibitory neurotransmitter of striatal, pallidal, and substantia nigra (pars reticulata) projection neurons.

Of the catecholamines, dopamine has the most pervasive role but its influence can be excitatory or inhibitory depending on the site of action and the subtype of dopamine receptor. Disturbances of dopamine signaling are essential abnormalities of several CNS disorders including parkinsonism, schizophrenia, attention deficit hyperactivity disorder, and drug abuse. Within the basal ganglia, the areas richest in dopamine are the substantia nigra, where it is synthesized in the nerve cell bodies of the pars compacta, and the termination of these fibers in the striatum. In the most simplified models, stimulation of the dopaminergic neurons of the substantia nigra induces a specific response in the striatum—namely, an inhibitory effect on the already low firing rate of neostriatal neurons.

[a]Acts through direct striatal projection neurons.
[b]Acts through indirect striatal projection neurons.
GP, globus pallidus; SN, substantia nigra.

However, the effects of dopamine have proved even more difficult to resolve, in large part because there are now five known types of postsynaptic dopamine receptors (D1–D5), each with a particular anatomic distribution and pharmacologic action. This heterogeneity is exemplified in the excitatory effect of dopamine on the small spiny neurons of the putamen and an inhibitory effect on others. Viewed from the perspective of the direct and indirect pathways, dopamine enhances the activity of the former and inhibits the latter, resulting in a net disinhibition of thalamic nuclei and a release of cortical motor function.

The five types of dopamine receptors are found in differing concentration throughout various parts of the brain, each displaying differing affinities for dopamine itself and for various drugs and other agents (Table 4-2; also see Jenner). The D1 and D2 receptors are highly concentrated in the striatum and are the ones most often implicated in diseases of the basal ganglia; D3 in the nucleus accumbens, D4 in the frontal cortex and certain limbic structures, and D5 in the hippocampus and limbic system. In the striatum, the effects of dopamine act as a class of "D1-like" (D1 and D5 subtypes) and "D2-like" (D2, D3, and D4 subtypes) receptors. Activation of the D1 class stimulates adenyl cyclase, whereas D2 receptor binding inhibits this enzyme. Whether dopamine functions in an excitatory or inhibitory manner at a particular synapse is determined by the local receptor. As mentioned earlier, excitatory D1 receptors predominate on the small spiny putaminal neurons that are the origin of the direct striatopallidal output pathway, whereas D2 receptors mediate the inhibitory influence of dopamine on the indirect striatopallidal output, as indicated in Fig. 4-4.

Some of the clinical and pharmacologic effects of dopamine are made clear by considering both the anatomic sites of various receptors and their physiologic effects. For example, it appears that drug-induced parkinsonian syndromes and tardive dyskinesias (described further on) are prone to occur when drugs are administered that competitively bind to the D2 receptor, but that the newer antipsychosis drugs, which produce fewer of these effects, have a stronger affinity for the D4 receptor. However, the situation is actually far more complex, in part because of the synergistic activities of D1 and D2 receptors, each potentiating the other at some sites of convergence, and the presence on the presynaptic terminals of nigrostriatal neurons of D2 receptors, which inhibit dopamine synthesis and release.

In contrast to the almost instantaneous actions of glutamate and its antagonist, GABA, the monoamines may have more protracted effects, lasting for seconds or up to several hours. Dopamine and related neurotransmitters therefore have a slower influence through the "second messenger" cyclic adenosine monophosphate (cAMP), which, in turn, controls the phosphorylation or dephosphorylation of numerous intraneuronal G-proteins. These intracellular effects have been summarized by Greengard.

The effects of certain drugs, some no longer in use but still instructive, are best comprehended by understanding the manner in which they alter neurotransmitters. Several drugs—namely reserpine, the phenothiazines, and the butyrophenones (notably haloperidol)—induce prominent parkinsonian syndromes. Reserpine, for example, depletes the striatum and other parts of the brain of dopamine; haloperidol and the phenothiazines work by

a different mechanism, probably by blocking dopamine receptors within the striatum.

The basic validity of the physiologic–pharmacologic model outlined here is supported by the observation that excess doses of L-dopa or of a direct-acting dopamine receptor agonist lead to excessive motor activity. Furthermore, the therapeutic effects of the main drugs used in the treatment of Parkinson disease are understandable in the context of neurotransmitter function. To correct the basic dopamine deficiency from a loss of nigral cells that underlies Parkinson disease, attempts were at first made to administer dopamine directly. However, dopamine as such cannot cross the blood–brain barrier and therefore has no therapeutic effect. But its immediate precursor, L-dopa, does cross the blood–barrier and is effective in decreasing the symptoms of Parkinson disease as well as of the above-described MPTP-induced parkinsonism. This effect is enhanced by the addition of an inhibitor of dopa decarboxylase, an important enzyme in the catabolism of dopamine. The addition of an enzyme inhibitor of this type (carbidopa or benserazide) to L-dopa results in an increase of dopamine concentration in the brain, while sparing other organs. The benefit of combining L-dopa with carbidopa is to minimize the systemic side effects of peripheral dopamine, such as nausea, vomiting, and hypotension. Similarly, drugs that inhibit catechol *O*-methyltransferase (COMT), another enzyme that metabolizes dopamine, prolong the effects of administered L-dopa.

Acetylcholine (ACh), long established as the neurotransmitter at the neuromuscular junction and the autonomic ganglia, is also physiologically active in the basal ganglia. The highest concentration of ACh, as well as of the enzymes necessary for its synthesis and degradation (choline acetyl transferase and acetylcholinesterase), is in the striatum. Acetylcholine is synthesized and released by the large but sparse (Golgi type 2) nonspiny striatal neurons. It has a mixed but mainly excitatory effect on the more numerous spiny neurons within the putamen that constitute the main origin of the direct and indirect pathways described above. It is likely that the effectiveness of atropinic agents—which have been used empirically for many years in the treatment of Parkinson disease and dystonia—depends on their capacity to antagonize ACh at sites within the basal ganglia and in projections from the pedunculopontine nuclei. Acetylcholine also appears to act on the presynaptic membrane of striatal cells and to influence their release of neurotransmitters, as discussed below. In addition, the basal ganglia contain other biologically active substances—substance P, enkephalin, cholecystokinin, somatostatin, and neuropeptide Y—which enhance or diminish the effects of other neurotransmitters, that is, they act as neuromodulators.

Because of the pharmacologic effects of ACh and dopamine, it was originally postulated by Ehringer and Hornykiewicz (the latter originated the idea) that a functional equilibrium exists in the striatum between the excitatory activity of ACh and the inhibitory activity of dopamine. In Parkinson disease, the decreased release of dopamine by the substantia nigra onto the striatum disinhibits neurons that synthesize ACh, resulting in a predominance of cholinergic activity—a notion supported by the observation that parkinsonian symptoms are aggravated by centrally acting cholinergic drugs and improved by anticholinergic drugs. According to this theory, administration of anticholinergic drugs restores the ratio between dopamine and ACh, with the new equilibrium being set at a lower-than-normal level because the striatal levels of dopamine are low to begin with. This view has been validated in clinical practice in that one observes a beneficial effect on parkinsonian symptoms after the administration of anticholinergic agents. The use of drugs that enhance dopamine synthesis or its release, or that directly stimulate dopaminergic receptors in the striatum represents another more direct method of treating Parkinson disease as outlined in Chap. 38.

The Pathology of Basal Ganglionic Disease

The extrapyramidal motor syndrome as we know it today was first delineated on clinical grounds and so named by S. A. K. Wilson in 1912. In the disease that now bears his name and that he called hepatolenticular degeneration, the most striking abnormality was a bilaterally symmetrical degeneration of the putamen, sometimes to the point of cavitation. To these lesions, Wilson correctly attributed the characteristic symptoms of rigidity and tremor. Shortly thereafter, van Woerkom described a similar clinical syndrome in a patient with acquired liver disease (Wilson's cases were familial), the most prominent lesions again consisting of foci of neuronal degeneration in the striatum. Clinicopathologic studies of Huntington chorea—beginning with those of Meynert (1871) and followed by those of Jelgersma (1908) and Alzheimer (1911)—related the excessive movements and rigidity characteristic of the disease to a loss of nerve cells in the striatum. In 1920, Oskar and Cecile Vogt gave a detailed account of the neuropathologic changes in several patients who had been afflicted with choreoathetosis since early infancy; the changes, which they described as a "status fibrosus" or "status dysmyelinatus," were confined to the caudate and lenticular nuclei. Surprisingly, it was not until 1919 that Tretiakoff demonstrated the underlying cell loss of the substantia nigra in cases of what was then called paralysis agitans and is now known as Parkinson disease. Finally, a series of observations, culminating with those of J. Purdon Martin and later of Mitchell and colleagues, related hemiballismus to lesions in the subthalamic nucleus of Luys and its immediate connections. While these observations have been invaluable, it has become apparent from clinical work that none of the relationships between anatomic loci and movement disorders are exclusive and the same movement disorder can result from lesions at one of several sites.

Another broad perspective on the result of focal damage in the basal ganglia was afforded by Bhatia and Marsden, who reviewed 240 cases based on CT and MRI in which there were lesions in the caudate, putamen, and globus pallidus associated with movement abnormalities. Dystonia was the most common finding, and chorea and parkinsonism were infrequent. It was also notable that a common associated behavioral abnormality was

Table 4-3

CLINICOPATHOLOGIC CORRELATIONS OF EXTRAPYRAMIDAL MOVEMENT DISORDERS

SYMPTOMS	PRINCIPAL LOCATION OF MORBID ANATOMY
Unilateral plastic rigidity with rest tremor (Parkinson disease)	Contralateral substantia nigra plus (?) other mesencephalic structures
Unilateral hemiballismus and hemichorea	Contralateral subthalamic nucleus of Luys or luysial–pallidal connections
Chronic chorea of Huntington type	Caudate nucleus and putamen
Athetosis and dystonia	Contralateral striatum (pathology of dystonia musculorum deformans
Cerebellar incoordination, intention tremor, and hypotonia	Ipsilateral cerebellar hemisphere; ipsilateral middle or inferior cerebellar peduncle; brachium conjunctivum (ipsilateral if below decussation, contralateral if above)
Decerebrate rigidity, i.e., extension of arms and legs, opisthotonos	Usually bilateral in tegmentum of upper brainstem at level of red nucleus or between red and vestibular nuclei
Palatal and facial myoclonus (rhythmic)	Ipsilateral central tegmental tract with denervation of inferior olivary nucleus and nucleus ambiguus
Diffuse myoclonus	Neuronal degeneration, usually diffuse or predominating in cerebral or cerebellar cortex and dentate nuclei

abulia (apathy and loss of initiative), in those with caudate lesions. The deficiencies of this type of case analysis (i.e., the crudeness of early imaging studies obtained without regard to the temporal aspects of the clinical disorder), conceded by the authors, are obvious. Needed are detailed anatomic (postmortem) studies of cases in which the disturbances of function were stable for many months or years. However, restating the comments above, there is no consistent association between any type of movement disorder and a particular location in the basal ganglia.

As a prelude to the next section, Table 4-3 summarizes the clinicopathologic correlations of extrapyramidal movement disorders that are accepted by most neurologists; it must be emphasized, however, that there is still some uncertainty as to the finer details.

SYMPTOMS OF BASAL GANGLIA DISEASE

In broad terms, all motor disorders consist of functional deficits (or negative symptoms) and conversely, excessive motor activity (positive symptoms), the latter being ascribed to the release or disinhibition of the activity of undamaged parts of the motor system. When diseases of the basal ganglia are analyzed along these lines, bradykinesia, hypokinesia, and loss of normal postural reflexes stand out as the primary negative symptoms, and tremor, rigidity, and the involuntary dyskinetic movements of chorea, athetosis, ballismus, and dystonia, as the positive ones. Disorders of phonation, articulation, and locomotion due to basal ganglia disease are more difficult to classify. In some instances, this group of signs is clearly a consequence of rigidity and postural disorders, whereas in others, where rigidity is slight or negligible, they seem to represent primary deficiencies. The changes in gait related to diseases of the basal ganglia are the result of both fundamental alterations in tone and posture as well as disruption of the more inherent control of walking by the extrapyramidal system. Psychological stress and anxiety generally worsen the abnormal movements in extrapyramidal syndromes, just as relaxation improves them. A role for the basal ganglia in cognitive function and abnormal behavior is hinted at provocatively in Parkinson disease, progressive supranuclear palsy, Tourette syndrome, and other processes (Ring and Serra-Mestres). Slowness in thinking (bradyphrenia) in some of these disorders was alluded to earlier, but is inconsistent. Again, it would be an oversimplification to assign primary importance to the presence of depression, dementia, psychosis, and other disturbances in disease of the basal ganglia or to view changes in these structures as proximate causes of obsessive-compulsive and other behavioral disorders; rather, a role as part of a larger circuitry is likely. All that can be stated is that the basal ganglia modulate complex motor and to a lesser extent, cognitive behavior, but the precise nature of their effect is not known at this time.

Hypokinesia and Bradykinesia

The terms hypokinesia and akinesia (the extreme form of hypokinesia) refer to a reduction in the spontaneous movements of an affected part and a failure to engage it freely in the natural actions of the body. In contrast to what occurs in paralysis (the primary symptom of corticospinal tract lesions), strength is not significantly diminished. Also, hypokinesia is unlike apraxia, in which a lesion erases the pattern of movements necessary for an intended act, leaving other actions intact. *Hypokinesia* is expressed most clearly in the parkinsonian patient, where it takes the form of an extreme underactivity ("poverty") of movement. The frequent automatic, habitual movements observed in the normal individual—such as putting the hand to the face, folding the arms, or crossing the legs—are absent or greatly reduced. In looking to one side, the eyes move, but not the head. In arising from a chair, there is a failure to make the usual small preliminary adjustments, such as pulling the feet back, putting the hands on the arms of the chair, and so forth. Blinking is infrequent. Saliva is swallowed less frequently and drooling results. The face lacks expressive mobility ("masked facies," or hypomimia). Speech is rapid, mumbling (or "cluttered"), and monotonic, and the voice is soft.

Bradykinesia connotes slowness of movement, another aspect of the same physiologic difficulty as reflected in hypokinesia. Not only is the parkinsonian patient slightly "slow off the mark" (displaying a longer-than-normal interval between a command and the first contraction of muscle—that is, increased reaction time), but the velocity of movement, or the time from onset to completion of movement, is slower than normal. The extremes of hypokinesia or of bradykinesia can result in a complete impediment of movement, akinesia, a sign that may also result from several other disorders of motor function and volitional motor initiation. Hallett equates akinesia with a prolonged reaction time and bradykinesia with a prolonged time of execution. For a time, bradykinesia was attributed to the frequently associated rigidity, which could reasonably hamper all movements, but the limitation of this explanation became apparent when it was discovered that an appropriately placed stereotactic lesion in a patient with Parkinson disease may abolish rigidity while leaving the hypokinesia unaltered. Thus it appears that apart from their contribution to the maintenance of posture, the basal ganglia provide an essential element for the performance of the large variety of voluntary and semiautomatic actions required for the full repertoire of natural human motility. That cells in the basal ganglia participate in the initiation of movement is also evident from the fact that the firing rates in these neurons increase before movement is detected clinically.

An analysis of ballistic (rapid) movements in the parkinsonian patient, that the normal triphasic sequence of agonist–antagonist–agonist activation, as described in the next chapter, is intact but lacks the amplitude (number of activated motor units) to complete the movement normally (Hallett and Khoshbin). Several smaller triphasic sequences are then needed, which slow the movement. The patient experiences these phenomena as not only slowness but also a perceived weakness.

In terms of pathologic anatomy and physiology, bradykinesia may be caused by any process or drug that interrupts the cortico–striato–pallido–thalamic circuit. Clinical examples include reduced dopaminergic input from the substantia nigra to the striatum, as in Parkinson disease; dopamine receptor blockade by neuroleptic drugs; extensive degeneration of striatal neurons, as in striatonigral degeneration and the rigid form of Huntington chorea; and destruction of the medial pallidum, as in Wilson disease. As illustrated in Fig. 4-4*B*, which gives a schematic representation of the hypokinetic state of Parkinson disease, changes in the cortico–striato–pallido–thalamic circuit (in this case, mainly the direct striatopallidal pathway) can be interpreted in terms of altered neurochemical and resultant physiologic connectivity within the basal ganglia. The reciprocal situation, enhanced motor activity, is summarized in the analogous diagram for Huntington disease (Fig. 4-4*C*), in which a reduction in the activity of the indirect striatopallidal pathway leads to enhanced excitatory motor drive in the thalamocortical motor pathway.

Several other disorders of voluntary movement may also be observed in patients with diseases of the basal ganglia. A persistent voluntary contraction of hand muscles, as in holding a pencil, may fail to be inhibited, so that there is interference with the next willed movement. This has been termed tonic innervation, or *blocking*, and may be brought out by asking the patient to repetitively open and close a fist or tap a finger. Attempts to perform an alternating sequence of movements may be blocked at one point, or there may be a tendency for the voluntary movement to adopt the frequency of a coexistent tremor (*entrainment*).

Disorders of Postural Fixation, Equilibrium, and Righting

These deficits are also demonstrated most clearly in the parkinsonian patient. The prevailing posture is one of involuntary flexion of the trunk, limbs, and the neck, which gives the parkinsonian individual a characteristic appearance, even at a distance from the observer, as described by Parkinson, "A propensity to bend the trunk forwards, and to pass from a walking to a running pace." Anticipatory and compensatory righting reflexes, referring to mechanisms that maintain an upright posture, are also manifestly impaired. This occurs early in the course of progressive supranuclear palsy and later in Parkinson disease. The inability of the patient to make appropriate postural adjustments to tilting or falling and his inability to move from the reclining to the standing position are closely related phenomena. A gentle push on the patient's sternum or a tug on the shoulders may cause a fall or start a series of small corrective steps that the patient can not control (festination). These basal ganglionic postural abnormalities are not attributable to weakness or to defects in proprioceptive, labyrinthine, or visual function, the principal forces that control the normal posture of the head and trunk.

Rigidity and Alterations in Muscle Tone

In the form of altered muscle tone known as rigidity, the muscles are continuously or intermittently firm and tense. Although brief periods of electromyographic silence can be obtained in selected muscles possibly by persistent attempts to relax the limb, there is obviously a low threshold for involuntary sustained muscle contraction, and this is present during most of the waking state, even when the patient appears quiet and relaxed. When passively moving the limb, one may sense this intermittent relaxation, a phenomenon known as cogwheeling. Whether the cogwheel sign is due to this phenomenon or simply a tremor superimposed on rigidity is not clear. Both may contribute to the cogwheel sign (see further on). In contrast to spasticity, the increased resistance on passive movement that characterizes rigidity is not preceded by an initial "free interval" and has an even or uniform quality throughout the range of movement of the limb, like that experienced in bending a lead pipe or pulling a strand of toffee. The contrasting terms clasp-knife for spasticity and lead-pipe for rigidity have been applied to the examiner's physical perception on attempting to smoothly manipulate the patient's limb through an arc of movement. Moreover, the rigidity of extrapyramidal disorder is not velocity dependent, as it is in spasticity. The tendon reflexes are not enhanced in the rigid limb as they are in spasticity and, when released, the limb does not resume its original position, as happens in spasticity.

Rigidity usually involves both flexor and extensor muscle groups, but it tends to be more prominent in muscles that maintain a flexed posture, that is, in the flexor muscles of trunk and limbs. It appears to be somewhat greater in the large muscle groups, but this may be merely a matter of muscle mass. Certainly, the small muscles of the face and tongue and even those of the larynx are often affected by rigidity. Concordant with the physical examination, in the electromyographic tracing, motor-unit activity is more continuous in rigidity than in spasticity, persisting even after apparent relaxation.

A special feature that may accompany rigidity, first noted by Negro in 1901, is the cogwheel phenomenon mentioned above. When the hypertonic muscle is passively stretched, for example, when the hand is dorsiflexed, one encounters a rhythmically interrupted, ratchet-like resistance. Many consider that this phenomenon represents an underlying tremor that, if not manifestly present, emerges faintly during manipulation. In that case, it would not be a fundamental property of rigidity and would be found in many tremulous states. However, numerous instances of severe tremor with minimally perceptible cogwheeling, and the opposite, suggest to us on clinical grounds that the phenomenon may be more complex.

Rigidity is characteristically variable in severity at different times; in some patients with involuntary movements, particularly in those with chorea or dystonia, the limbs may actually be intermittently or persistently hypotonic. Rigidity is a prominent feature of many basal ganglionic diseases, such as Parkinson disease, Wilson disease, multiple system atrophy (formerly striatonigral degeneration), progressive supranuclear palsy, dystonia musculorum deformans (discussed further on and in Chap. 38), exposure to neuroleptic drugs, and mineralization of the basal ganglia (Fahr disease).

Another distinctive type of variable resistance to passive movement is one in which the patient seems unable to relax a group of muscles on request. When the limb muscles are passively stretched, the patient appears to actively resist the movement (gegenhalten, *paratonia*, or oppositional resistance). Natural relaxation normally requires concentration on the part of the patient. If there is inattentiveness—as happens with diseases of the frontal lobes, dementia, other confusional states, and functional motor disorders—this type of oppositional resistance may be mistaken for parkinsonian rigidity but this is not a manifestation of basal ganglia disorder *per se* but may indicate that the connections of the basal ganglia to the frontal lobes are impaired. A similar difficulty in relaxation is observed normally in small children. Also not to be mistaken for rigidity or paratonia is the "waxy flexibility" displayed by the psychotic-catatonic patient when a limb placed in a suspended position is maintained for minutes in the identical posture (*flexibilitas cerea*).

Chorea, Athetosis, Ballismus, Dystonia

These involuntary hyperkinetic symptoms are described as discrete clinical phenomenon, readily distinguishable from the others. Although distinctions are made between chorea, athetosis, and dystonia, even their most prominent differences—the discreteness and rapidity of choreic movements and the slowness of athetotic ones—are more apparent than real. As pointed out by S. A. Kinnier Wilson, involuntary movements may follow one another in such rapid succession that they become confluent and therefore appear to be slow. They usually occur together or blend imperceptibly into each other and have many points of clinical similarity. There are reasons to believe that they have a common anatomic and physiologic basis although distinct sites in the brain have been tentatively implicated for each. One must be mindful that chorea, dystonia, and athetosis (moving dystonia), are symptoms and are not to be equated with disease entities that happen to incorporate one of these terms in their names (e.g., Huntington chorea, dystonia musculorum deformans). Here the discussion is limited to the symptoms. The diseases of which these symptoms are a part are considered mainly in Chap. 38.

Somewhat more ambiguous but in common clinical use is the term dyskinesia. It encompasses all the active movement phenomena that are a consequence of disease of the basal ganglia, usually implying an element of dystonia. It has also been used to refer more specifically to the undifferentiated excessive movements that are induced in Parkinson patients at the peak of L-dopa effect and to numerous dystonic and athetotic movements that may follow the use of neuroleptic drugs ("tardive dyskinesias") that are discussed further on.

Chorea

Derived from the Greek word meaning "dance," chorea refers to involuntary arrhythmic movements of a forcible, rapid, jerky type. These movements may be simple or quite elaborate and of variable distribution. Although the movements are purposeless, the patient may incorporate them into a deliberate act, as if to make them less noticeable. When superimposed on voluntary actions, they may assume an exaggerated and bizarre character. Grimacing and peculiar respiratory sounds may be other expressions of the disorder. Usually the movements are discrete, but if very numerous, they become confluent and then resemble athetosis, as described below. In moments when the involuntary movements are held in abeyance, volitional movements of normal strength are possible; but they also tend to be excessively quick and poorly sustained. The limbs are often slack or hypotonic and because of this, the knee jerks tend to be pendular; in other words, with the patient sitting on the edge of the examining table and the foot free of the floor, the leg swings back and forth several times in response to a tap on the patellar tendon, rather than once or twice, as it does normally. A choreic movement may be superimposed on the reflex movement, checking it in flight, so to speak.

Chorea differs from myoclonus mainly with respect to the speed of the movements; the myoclonic jerk is much faster and may involve single muscles or part of a muscle as well as groups of muscles. Failure to appreciate these differences often results in an incorrect diagnosis. The hypotonia as well as the pendular reflexes that accompany chorea may also occur in disturbances of cerebellar function. Lacking, however, are "intention"

Table 4-4

DISEASES ASSOCIATED WITH CHOREA

Inherited disorders
Huntington disease
Benign hereditary chorea
Neuroacanthocytosis
Dentatorubropallidoluysian atrophy
Wilson disease
Immune-mediated chorea
Sydenham chorea
Chorea gravidarum
Lupus erythematosus
Antiphospholipid antibodies
Paraneoplastic, often with other movements
Drug-induced chorea
Neuroleptics (phenothiazines, haloperidol, metoclopramide, and others)
Oral contraceptives
Phenytoin (occasionally other antiepileptic drugs)
Excess dosages of L-dopa and dopamine agonist medications
Cocaine
Chorea symptomatic of systemic disease
Thyrotoxicosis
Polycythemia vera
Hyperosmolar, nonketotic hyperglycemia
Toxoplasmosis in AIDS
Hemichorea
Stroke
Tumor
Vascular malformation

(meaning goal directed) action tremor and true incoordination or ataxia. In some circumstances, it may be useful diagnostically to distinguish chorea from myoclonus in that the underlying causes may be quite different.

Table 4-4 lists diseases characterized mainly by chorea or localized lesions that may at times cause chorea. Of the degenerative conditions, chorea is a major feature of Huntington disease, in which the movements tend more typically to be a merging of choreiform and the below described athetotic (*choreoathetotic*) motions. Not infrequently, chorea has its onset in late life without the other identifying features of Huntington disease. It is then referred to as senile chorea, a term that is hardly helpful in understanding the process. Its relation to Huntington chorea in any individual case is settled by genetic testing. Several less common degenerative conditions are associated with chorea, among them dentatorubropallidoluysian atrophy (DRPLA) and a form of chorea associated with acanthocytosis of red blood cells. Also, there is an inherited form of chorea of childhood onset without dementia that has been referred to as benign hereditary chorea. There may be subtle additional ataxia of gait, as noted by Breedveld and colleagues. These are discussed in Chap. 38.

Typical choreic movements are the dominant feature of several immune-related conditions, perhaps the best characterized being Sydenham chorea that is strongly linked to streptococcal infection, mainly in women. Striatal abnormalities, usually transient and rarely persistent, have been demonstrated by MRI (Emery and Vieco). It is perhaps not surprising that antibodies directed against cells of the basal ganglia have been detected in both acute and late Sydenham chorea (Church et al). Following from the connection to streptococcal infection and the detection of these antibodies, it has been suggested in recent years that the spectrum of poststreptococcal disorders can be extended to tic and obsessive-compulsive behavior in children (PANDAS syndrome discussed in a later section). In these cases, the neurologic problems are said to arise suddenly, subside, and return with future streptococcal infections, as discussed further on. This seems unlikely to explain chorea in adults. There also exists a variety of chorea associated with pregnancy (chorea gravidarum), which in the past had a close linkage to prior episodes of Sydenham chorea. Alternatively, pregnancy may expose lupus-related chorea or be concordant with the onset of Huntington chorea. However, the elicitation of chorea by oral contraceptives in the modern era, as noted below, suggests a hormonal rather than immune causation in many cases. There have been instances of paraneoplastic chorea associated in a very few cases with lung cancer and anti-CRMP or anti-Hu antibodies (O'Toole and colleagues and Vernino et al). The paraneoplastic variety may combine several aspects of chorea with athetosis, ballismus, or dystonia; and inflammatory lesions are found in the striatum (see Chap. 30).

The use of oral contraceptives sometimes elicits chorea in an otherwise healthy young woman, but many such patients have underlying systemic lupus erythematosus and antiphospholipid antibodies. Whether the chorea (usually unilateral) is the result of a small infarction (as suggested by a mild hemiparesis on the affected side) or is an immunologic condition is not settled. The reemergence of chorea in these circumstances as steroids are withdrawn or birth control pills are introduced suggests a more complex process than simply a small, deep infarction—perhaps something akin to Sydenham chorea as discussed above. A connection between hemichorea and the antiphospholipid syndrome alone, without lupus, is more tenuous.

The chronic administration of phenothiazine drugs or haloperidol (or an idiosyncratic reaction to these drugs) is a common cause of extrapyramidal movement disorders of all types, including chorea; these may become manifest during use of the drug or in a delayed "tardive" fashion, as already mentioned. The newer antipsychosis drugs (the atypical neuroleptics) have been less frequently associated with the problems. Excess dopamine administration in advanced Parkinson disease is perhaps the most common cause of a choreiform dyskinesia in neurologic practice, but the movements tend to be more complex and continuous than those seen in chorea. Drugs with anti-dopamine features used for non-psychiatric purposes, such as metoclopramide, are currently among the most common causes of tardive dyskinesia. The use of phenytoin or other anticonvulsant drugs may cause chorea in sensitive individuals. A transitory chorea may occur in the course of an acute metabolic derangement, mainly with hyperosmolar hyperglycemia, hypoglycemia, or hyponatremia, and with the inhalation of crack cocaine.

Rarely, chorea complicates hyperthyroidism, polycythemia vera, lupus erythematosus, or some forms of cerebral arteritis. AIDS has emerged as a cause of a few

cases of subacute progressive movement disorders that are initially asymmetrical. The usual associations of chorea in AIDS have been with focal lesions in or near basal ganglionic structures such as toxoplasmosis, progressive multifocal leukoencephalopathy, and lymphoma, but several instances of chorea are not explained by any of these focal lesions. A number of rare paroxysmal kinesigenic disorders, discussed later in this chapter, may have a choreic component.

Chorea may be limited to one side of the body (hemichorea). When the involuntary movements involve proximal limb muscles and are of wide range and flinging in nature, the condition is called hemiballismus (see further on under that heading). A cerebral infarction is the usual cause of both disorders.

The frequency of the various causes of chorea (Piccolo and colleagues) in perspective. Of consecutive neurologic admissions to two general hospitals, there were 23 cases of chorea, of which 5 were drug induced, 5 were AIDS related, and 6 were caused by stroke. Sydenham chorea and arteritis were each found in 1 case. In 4 cases, no cause could be determined, and 1 proved to be Huntington disease.

The precise anatomic basis of chorea is often uncertain or at least inconsistent between cases. Transient chorea or ballismus arises from infarctions in any part of the striatum, particularly in the caudate, on the side opposite to the movement. In Huntington chorea, there are obvious lesions in the caudate nucleus and putamen. Yet one often observes vascular lesions in these parts without chorea. The localization of lesions in Sydenham chorea and other choreic diseases has not been determined beyond a generalized disturbance in the striatum, which is evident in some imaging studies. It is of interest that in instances of chorea related to acute metabolic disturbances, there are sometimes small infarctions in the basal ganglia or metabolic changes in the lenticular nucleus, as shown by imaging studies. One suspects from their close clinical similarity that chorea and hemiballismus (see below) relate to disorders of the same system of neurons.

Athetosis

This term stems from a Greek word meaning "unfixed" or "changeable." The condition is characterized by an inability to sustain the fingers and toes, tongue, or any other part of the body in one position. The maintained posture is interrupted by relatively slow, writhing or twisting, sinuous, purposeless movements that tend to flow into one another. As a rule, the abnormal movements are most pronounced in the digits and hands, face, tongue, and throat, but no group of muscles is spared. One can detect as the basic patterns of movement an alternation between extension–pronation and flexion–supination of the arm and between flexion and extension of the fingers, the flexed and adducted thumb being trapped by the flexed fingers as the hand closes. Other characteristic movements are eversion–inversion of the foot, retraction and pursing of the lips, twisting of the neck and torso, and alternate wrinkling and relaxation of the forehead or forceful opening and closing of the eyelids. The movements appear as slower than those of chorea, but all gradations between the two are seen; in some cases, it is impossible to distinguish between them, hence the term *choreoathetosis*. An apt description could be of a moving dystonia (see below). Discrete voluntary movements of the hand are executed more slowly than normal and attempts to perform them may result in a co-contraction of antagonistic muscles and a spread (overflow) of contraction to muscles not normally required in the movement. The overflow appears related to a failure of the striatum to suppress the activity of unwanted muscle groups. Some forms of athetosis occur only during the performance of projected movement (intention or action athetosis).

Athetosis may affect all four limbs or may be unilateral, especially in children who have suffered a hemiplegia early in life (posthemiplegic athetosis). Many athetotic patients with destructive focal brain lesions exhibit variable degrees of rigidity and motor deficit as a result of associated corticospinal tract disease; these may account for the slower quality in these patients of athetosis compared to chorea. In other patients with generalized choreoathetosis, as pointed out above, the limbs may be intermittently hypotonic.

The combination of athetosis and chorea of all four limbs is a cardinal feature of Huntington disease and of a state known as double athetosis, a form of cerebral palsy that begins in childhood. Athetosis appearing in the first years of life is usually the result of a congenital or postnatal condition such as hypoxia or, now rarely, kernicterus. Postmortem examinations in some of the cases have disclosed a unique pathologic change, status marmoratus, of probable hypoxic etiology in the striatum (see Chap. 37). In cases, of probable kernicteric (hyperbilirubinemic) etiology, there is a loss of nerve cells and myelinated fibers—a status dysmyelinatus—in the same regions. In adults, athetosis may occur as an episodic or persistent disorder in hepatic encephalopathy, as a manifestation of chronic intoxication with phenothiazines or haloperidol, and as a feature of certain degenerative diseases, most notably Huntington chorea but also Wilson disease, Leigh disease, and other mitochondrial disease variants; less frequently athetosis may be seen with Niemann-Pick (type C) disease, Kufs disease, neuroacanthocytosis, and ataxia telangiectasia, all of which are described in later chapters. It may also occur as an effect of excessive L-dopa in the treatment of Parkinson disease, in which case it appears to be caused by a decrease in the activity of the subthalamic nucleus and the internal segment of the globus pallidus (Mitchell et al). Athetosis, usually in combination with chorea, may occur rarely in patients with AIDS and in those taking antiepileptic drugs. Localized forms of athetosis may occasionally follow vascular lesions of the lenticular nucleus or thalamus, as in the cases described by Dooling and Adams.

Ballismus

This term designates uncontrollable, large amplitude, poorly patterned flinging movement of an entire limb. It may be conceptualized as big chorea and is closely related to athetosis, indicated by the frequent coexistence of these movement abnormalities and the tendency for ballismus to blend into a less-obtrusive choreoathetosis of the distal parts of the affected limb. Ballistic movements are usually

unilateral (hemiballismus) and the result of an acute lesion of or near the contralateral subthalamic nucleus or immediately surrounding structures (infarction or hemorrhage, less often a demyelinative or other lesion). Rarely, a transitory form is linked to a subdural hematoma or thalamic or parietal lesion. The flinging movements may be almost continuous or intermittent, occurring several times a minute, and of such dramatic appearance that it is not unusual for them to be regarded as functional in nature.

Bilateral ballismus is infrequent and usually asymmetrical; here a metabolic disturbance, particularly nonketotic hyperosmolar coma, is the usual cause. In combination with choreoathetosis, a paraneoplastic process is another rare cause. When ballismus persists for weeks on end, as it often did before effective treatment became available, the continuous forceful movements resulted in exhaustion, weight loss, and even death. In most cases, medication with haloperidol or phenothiazine suppresses the violent movements. In extreme cases, stereotactic lesions or implanted stimulating electrodes placed in the ventrolateral thalamus and zona incerta have proved effective (Krauss and Mundinger).

Dystonia

Dystonia is an unnatural spasmodic movement or posture that puts the limb in a twisted position. It is often patterned, repetitive or tremulous and can be initiated or worsened by attempted movement. There is unwanted overflow contraction of adjacent muscles and a common feature is involuntary co-contraction of agonist and antagonist muscles. Dystonia may take the form of an overextension or overflexion of the hand, inversion of the foot, lateral flexion or retroflexion of the head, torsion of the spine with arching and twisting of the back, forceful closure of the eyes, or a fixed grimace (Fig. 4-5).

Dystonia, like athetosis, may vary considerably in severity and may show striking fluctuations in individual patients. Dystonia may be limited to the facial, cervical, or trunk muscles or to those of one limb, and it may cease when the body is in repose and during sleep. Severe instances result in grotesque movements and distorted positions of the body; sometimes the whole musculature seems to be thrown into spasm by an effort to move an arm or to speak. In its early stages, it may be interpreted as an

Figure 4-5. *A*. Generalized dystonia caused by exposure to neuroleptic drugs. (Reproduced with permission from Ray L. Watts, David G. Standaert, José A. Obeso. *Movement Disorders*, 3rd edition. Copyright © 2012 by The McGraw-Hill Companies, Inc. All rights reserved.)

annoying mannerism or functional in nature. Only later, in the face of persisting postural abnormality, and the emerging character of other aspects of an underlying illness, is the correct diagnosis made.

Causes of generalized dystonia (see Table 4-5) Generalized dystonia is seen in its most pronounced form as an uncommon heritable disease, dystonia musculorum deformans, which is associated with a mutations in the DYT gene. It was in relation to this disease that Oppenheim and Vogt in 1911 introduced the term dystonia. Dystonia also occurs as a manifestation of many other diseases, each of which is characteristic of a certain age group. These include the aforementioned double athetosis caused by hypoxic damage to the fetal or neonatal brain (a form of cerebral palsy), kernicterus, pantothenate kinase-associated neurodegeneration (formerly Hallervorden-Spatz disease), Huntington disease, Wilson disease, lysosomal storage diseases, striatopallidodentatal calcification (Fahr disease, sometimes caused by hypoparathyroidism), certain forms of thyroid disease, and exposure to neuroleptic drugs, as discussed below.

A distinct subset of patients with an idiopathic dystonia (Segawa disease, described also by Nygaard et al and discussed in Chap. 38) responds to extremely small doses of L-dopa. This disorder is familial, usually autosomal dominant, and the dystonia-athetosis may be combined with elements of parkinsonism. Marked diurnal fluctuation of symptoms is characteristic, with the movement disorder worsening as the day wears on and improving with sleep. Another rare hereditary dystonia, termed rapid onset dystonia-parkinsonism, has its onset in adolescence or early adulthood and is of interest because of the rapid evolution, at times within an hour but more often over days, of severe dystonic spasms, dysarthria, dysphagia, and postural instability with bradykinesia (Dobyns et al). Dystonia is a component of several obscure multisystem degenerations that may include diverse features such as optic neuropathy and striatal necrosis.

A frequent cause of acute generalized dystonic reactions, more so in the past, had been from exposure to the class of neuroleptic drugs—phenothiazines, butyrophenones, or metoclopramide—and even with the newer agents such as olanzapine, which have the advantage of producing these side effects less frequently. A characteristic, almost diagnostic, example of the acute drug-induced dystonias consists of retrocollis (forced extension of the neck), arching of the back, internal rotation of the arms, and extension of the elbows and wrists—together simulating opisthotonos. These reactions respond relatively predictably to diphenhydramine or benztropine. L-dopa, calcium channel blockers, and several antiepileptic drugs and anxiolytics are among a long list of other medications that may on occasion induce dystonia, as listed in Table 4-5. The acute dystonic drug reactions are idiosyncratic and probably now as common as the tardive dyskinesias that had in the past followed long-standing use of a medication.

In the literature, there have been reported cases of limb injury and subsequent reflex sympathetic dystrophy (see Chap. 10) that were accompanied by movement disorders, particularly dystonia. The nature and mechanism of this association are uncertain. Finally, a peculiar and dramatic spasm of a limb or the entire body may be seen in patients with multiple sclerosis. The movements have aspects of dystonia and may be provoked by hyperventilation but they may not be, strictly speaking, dystonic. They are most likely to occur in patients with large demyelinative lesions of the cervical spinal cord.

Restricted or fragmentary forms of dystonia are the types most commonly encountered in clinical practice. Characteristically the spasms involve only the orbicularis oculi and face or mandibular muscles (blepharospasm or omandibular dystonia), tongue, cervical muscles (torticollis), hand (writer's cramp), or foot. There may be an associated tremor, or tremor may be the only manifestation of an early dystonia. These are described further on and in Chap. 38.

Hemidystonia represents an unusual form of acquired movement that is rarely pure. In an analysis of 33 cases and 157 previously published ones (Chuang and colleagues) stroke, mainly in the contralateral putamen, was most often responsible. Traumatic and perinatal damage accounted for several cases and a large proportion had no lesions found by imaging studies. In traumatic cases, there was a delay of several years between the injury

Table 4-5

DISEASES ASSOCIATED WITH DYSTONIA

Inherited disorders
Huntington chorea
Dystonia musculorum deformans (recessive and autosomal-dominant forms)
Juvenile dystonia—Parkinson syndrome (L-dopa–responsive)
Dystonia with other heredodegenerative disorders (neural deafness, striatal necrosis with optic nerve affection, paraplegic amyotrophy)
Rapid-onset dystonia-parkinsonism
Focal dystonias and occupational spasms, some of which are allied with hereditary torsion dystonia
Parkinson disease (occasional but frequent as an effect of L-Dopa)
Progressive supranuclear palsy
Drug-induced dystonias
Acute and chronic phenothiazine, haloperidol, metoclopramide, and other neuroleptic intoxications
L-dopa excess in Parkinson disease
Antiepileptic, anxiolytic, and other drugs
Symptomatic (secondary) dystonias
Wilson disease
Double athetosis (cerebral palsy) caused by cerebral hypoxia
Kernicterus
Acquired hepatocerebral degeneration
HIV infection and related focal brain lesions
Lysosomal storage diseases
Multiple sclerosis with cord lesion
Paraneoplastic striatopallidodentatal calcification (Fahr disease)
Toxic necrosis of lenticular nuclei (e.g., methanol) can be delayed
Dystonia with reflex sympathetic dystrophy
Idiopathic focal dystonias
Spasmodic torticollis
Blepharospasm
Hemifacial spasm
Oromandibular dystonia
Spasmodic dysphonia
Writer's cramp and other occupational spasms

and the start of the movements; these authors also commented on the resistance of this syndrome to drug treatment. Certain dystonias are associated with very specific motor programs, often ones that are frequently repeated. One example are the occupational dystonias, which can threaten the performing career of talented artists (pianists, dancers, reed players, etc).

Treatment

In the focal dystonias, the most effective treatment has proved to be the periodic injection of botulinum toxin into the affected muscles as discussed earlier and emphasized later in the chapter. The acute dystonic drug reactions are treated as noted above. Numerous drugs have been used to treat idiopathic chronic generalized dystonia, with a notable lack of success. Fahn reported beneficial effects (more so in children than in adults) with the anticholinergic agents, trihexyphenidyl, benztropine, and ethopropazine given in large doses—which are achieved by increasing the medications very gradually.

The drug-induced tardive dyskinesias require specialized treatment, as described in later chapters and further on. Deutetrabenazine and reserpine, centrally active monoamine-depleting agents, may be effective. The offending drug may be at first stopped in patients who have not already ceased taking it, but this often leads to worsening of the movements. Reinstitution of the offending drug or high doses of anticholinergic agents is then sometimes necessary but is only partially effective and requires that the patient tolerate the other effects of the medication such as sedation and parkinsonism. The problem has become less frequent with the introduction of the newer classes of antipsychosis drugs.

Stereotactic surgery on the pallidum and ventrolateral thalamus, a treatment introduced by Cooper in the middle of the last century, had generally positive but unpredictable results in generalized dystonia. In recent years there has been a renewed interest in a modern derivative of this form of treatment, deep brain stimulation. In a controlled trial, the effectiveness of this approach has been demonstrated by stimulating the posteroventral globus pallidus bilaterally (Vidailhet and colleagues). Patients had an average improvement of 50 percent on most scores of dystonic movement over 1 year. Increasingly, this is the method resorted to in cases of severe generalized dystonia.

Paroxysmal Choreoathetosis and Dystonia

Under the names paroxysmal kinesigenic dyskinesia, familial paroxysmal choreoathetosis, and periodic dystonia, among others, are several uncommon sporadic or familial disorders characterized by paroxysmal attacks of choreoathetotic movements or dystonic spasms of the limbs and trunk. Both children and young adults are affected.

There are three main forms of familial paroxysmal choreoathetosis and dystonia. Various genes and mutations have been implicated, some of which involve ion channels. One clinical type, which has an autosomal dominant (less often recessive) pattern of inheritance and a tendency to affect males, begins in adolescence or earlier and abates later in life. It is characterized by numerous brief (several minutes) attacks of dystonia or choreoathetosis provoked by sudden movement, startle, or hyperventilation—hence the name paroxysmal kinesigenic choreoathetosis. There may be many dozens of attacks per day or occasional ones. This disorder responds well to antiepileptic medication, particularly to phenytoin and carbamazepine. Mutations of PRRT2, the proline-rich transmembrane protein, have been identified as the cause in some families and link the disease to a variety of infantile convulsions as summarized by Gardiner and colleagues.

In a second nonkinesigenic type, such as described by Mount and Reback and subsequently by Lance and by Plant et al, the attacks take the form of persistent (5 min to 4 h) dystonic spasms and reportedly have been precipitated by the ingestion of alcohol or coffee or by fatigue but not by movement. The attacks may be predominantly one-sided or bilateral. Attacks may occur every several days or be separated by years. A favorable response to benzodiazepines (clonazepam) has been reported, even when the drug is given on alternate days (Kurlan and Shoulson). This form of the disease is inherited as an autosomal dominant trait; a few families have displayed diplopia and spasticity and others have shown a familial tendency to infantile convulsions. There are several variations of this nonkinesigenic illness, each with a different implicated gene mutation.

A third type, formerly thought to be a variant of the Mount-Reback type mentioned above, is precipitated by prolonged exercise. In addition to a response to benzodiazepines, it has the unique characteristic of improving with acetazolamide.

More common than these familial dyskinesias are sporadic cases secondary to focal brain lesions such as stroke, trauma, encephalitis, perinatal anoxia, multiple sclerosis, HIV encephalitis or as a result of associated toxoplasmosis, lymphoma; and generalized metabolic disorders such as hypoparathyroidism, thyrotoxicosis, and particularly, nonketotic hyperosmolarity. Demirkirian and Jankovic classified the acquired paroxysmal dyskinesias according to the duration of each attack and the event or activity that precipitates the abnormal movements (kinesigenic, nonkinesigenic, exertional, or hypnagogic). As with the familial cases, the acquired kinesigenically induced movements often improve with antiepileptic drugs; some cases respond particularly to clonazepam.

The most severe instances of paroxysmal dyskinesia in our experience have been related to multiple sclerosis previously mentioned ("tetanoid spasms"), and from the secondary brain lesions of HIV. These patients are relatively unresponsive to medications. Also, it should be recalled that oculogyric crises and other nonepileptic spasms (Chap. 13) have occurred episodically in patients with postencephalitic parkinsonism; these phenomena are now rarely seen with acute and chronic phenothiazine intoxication and with Niemann-Pick disease (type C).

TREMOR

Tremor may be defined as involuntary rhythmic oscillatory movement produced by alternating or irregularly synchronous contractions of reciprocally innervated muscles.

Table 4-6

MAIN TYPES OF TREMOR

TYPE OF TREMOR	FREQUENCY, HZ	PREDOMINANT LOCATION	ENHANCING AGENTS	ATTENUATING AGENTS
Physiologic (enhanced)	8–13	Hands	Epinephrine, β-adrenergics	Alcohol, β-adrenergic antagonists
Parkinson (rest)	3–5	Hands and forearms, fingers, feet, lips, tongue	Emotional stress	L-dopa, anticholinergics
Cerebellar (intention, ataxic, "rubral")	2–4	Limbs, trunk, head	Emotional stress	—
Postural, or action	5–8	Hands	Anxiety, fright, β-adrenergics, alcohol withdrawal, xanthines, lithium, exercise, fatigue	β-adrenergic antagonists in some cases
Essential (familial, senile)	4–8	Hands, head, vocal cords	Same as above	Alcohol, propranolol, primidone
Alternate beat	3.5–6	Hands, head	Same as above	Clonazepam, alcohol, β-adrenergic antagonists
Orthostatic	14–16, irregular	Legs	Quiet standing	Repose, walking, clonazepam, valproate
Tremor of neuropathy	4–7	Hands	—	—
Palatal tremor	1–2 (60–100/min)	Palate, sometimes facial, pharyngeal, proximal limb muscles	—	Clonazepam, valproate
Dystonic	Irregular	Concordant with focal dystonia	—	Local botulinum toxin, gestes

Its rhythmic quality distinguishes tremor from the other involuntary movements described earlier, and its oscillatory nature distinguishes it from myoclonus and asterixis. The many varieties of tremor can be considered in terms of their frequency, amplitude, location, and positional activation, and the enhancement or attenuation of the tremor by certain drugs. In some processes, such as Parkinson disease, more than one tremor may be displayed, and tremor may be a component of other movement disorders such as dystonia and cerebellar ataxia. The characteristics of the main tremors seen in practice are summarized in Table 4-6.

A normal, or physiologic, tremor is embedded in the motor system. The movement is so fine that it can barely be seen by the naked eye, and then only if the fingers are firmly outstretched; asking the patient to aim a laser pointer at a distant target will often expose the tremor. It is present in all contracting muscle groups and persists throughout the waking state and even in certain phases of sleep. It ranges in frequency between 8 and 13 Hz, the dominant rate being 10 Hz in adulthood and somewhat less in childhood and old age. Several hypotheses have been proposed to explain physiologic tremor, a traditional one being that it reflects the passive vibration of body tissues produced by mechanical activity of cardiac origin, but this cannot be the whole explanation. As Marsden has pointed out, several additional factors—such as spindle input, the unfused grouped firing rates of motor neurons, and the natural resonating frequencies and inertia of the muscles and other structures—are probably of greater importance. Certain abnormal tremors, namely, the metabolic varieties of postural or action tremor and at least one type of familial tremor, are considered by some to be variants or exaggerations of physiologic tremor—that is, "enhanced physiologic tremor," as discussed further on.

In patients with pathologic tremor of almost any type, there are recorded rhythmic burst discharges of unitary cellular activity in the nucleus intermedius ventralis of the thalamus (as well as in the medial pallidum and subthalamic nucleus) synchronous with the beat of the tremor (Narabayashi). Neurons that exhibit the synchronous bursts are arranged somatotopically and respond to kinesthetic impulses from the muscles and joints involved in the tremor but that is not to say that there is a causal relationship between this activity and the tremor. A stereotaxic lesion in this region of the thalamus abolishes the tremor. The effectiveness of a thalamic lesion may be a result of interruption of pallidothalamic and dentatothalamic projections or, more likely, of projections from the ventrolateral thalamus to the premotor cortex, as the impulses responsible for tremor are ultimately transmitted by the lateral corticospinal tract. Some of what is known about the physiology of specific tremors are noted in the following paragraphs.

Action Tremors

Action tremors are evident during the use of the affected body part, as opposed to tremor that is apparent in a position of rest or repose. Action tremors can be roughly divided into two categories: goal-directed action tremor of the ataxic type related to cerebellar disorders (discussed in Chap. 5) and postural tremors, which are either the enhanced physiologic variety or essential (genetic) tremor (Fig. 4-6). A postural tremor occurs with the limbs and trunk actively maintained in certain positions (such as holding the arms outstretched) and may persist throughout active movement. More particularly, the tremor is absent when the limbs are relaxed but becomes evident

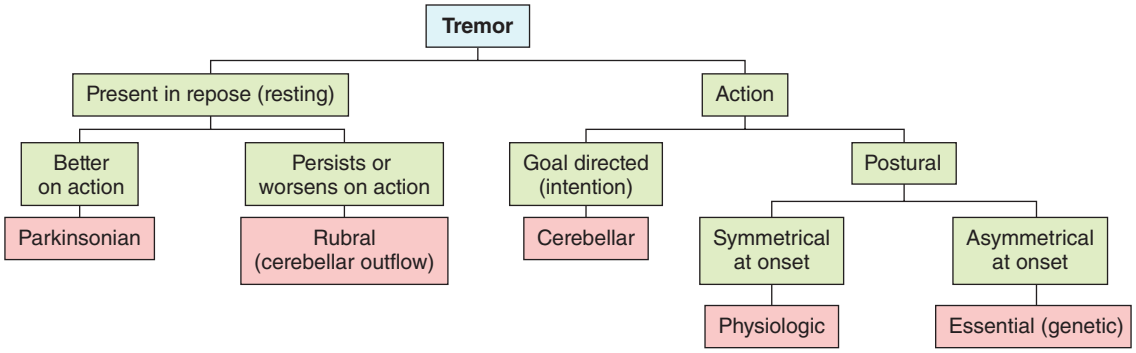

Figure 4-6. Tremor branch diagram.

when the muscles are activated. The tremor is accentuated as greater precision of movement is demanded, but it does not approach the degree of augmentation seen with cerebellar intention tremor. Most cases of action tremor are characterized by relatively rhythmic bursts of grouped motor neuron discharges that occur not quite synchronously in opposing muscle groups as shown in Fig. 4-7. Slight inequalities in the strength and timing of contraction of opposing muscle groups account for the tremor. In contrast, rest (parkinsonian) tremor is characterized by alternating activity in agonist and antagonist muscles.

Enhanced physiologic tremor The type of action tremor that seems merely to be an exaggeration of the above-described physiologic tremor, can be brought out in most normal persons. It has the same fast frequency as physiologic tremor (about 10 Hz; see Fig. 4-7*A*) but with greater amplitude. Such a tremor, best elicited by holding the arms outstretched with fingers spread apart, is characteristic of intense fright and anxiety (hyperadrenergic

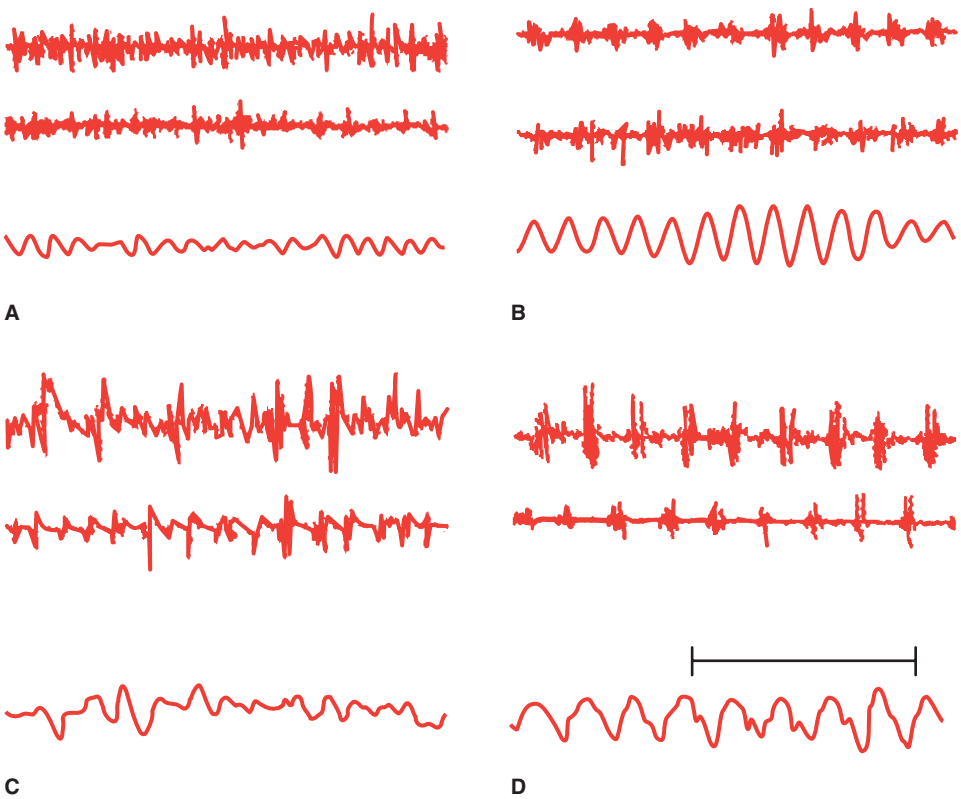

Figure 4-7. Types of tremor. In each, the lowest trace is an accelerometric recording from the outstretched hand; the upper two traces are surface EMG from the wrist extensor (upper) and flexor (middle) muscle groups. *A*. A physiologic tremor; there is no evidence of synchronization of EMG activity. *B*. Essential (familial) tremor; the movements are very regular and EMG bursts occur simultaneously in antagonistic muscle groups. *C*. Neuropathic tremor; movements are irregular and EMG bursts vary in timing between the two groups. *D*. Parkinsonian ("rest") tremor; EMG bursts alternate between antagonistic muscle groups. Calibration is 1 s. (Reproduced with permission from Dr. Robert R. Young, MD.)

states), certain metabolic disturbances (hyperthyroidism, hypercortisolism, hypoglycemia), pheochromocytoma, intense physical exertion, withdrawal from alcohol and other sedative drugs, and the toxic effects of several drugs—lithium, nicotinic acid, xanthines (coffee, tea, aminophylline), cocaine, methamphetamine, methylphenidate, other stimulant drugs, and corticosteroids. Young and colleagues have determined that the enhancement of physiologic tremor that occurs in metabolic and toxic states is not a function of the CNS but is instead a consequence of stimulation of muscular beta-adrenergic receptors by increased levels of circulating catecholamines.

A special type of postural action tremor, closely related to the enhanced physiologic tremor, occurs as the most prominent feature of the early stages of withdrawal from alcohol or other sedative (benzodiazepines, barbiturates) following a sustained period of use. Two tremors of slightly different frequency, one of which is indistinguishable from essential tremor have been described (LeFebvre-D'Amour and colleagues). Either of these may occur as the individual emerges from a relatively short period of intoxication ("morning shakes"). Many alcoholics, on recovery from the withdrawal state, exhibit a persistent tremor of essential (familial) type, described below. The mechanisms involved in alcohol withdrawal symptoms are discussed in Chap. 41, Disorders of the Nervous System Caused by Alcohol, Drugs, Toxins, and Chemical Agents.

Action tremors are seen in some other clinical settings. Many drugs can cause tremor either as direct or an idiosyncratic effect. At times it is difficult to determine if the drug is simply exaggerating a preexisting tremor, but most often, the tremor is only evident with the drug and ceases when the drug is withdrawn. The main examples are anticonvulsant medications, particularly valproate; bronchodilators and adrenergic drugs such as aminophylline, cocaine, and thyroxine; gastrointestinal drugs such as metoclopramide and cimetidine; psychiatric drugs, mainly lithium but also amitriptyline, the selective serotonin reuptake inhibitors, and haloperidol; and immunosuppressants such as tamoxifen, tacrolimus, cyclosporine, and interferon-alpha. A more complete discussion of drug-induced tremors can be found in the review by Morgan and Sethi. A coarse action tremor, sometimes combined with myoclonus, accompanies various types of meningoencephalitis (e.g., in the past, it was quite common with syphilitic general paresis) and certain intoxications (methyl bromide and bismuth).

Essential (Familial; Genetic) Tremor

This, the commonest type of tremor, is of lower frequency (4 to 8 Hz) than physiologic tremor and is unassociated with other neurologic changes; thus it is called "essential." It is usually at the lower end of this frequency range and of variable amplitude. Aside from its rate, the identifying feature is its appearance or enhancement with attempts to maintain a static limb posture or to produce a smooth trajectory of movement. Like many other tremors, essential tremor is worsened by emotion, exercise, and fatigue. One infrequent type of essential tremor is faster and of the same frequency (6 to 8 Hz) as enhanced physiologic tremor. Essential tremor may increase in severity to a point where the patient's handwriting becomes illegible and he cannot bring a spoon or glass to his lips without spilling its contents. Eventually, all tasks that require manual dexterity become difficult or impossible. The pathophysiology of this tremor and its treatment are discussed further on.

Typical essential tremor occurs in several members of a family, for which reason it has been called familial, genetic, or hereditary essential tremor. Inheritance is in an autosomal dominant pattern with high penetrance. The idiopathic and familial types cannot be distinguished based on their physiologic and pharmacologic properties and probably should not be considered as separate entities. This condition had been referred to as "benign essential tremor," but this is hardly so in many patients in whom it worsens with age and interferes with normal activities.

Essential tremor most often makes its appearance late in the second decade, but it may begin in childhood and then persist. A second peak of increased incidence occurs in adults older than 35 years of age. It is a relatively common disorder, with an estimated prevalence of 415 per 100,000 persons older than the age of 40 years (Haerer et al). As described by Elble, the tremor frequency diminishes slightly with age while its amplitude increases. The tremor practically always begins in the hands and may be relatively symmetrical of it may be asymmetrical, even unilateral, at the time it is first recognized. However, with careful analysis of the history, it often appears first in the dominant hand and an emerging concept has been that it is more often asymmetric than stated in older descriptions. It is also possible, of course, that the patient does not find a mild bilateral tremor troublesome until it affects activities that are dependent on the dominant hand. However, a severe isolated arm or leg tremor, or a predominant finger tremor, should still suggest another disease (Parkinson disease or focal dystonia, as described further on).

The tremor may remain limited to the upper limbs or to a side-to-side or nodding movement of the head; tremor of the chin may be added or may occur independently. In certain cases of essential tremor, there is additional involvement of the jaw, lips, tongue, and larynx, the latter imparting a severe quaver to the voice (voice tremor). Infrequently, the tremor of the head or voice precedes that of the hands. The head tremor is also postural in nature and disappears when the head is supported. It has also been noted that the limb and head tremors tend to be muted when the patient walks, in contrast to most parkinsonian tremors. In some patients whose tremor remained isolated to the head for a decade or more, there has been little if any progression to the arms and almost no increase of the amplitude of movement.

The lower limbs are usually spared or only minimally affected. In the large series of familial tremor cases by Bain and colleagues, solitary jaw or head tremor was not found but we have observed isolated head tremor, as noted. Most patients with essential tremor will have identified the amplifying effects of anxiety and the ameliorating effects of alcohol on their tremor. The tremor may become greatly exaggerated during emergence from anesthesia in a few patients.

Electromyographic studies reveal that the tremor is generated by rhythmic and almost simultaneous bursts

of activity in pairs of agonist and antagonist muscles (Fig. 4-7*B*). Less often, especially in the tremors at the lower range of frequency, the activity in agonist and antagonist muscles alternates ("alternate beat tremor"), a feature more characteristic of Parkinson disease, which the tremor then superficially resembles (see below). Tremor of either pattern may be disabling, but the less common, slower, alternate-beat tremor tends to be of higher amplitude, is more of a handicap, and is usually more resistant to treatment.

Pathophysiology Only a few cases of essential tremor have been examined postmortem, and these have disclosed no consistent lesion to which the tremor could indisputably be attributed (Herskovits and Blackwood; Cerosimo and Koller). A singular case of a 90-year-old woman demonstrated more extensive cerebellar cortical and dentate nucleus cell loss and reactive changes than had been previously reported (Louis and colleagues).

The question of the existence and locus of a generator for essential tremor as opposed to the unbalancing of a feedback loop system, is unresolved. As indicated by McAuley, various studies demonstrate that rhythmic tremor activity is not primarily generated in the cortex. Based on electrophysiologic recordings in patients, two likely origins of oscillatory activity are the olivocerebellar circuits and the thalamus. Whether a specific structure possesses intrinsic rhythmicity or, as currently favored, the tremor is an expression of reciprocal oscillations in circuits of the dentato–brainstem–cerebellar or thalamic–tegmental systems is not at all clear. Studies of blood flow in patients with essential tremor affirm that the cerebellum is rhythmically activated (Colebatch and coworkers); on this basis, it has been argue that there is a release of an oscillatory mechanism in the olivocerebellar pathway. Dubinsky and Hallett demonstrated that the inferior olives also become hypermetabolic when essential tremor is activated, but this has been questioned by Wills and colleagues who recorded increased blood flow in the cerebellum and red nuclei, but not in the olive. These proposed mechanisms of tremor have been extensively reviewed (Elble and also Hallett).

Although this disorder is familial, almost always autosomal dominant, a single genetic site has not yet been established; several candidate polymorphisms have been tentatively proposed.

Treatment A curious fact about essential tremor of the typical (non–alternate-beat) type is that it can be suppressed by a small amount of alcohol in more than 75 percent of patients; but once the effects of the alcohol have worn off, the tremor returns and may even worsen for a time. Of more therapeutic interest, essential tremor is inhibited by the beta-adrenergic antagonist propranolol (between 80 and 200 mg per day in divided doses or as a sustained-release preparation) taken orally, usually remaining effective over a long period of time. Often it takes several days or weeks for the therapeutic effect to be evident. The benefit is variable and often incomplete; most studies indicate that 50 to 70 percent of patients have some symptomatic relief but may complain of side effects such as fatigue, erectile dysfunction, and bronchospasm (Young and colleagues). Several but not all other beta-blocking drugs are similarly effective: metoprolol and nadolol, which may be better tolerated than propranolol, are the ones most extensively studied, but they have yielded less consistent results compared to propranolol. The capacity of the beta-blocking drug to cross the blood–brain barrier may correlate with effectiveness. The relative merits of different drugs in this class are discussed by Louis and by Koller et al.

The mechanism and site of action of beta-blocking agents are not known with certainty. It is blockade of the beta-2 adrenergic receptor that is most closely aligned with reduction of the tremor. Young and associates have shown that neither propranolol nor ethanol, when injected intraarterially into a limb, decreases the amplitude of essential tremor. These findings, and the delay in action of medications, suggest that their therapeutic effect is due less to blockade of the peripheral beta-adrenergic receptors than to their action on structures within the CNS. This contrasts with the earlier mentioned muscle receptor-mediated effect of adrenergic compounds in physiologic tremor. It is possible that ambiguity regarding the action of beta-blocking drugs is the result of their effect on physiological tremor that is superimposed on essential tremor.

The barbiturate drug primidone has also been effective in controlling essential tremor and may be tried in patients for whom beta-blocking medications and not effective or tolerated. The side effects may be drowsiness, nausea, and slight ataxia. Treatment should be initiated at 25 mg twice or three times per day and increased slowly in order to minimize these effects. Gabapentin, topiramate (Connor), mirtazapine, a variety of benzodiazepines, and a large number of other drugs have been used generally with limited success and should be considered third-line therapies; these alternatives are discussed by Louis. Amantadine also has a modest effect on tremor and may be used as an adjunct.

The alternate-beat, slow, high-amplitude, kinetic-predominant type of essential tremor is more difficult to suppress but has reportedly responded to clonazepam (Biary and Koller). Alcohol and primidone have less effect than they do in typical essential tremor. Indeed, the tremor has often been resistant to most attempts at suppression, for which reason surgical approaches are now being used (see further on).

Injections of botulinum toxin into a portion of a limb can reduce the severity of essential tremor locally, but the accompanying weakness of arm and hand muscles often proves unacceptable to the patient. The same medication injected into the vocal cords can suppress severe voice tremor (Adler et al as well as by others), but caution must be exercised to avoid paralyzing the cords. Doses as low as 1 U of toxin injected into each cord may be effective, with a latency of several days. The long-term repeated use of this treatment has not been adequately studied for essential-type limb or voice tremor.

In resistant cases of essential tremor of the fast or slow variety, stimulation by electrodes implanted or ablative lesions in the ventral medial nucleus of the thalamus or the internal segment of the globus pallidus (of the same type used to treat Parkinson disease) has produced a response over many years; (Sydow and colleagues). Lesions produced by focused ultrasound placed in similar targets particularly

the ventral intermediate thalamic nucleus have been quite effective (Elias et al).

Tremor of Polyneuropathy

Adams and coworkers described a disabling action tremor in patients with chronic demyelinating and paraproteinemic polyneuropathies. It is a particularly prominent feature of the polyneuropathy caused by immunoglobulin M (IgM) antibodies to myelin-associated glycoprotein (MAG). The movements simulate a coarse essential, or ataxic, tremor and typically worsen if the patient is asked to hold his finger near a target. The EMG pattern is more irregular than that in essential (familial) tremor (Fig. 4-7*C*). Pedersen and colleagues have found it to vary greatly in amplitude with considerable side-to-side oscillation, which is induced by co-contracting muscle activity; they also found little suppression of the tremor with loading of the limb, unlike most other organic tremors. It is hypothesized that there is a disturbance of muscle spindle afferents.

Some cases of acute or chronic inflammatory neuropathy or ganglionopathy may be marked by a similar and prominent ataxic tremor and a faster action tremor. A special type of Guillain-Barré syndrome (Fisher variant) is characterized by a tremor that is indistinguishable from the ataxic type but probably has a peripheral basis. Also, the inherited disease, peroneal muscular atrophy (Charcot-Marie-Tooth disease), may be associated with tremor of the essential type but the two may be coincident rather than directly related; this combination of symptoms was the basis on which Roussy and Levy incorrectly set it apart as a distinct disease. Chap. 43 discusses these polyneuropathies.

Parkinsonian (Repose, Rest) Tremor

This is a coarse, rhythmic tremor with a frequency of 3 to 5 Hz, characterized by bursts of activity that alternate between opposing muscle groups. The tremor is most often localized in one or both hands and forearms and less frequently in the feet, jaw, lips, or tongue (Fig. 4-7*D*). It occurs when the limb is in an attitude of repose and is suppressed or diminished by willed movement, at least momentarily, only to reassert itself once the limb assumes a new position. Even though it is termed a "resting" tremor, maintaining the arm in an attitude of repose requires a certain degree of muscular contraction, albeit slight. If the tremulous hand is completely relaxed, as it is when the arm is fully supported at the wrist and elbow, the tremor usually disappears. It is difficult, however, for the parkinsonian patient to relax and instead, it is typical to maintain a state of slight tonic contraction of the trunk and proximal muscles.

Parkinsonian tremor is "alternating" in the sense that it takes the form of flexion–extension or abduction–adduction of the fingers or the hand; pronation–supination of the hand and forearm is also a common presentation. Flexion–extension of the fingers in combination with adduction–abduction of the thumb yields the characteristic "pill-rolling" tremor of Parkinson disease. The tremor continues and may worsen while the patient walks, unlike essential tremor; indeed, it may first become apparent to the patient during walking. When the legs are affected, the tremor takes the form of a flexion–extension movement of the foot, sometimes the knee. In the jaw and lips, it is seen as up-and-down and pursing movements, respectively. The eyelids, if they are closed lightly, tend to flutter rhythmically (blepharoclonus), and the tongue, when protruded, may move in and out of the mouth at about the same tempo as the tremor elsewhere.

The cogwheel effect is a ratchet-like interruption perceived by the examiner on passive movement of an extremity (the Negro sign) as mentioned earlier. It is said by many authors to be no more than a palpable tremor superimposed on rigidity and as such, is not specific for Parkinson disease although it is most often recognized in that condition. This explanation is called into question by the numerous cases in which Parkinson patients display minimal or no resting tremor but nonetheless have the cogwheel phenomenon. Cogwheeling can be brought out by having the patient engage the opposite limb, such as tracing circles in the air; called the Froment sign, this finding was originally described in essential tremor.

The parkinsonian tremor frequency is surprisingly constant over long periods, but the amplitude is variable. Emotional stress augments the amplitude and may add to the effects of an enhanced physiologic or essential tremor. With advance of the disease, increasing rigidity of the limbs obscures or reduces it. It is curious how little the tremor interferes with voluntary movement; for example, it is possible for a tremulous patient to raise a full glass of water to his lips and drain its contents without spilling a drop; this is not always the case with "benign" essential tremor, as already emphasized.

Almost always in Parkinson disease, the tremor is asymmetric and at the outset may be entirely unilateral. There is not a close correspondence between the degree of tremor and the degree of rigidity or akinesia. A bilateral parkinsonian type of tremor may also be seen in elderly persons without akinesia, rigidity, or mask-like facies. In some of these patients, the tremor is followed years later by the other manifestations of Parkinson disease, but in others it is not, remaining unchanged or progressing very slowly, unaffected by anti-Parkinson drugs. This entity probably equates with the earlier mentioned alternate beat type of essential tremor. Patients with Wilson disease or an acquired form of hepatocerebral degeneration may also show a tremor of parkinsonian type, usually mixed with ataxic tremor and other extrapyramidal motor abnormalities. An alternating tremor may be seen in toxin and drug-induced parkinsonism but it is relatively symmetric and tends not to be a prominent feature. The tremor of postencephalitic parkinsonism (which is now virtually extinct) often had greater amplitude than typical parkinsonian tremor and involved proximal muscles.

Parkinsonian tremor is suppressed to some extent by the anticholinergic drugs benztropine and trihexyphenidyl; it is also suppressed less consistently but sometimes impressively by L-dopa and dopaminergic agonist drugs. Parkinsonian tremor is often associated with an additional tremor of faster frequency; the latter is of essential type and responds better to beta-blocking drugs than to anti-Parkinson medications. Stereotactic lesions or electrical

stimulation in the basal ventrolateral nucleus of the thalamus diminishes or abolishes tremor contralaterally; other stimulation sites such as the internal segment of the globus pallidus and the subthalamic nucleus are also effective but possibly to a lesser degree. Chap. 38 discusses the treatment of Parkinson disease in greater detail.

Pathophysiology The anatomic basis of parkinsonian tremor is not known. In Parkinson disease, the visible lesions predominate in the substantia nigra, and this was true also of the postencephalitic form of the disease. In animals, however, experimental lesions confined to the substantia nigra or striatopallidum do not result in tremor. Moreover, not all patients with lesions of the substantia nigra have tremor; in some, there is only bradykinesia and rigidity. In a group of patients poisoned with the toxin MPTP, a meperidine analog that destroys the neurons of the substantia nigra pars compacta, only half developed a tremor, which had more of the characteristics of a proximal action or postural tremor than of a rest tremor as discussed by Burns and colleagues. In all likelihood, these inconsistencies reflect the complex influence of dopamine on a number of basal ganglionic structures.

Ward and others have produced a Parkinson-like tremor in monkeys by placing a lesion in the ventromedial tegmentum of the midbrain, just caudal to the red nucleus and dorsal to the substantia nigra. He postulated that interruption of the descending fibers at this site liberates an oscillating mechanism in the lower brainstem; this presumably involves limb innervation via the reticulospinal pathway. Alternative possibilities are that the lesion in the ventromedial tegmentum interrupts the brachium conjunctivum, a tegmental–thalamic projection, or the descending limb of the superior cerebellar peduncle, which functions as a link in a dentatoreticular–cerebellar feedback mechanism (see Fig. 5-3). The differential effect of drugs on tremor and bradykinesia suggests that they must have separate mechanisms.

Intention (Ataxic, Cerebellar, Goal-Directed Action) Tremor

As will be discussed in Chap. 5, the word intention is ambiguous in this context because the tremor itself is not intentional and occurs not when the patient intends to make a movement but only during the most demanding phases of active performance. In this sense, it is a kinetic or action tremor, but the latter term has connotations of the essential tremor to neurologists, as described earlier. The term ataxic is a suitable substitute for intention because this tremor is always combined with cerebellar ataxia and adds to it. Its salient feature is that it requires for its full expression the performance of an exacting, precise, projected movement. The tremor is absent both when the limbs are inactive and during the first part of a voluntary movement, but as the action continues and fine adjustments of the movement are demanded (e.g., in touching the tip of the nose or the examiner's finger), an irregular interruption of forward progression appears. These side-to-side oscillations are rhythmic and may continue for several beats after the target has been reached. Unlike essential and parkinsonian tremors, the oscillations occur in more than one plane but are mainly horizontal and perpendicular to the trajectory of movement. The tremor and ataxia may seriously interfere with the patient's performance of skilled acts. In some patients, there is a rhythmic oscillation of the head on the trunk (titubation), or of the trunk itself, at approximately the same rate. As already indicated, this type of tremor points to disease of the cerebellum or its outflow connections, but certain peripheral nerve diseases may simulate it.

Ataxic tremor has been produced in monkeys by inactivating the deep cerebellar nuclei or by sectioning the superior cerebellar peduncle or the brachium conjunctivum below its decussation. A lesion of the nucleus interpositus or dentate nucleus causes an ipsilateral tremor of ataxic type, as one might expect, associated with other manifestations of cerebellar ataxia. In addition, such a lesion gives rise to a "simple tremor," which is the term that Carpenter applied to a "resting" or parkinsonian tremor. He found that the latter was most prominent during the early postoperative period and was less enduring than ataxic tremor. Nevertheless, the concurrence of the two types of tremor and the fact that both can be abolished by ablation of the contralateral ventrolateral thalamic nucleus suggest that they have related neural mechanisms, at least in monkeys.

There is another, higher amplitude tremor associated with cerebellar ataxia, in which every movement, even lifting the arm slightly or maintaining a static posture with the arms held out, results in a wide-ranging, rhythmic 2- to 5-Hz "wing-beating" movement. This tremor can be of enough force to throw the patient off balance. In such cases, the lesion is usually in the midbrain, involving the rostral projections of the dentatorubrothalamic fibers and the medial part of the ventral tegmental reticular nucleus. Because of the location of the lesion in the region of the red nucleus, Holmes originally called this a rubral tremor. However, experimental evidence in monkeys indicates that the tremor is produced not by a lesion of the red nucleus per se but by interruption of fibers that traverse this nucleus—that is, the cerebellar efferent fibers that form the superior cerebellar peduncle (Carpenter). This type of tremor is seen most often in patients with multiple sclerosis or Wilson disease, occasionally with vascular and other lesions of the tegmentum of the midbrain and subthalamus, and rarely as an effect of antipsychosis medications. Beta-adrenergic blocking agents, anticholinergic drugs, and L-dopa have a little therapeutic effect. It is abolished by a surgical lesion in the opposite ventrolateral nucleus of the thalamus. Thalamic stimulation may be particularly helpful in severe cases that are the result of demyelinating lesions in the cerebellar peduncles.

Geniospasm

This is a strongly familial episodic tremor disorder of the chin and lower lip that begins in childhood and may worsen with age. Psychological stress and concentration are known to precipitate the movements, which are described by Danek as "trembling." Rare instances involve other facial muscles. The disorder must be distinguished from a similar tremor of the chin that is part of essential tremor, facial myokymia or fasciculations, and palatal tremor. Geniospasm results from a mutation on chromosome 9.

Primary Orthostatic Tremor

This is a rare but striking tremor isolated to the legs that is remarkable by its occurrence only during quiet standing and its cessation almost immediately on walking. It is difficult to classify and more relevant to disorders of gait than it is to tremors of other types. The frequency of the tremor has been recorded as approximately 14 to 16 Hz, making it difficult to observe and more easily palpable. An important accompanying feature is the sensation of severe imbalance, which causes the patient to assume a widened stance while standing; these patients are unable to walk a straight line (tandem gait). Many have observed prominent tonic contraction of the legs during standing, seemingly to overcome imbalance (see Heilman; Thompson et al). The arms are affected little or not at all. Often the first step or two when the patient begins to walk are halting, but thereafter, the gait is entirely normal. Because falls are infrequent, the symptoms are often attributed to a functional disorder. Tremulousness is not present when the patient is seated or reclining, but in the latter positions, it can be evoked by strong contraction of the leg muscles against resistance.

Electromyographic recordings demonstrate rhythmic co-contraction of the gastrocnemius and anterior tibialis muscles. Although some authors, such as Wee and colleagues, have classified the disorder as a type of essential tremor, most of its characteristics suggest otherwise. Sharott and coworkers consider it an exaggerated physiologic tremor in response to imbalance; others have suggested a spinal origin for the tremor because of an intrinsic rhythm at approximately 16 Hz that is generated by damaged spinal cord in patients with myelopathy.

Some patients have responded to the administration of clonazepam, gabapentin, primidone, or sodium valproate alone or in combination but it often proves difficult to treat. A few intractable cases have been treated with an implanted spinal cord stimulator (Krauss et al, 2005).

Dystonic Tremor

Tremors may be a feature of incipient dystonia as mentioned earlier. When the underlying dystonic posturing is not overt, the tremor may be ascribed to the essential variety or to a functional disorder. Dystonic tremor is focal, for example, superimposed on torticollis, or a dystonic hand. The movement is not entirely rhythmic, sometimes jerky, and often intermittent. These cases are also discussed further on in the section on focal dystonia. In addition, a fair number of patients with dystonia have an essential tremor.

Functional (Psychogenic) Tremor

Tremor may be a dramatic manifestation of a functional disorder. It simulates many types of organic tremor, often causing some difficulty in diagnosis. Psychogenic tremors are usually restricted to a single limb, often in the dominant hand; they are gross in nature and are less regular than the common static or action tremors. Importantly, they often diminish in amplitude or disappear if the patient is distracted as, for example, when asked to make a complex movement with the opposite hand. If the examiner restrains the affected hand and arm, the tremor may move to a more proximal part of the limb or to another part of the body ("chasing the tremor"). Other useful features in identifying functional tremor are paradoxical exaggeration of the tremor by loading the limb—for example, by having the patient hold a book or other heavy object—which reduces almost all other tremors with the exception of those produced by polyneuropathy. Functional tremor often acquires the frequency of a willed movement in a different limb.

Tremors of Complex Type

Not all tremors correspond exactly with those described above and several of them may coexist. It is common for one type of tremor to show a feature ordinarily considered characteristic of another. In some parkinsonian patients, for example, the tremor is accentuated rather than dampened by active movement; in others, the tremor may be very mild or absent in repose and become obvious only with movement of the limbs. As mentioned above, a patient with a typical parkinsonian tremor may, in addition, show a fine essential tremor of the outstretched hands and occasionally even an element of ataxic tremor as well. In a similar way, essential or familial tremor may, in its advanced stages, assume the aspects of a cerebellar tremor. Further examples include patients with essential tremor or ataxic tremor who also display a rhythmic parkinsonian tremor in relation to sustained postures.

Palatal Tremor ("Palatal Myoclonus")

This is a rare disorder consisting of rapid, rhythmic, involuntary movements of the soft palate. For many years it was thought to be a form of uniphasic myoclonus (hence the terms palatal myoclonus and palatal nystagmus). Because of the persistent rhythmicity, it is now classified as a tremor. There are two forms of this movement, according to Deuschl and colleagues. One is *essential palatal tremor* that reflects the rhythmic activation of the tensor veli palatini muscles; it has no known pathologic basis. The palatal movement may impart a repetitive audible click, which ceases during sleep. The second, more common form is a *symptomatic palatal tremor* caused by a diverse group of brainstem lesions that interrupt the central tegmental tract(s); (See Fig. 5-3). There is a latency of many months after the focal injury before the tremor becomes evident. It has been reported (Deuschl and coauthors 1990) that the experience of clicking is reported by patients with the essential, but not the symptomatic, variety. The frequency of the tremor varies greatly between patients and tends to be higher and remain fixed in the symptomatic variety.

Palatal tremor, in contrast to the essential type and all other tremors, persists during sleep and is sometimes associated with pendular nystagmus that is synchronized with the palatal movements. In some cases, the pharynx as well as the facial muscles, diaphragm, vocal cords, and even the muscles of the neck and shoulders participate in the persistent rhythmic movements. A similar phenomenon, in which contraction of the masseters occurs concurrently with pendular ocular convergence, has been observed in Whipple disease (oculomasticatory myorhythmia).

Magnetic resonance imaging (MRI) reveals no lesions to account for essential palatal tremor. In the symptomatic form, however, there are tegmental brainstem lesions

accompanied by conspicuous enlargement of the inferior olivary nucleus unilaterally or bilaterally. With unilateral palatal tremor, it is the contralateral olive that becomes enlarged. It has been proposed that the lesions in the symptomatic form interrupt the circuit (dentate nucleus–brachium conjunctivum–red nucleus-central tegmental tract–olivary nucleus–dentate nucleus) that Lapresle and Ben Hamida called the triangle of Guillain-Mollaret (see Fig. 5-3). The lesions have been vascular, neoplastic, demyelinating, or traumatic, and have been found mainly in midbrain or pontine portions of the central tegmental fasciculus.

The physiologic basis of palatal tremor remains conjectural. Matsuo and Ajax postulated a denervation hypersensitivity of the inferior olivary nucleus and its dentate connections, but others have suggested that the critical event is denervation not of the olive but of the nucleus ambiguous and the dorsolateral reticular formation adjacent to it. Dubinsky and colleagues have suggested that palatal tremor may be based on the same mechanism as postural tremor—that is, presumably a disinhibition and rhythmic coupling of neurons in the olive induced by a lesion of the dentato-olivary pathway.

The use of drugs in treating this movement disorder has met with variable success. Clonazepam (0.25 to 0.5 mg/d, increasing gradually to 3.0 to 6.0 mg/d), sodium valproate (250 mg/d, increasing to 1,000 mg/d), and gabapentin (up to 2,100 mg) have suppressed the movement in some cases, particularly the last of these drugs, which reportedly has had a dramatic effect in some patients. Also, tetrabenazine and haloperidol have been helpful on occasion. Selective injection of the palatal muscles with botulinum toxin, while technically demanding, affords modest relief; it is particularly helpful in eliminating the bothersome ear clicking.

ASTERIXIS

The movement disorder known as asterixis was described by Adams and Foley in patients with hepatic encephalopathy but it occurs with a variety of systemic metabolic disorders as mentioned below. It consists of arrhythmic lapses of sustained posture that allow gravity or the inherent elasticity of muscles to produce a sudden movement, which the patient then corrects, sometimes with overshoot. Later, Leavitt and Tyler and then Young and Shahani demonstrated that the initial interruption or lapse in posture is associated with EMG silence for a period of 35 to 200 ms. By interlocking EMG and electroencephalogram (EEG) recordings, it has been found that a sharp wave, probably generated in the motor cortex, immediately precedes the period of EMG silence (Ugawa et al). This confirmed that asterixis differs physiologically from both tremor and myoclonus, with which it was formerly confused; it had incorrectly been referred to as a "negative tremor" or "negative myoclonus."

Asterixis is most readily evoked by asking the patient to hold his arms outstretched with hands dorsiflexed or to dorsiflex the hands and extend the fingers while resting the forearms on the bed or the arms of a chair. Flexion movements of the hands may then occur arrhythmically once or several times a minute. The same lapses in sustained muscle contraction can be provoked in any muscle group—including, for example, the protruded tongue, the closed eyelids, or the flexed trunk muscles. Sometimes, asterixis can be elicited best by asking the patient to place his hand flat on a table and raise the index finger.

Asterixis was first observed in patients with hepatic encephalopathy but was later noted to occur with hypercapnia, uremia, and other metabolic and toxic encephalopathies including those caused by phenytoin and other antiepileptics, usually indicating that these drugs are present in excessive concentrations. Medications in classes other than the antiepileptics, particularly some antibiotics, cause the disorder from time to time, also usually when they are present at toxic levels.

Unilateral asterixis occurs in an arm and leg on the side opposite an anterior thalamic infarction or small hemorrhage, after stereotaxic thalamotomy, and with an upper midbrain lesion, usually as a transient phenomenon after stroke. Two series, came to a similar conclusion, namely, that unilateral asterixis is usually attributable to an acute thalamic stroke on the contralateral side, but there was an interesting variety of other localizations including the frontal lobe (anterior cerebral artery infarction), midbrain, and cerebellum in a few cases each (Kim and Montalban and colleagues). Our experience is limited to those arising from thalamic and overlying parietal vascular lesions. Many drugs may unmask unilateral asterixis that has its basis in an underlying lesion of the anterior thalamus. Of course, an individual with a metabolic encephalopathy and a hemiparesis, new or old, will only manifest asterixis on the normal side.

MYOCLONUS

Myoclonus specifies the very rapid, shock-like contractions of a group of muscles, irregular in rhythm and amplitude, and, with few exceptions, asynchronous and asymmetrical in distribution. If such contractions occur singly or are repeated in a restricted group of muscles, such as those of an arm or leg, the phenomenon is termed segmental myoclonus, whereas widespread, lightninglike, arrhythmic repeated contractions are referred to as polymyoclonus. In all forms of myoclonus, the muscle contraction is brief (20–50 ms)—that is, faster than that of chorea, with which it may be confused. The speed of the myoclonic contraction is the same whether it involves a part of a muscle, a whole muscle, or a group of muscles. The discussion that follows makes evident that each of the three phenomena has a distinctive pathophysiology and clinical implications.

A common and benign example of myoclonus, familiar to many persons, is the "sleep-start" that consists of a jerking of the body, particularly the torso, while falling asleep or occasionally, just prior to waking. Several other sleep-related syndromes involve repetitive leg movements that include an element of myoclonus. Rarely, the movements may extend to daytime behavior (Walters and colleagues). These sleep disorders are discussed in Chap. 18.

Several rapid movements of the limb or a part of a limb simulate myoclonus but have entirely different mechanisms and implications. For example, epilepsia partialis continua is a special type of epileptic activity in which one group of muscles—usually of the face, arm, or leg—is continuously (day and night) involved in a series of rhythmic monophasic contractions. These may continue for weeks, months, or years. The disorder appears to be cerebral in origin, but in most cases, its precise anatomic and physiologic basis cannot be determined (see Chap. 15 for further discussion). The related term clonus designates another rapid rhythmic contraction and relaxation of a group of muscles. Reference has already been made in Chap. 3 to relationship of clonus to spasticity and heightened tendon reflexes in diseases affecting the corticospinal tract. It is most easily elicited by forcefully dorsiflexing the ankle; a series of rhythmic jerks of small to moderate amplitude result.

Focal, Segmental, and Regional Myoclonus

Patients with idiopathic epilepsy may complain of a localized myoclonic jerk or a short burst of myoclonic jerks, occurring particularly on awakening and on the day or two preceding a major generalized seizure, after which these movements cease. One-sided or focal myoclonic jerks are the dominant feature of a form of childhood epilepsy—the so-called benign epilepsy with rolandic spikes (see Chap. 15).

The notion that monophasic-restricted myoclonus always emanates from the cerebral cortex, cerebellum, or brainstem cannot be sustained, as there are forms that are traceable to a purely spinal cause. The problem takes the form of an almost continuous arrhythmic jerking of a restricted group of muscles, often on one side of the body. Such a subacute spinal myoclonus of obscure origin was described many years ago, and similar cases continue to be cited in the literature (Campbell and Garland). We have seen several in which myoclonus was isolated to the musculature of the abdominal or thoracic wall on one side, or to the legs; only rarely were we able to establish a cause, and the spinal fluid has been normal. This form has been referred to as "propriospinal" when it involves repetitive flexion or extension myoclonus of the torso that is aggravated by stretching or action.

Examples of myelitis with irregular and strictly segmental myoclonic jerks (either rhythmic or arrhythmic) have been reported in humans and have been induced in animals by the Newcastle virus. Many such myelitic cases involve the legs or a few muscles of one leg. This type of myoclonus has occurred following zoster myelitis, postinfectious transverse myelitis, and rarely with multiple sclerosis, epidural cord compression, or after traumatic spinal injury. A paraneoplastic form has also been described, usually associated with breast cancer (see Chap. 30). When highly ionic contrast media was in the past used for myelography, painful spasms and myoclonus sometimes occurred in segments where the dye was concentrated by a block to the flow of spinal fluid.

Treatment is difficult and one resorts to a combination of antiepileptic drugs and benzodiazepines, just as in cerebral myoclonus. Levetiracetam reportedly has been successful when other drugs have failed (Keswani et al).

Focal myoclonus is also one of the notable features of degenerative neurologic conditions, particularly corticobasal ganglionic degeneration; it is generally seen in a limb that is made rigid by this process.

Diffuse Myoclonus (Polymyoclonus)

Under the title paramyoclonus multiplex, Friedreich, in 1881, described a sporadic instance of idiopathic widespread muscle jerking in an adult. It was probably in the course of this description that the term myoclonus was used for the first time. No other neurologic abnormalities accompanied the movement abnormality and its nature is obscure. We are not familiar with this process occurring in modern practice. Yet, there are many diseases in which multifocal or widespread asynchronous myoclonus is a manifestation, appropriately called polymyoclonus.

Several disparate disorders give rise to diffuse myoclonus. It may occur in pure or "essential" form as a benign, often familial, nonprogressive disease. A second broad category is allied with special forms of childhood epilepsy and there are several types that are associated with acquired neurologic diseases as discussed below, some quite serious in nature.

Essential (Familial) Myoclonus

Symptoms may begin at any period of life but usually appear first in childhood. This disorder may be of the same nature as the one described by Friedreich, as mentioned above. An autosomal dominant mode of inheritance is evident in some families. The myoclonus takes the form of irregular twitches of one or another part of the body, involving groups of muscles, single muscles, or even a portion of a muscle. As a result, an arm may suddenly flex, the head may jerk backward or forward, or the trunk may curve or straighten. The face, neck, jaw, tongue, ocular muscles, and diaphragm may twitch. According to Wilson, even fascicles of the platysma may twitch. Some muscle contractions cause no visible displacement of a limb. Some patients register little complaint, accepting the constant intrusions of motor activity with stoicism; they generally lead relatively normal, active lives. Seizures, dementia, and other neurologic deficits are notably absent, but several rare forms have been associated with axial dystonias. In a Mayo Clinic series reported, 19 of 94 cases of polymyoclonus were considered to be of this "essential" type (Aigner and Mulder).

Myoclonus in Epilepsy (See Also Myoclonic Seizures in Chap. 15)

Myoclonus may be a direct reflection of seizures but is also a separate nonepileptic manifestation in several neurodegenerative and storage diseases, of which seizures are an important component. For example, a relatively benign idiopathic condition, juvenile myoclonic epilepsy, is accompanied by myoclonic jerks when the patient is tired or has ingested alcohol. A more serious type of myoclonic epilepsy, identified with the names Unverricht and Lundborg, in the beginning is marked by polymyoclonus

as an isolated phenomenon, but later is associated with dementia and other signs of progressive neurologic disease. An outstanding feature of the latter is a remarkable sensitivity of the myoclonus to stimuli of all sorts. If a limb is passively or actively displaced, the resulting myoclonic jerk may lead, through a series of progressively larger synchronous jerks, to a generalized convulsive seizure. In late childhood, this type of stimulus-sensitive myoclonus is usually a manifestation of the juvenile form of lipid storage disease, which, in addition to myoclonus, is characterized by seizures, retinal degeneration, dementia, rigidity, pseudobulbar paralysis, and, in the late stages, by spastic quadriplegia.

Myoclonus may be associated with atypical petit mal and akinetic seizures in the Lennox-Gastaut syndrome (absence or petit mal variants); the patient often falls during the brief lapse of postural mechanisms that follows a single myoclonic contraction. Similarly, in the West syndrome of infantile spasms, the arms and trunk are suddenly flexed or extended in a single massive myoclonic jerk ("jackknife" or "salaam" seizures); mental regression occurs in 80 to 90 percent of these cases, even when the seizures are successfully treated. These types of special "myoclonic epilepsies" are discussed further below and in Chap. 15 in relation to epilepsy.

Another form of stimulus-sensitive (reflex) myoclonus, inherited as an autosomal recessive trait, begins in late childhood or adolescence, and is associated with neuronal inclusions (Lafora bodies thus Lafora-body disease) in the cerebral and cerebellar cortex and in brainstem nuclei. In yet another familial type (described under the title of Baltic myoclonus by Eldridge et al), autopsy has disclosed a loss of Purkinje cells but no inclusion bodies. Unlike Lafora-body disease, the Baltic variety of myoclonic epilepsy has a favorable prognosis, particularly if the seizures are treated with valproic acid.

Under the title of cherry-red-spot myoclonus syndrome, Rapin and associates have drawn attention to a familial (autosomal recessive) form of diffuse, incapacitating intention myoclonus associated with visual loss and ataxia. This disorder develops insidiously in adolescence. The earliest sign is a cherry-red spot in the macula that may fade in the chronic stages of the illness. The intellect is relatively unimpaired. A similar clinical syndrome of myoclonic epilepsy is seen in a variant form of neuroaxonal dystrophy and in the late childhood–early adult neuronopathic form of Gaucher disease, in which it is associated with supranuclear gaze palsies and cerebellar ataxia (see Chap. 36).

Diffuse Myoclonus with Acquired Neurologic Disease

The clinical settings in which one observes widespread random myoclonic jerks as a transient or persistent phenomenon in adults is most often an acquired metabolic disorder (prototypically uremic and anoxic encephalopathy) and in certain drug intoxications, notably with haloperidol, lithium, and amphetamines. For example, an acute onset of polymyoclonus with confusion occurs with lithium intoxication; once ingestion is discontinued, there is improvement (slowly over days to weeks) and the myoclonus is replaced by diffuse action tremors, which later subside. A second broad category of acquired myoclonus consists of structural brain diseases such as viral encephalitis, Creutzfeldt-Jakob disease, syphilitic general paresis, advanced Alzheimer, and Lewy body disease, corticobasal ganglionic degeneration, and occasionally Wilson disease. Table 4-7 lists these and others. A subacute encephalopathy with diffuse myoclonus may occur in association with the autoantibodies that characterize Hashimoto thyroiditis and in Whipple disease. Diffuse, severe myoclonus may be a prominent feature of early tetanus and strychnine poisoning. Polymyoclonus that occurs in the acute stages of anoxic encephalopathy should be distinguished from

Table 4-7

CAUSES OF GENERALIZED AND REGIONAL MYOCLONUS

Epileptic forms
- Unverricht-Lundborg disease
- Lafora-body disease
- Baltic myoclonus
- Benign epilepsy with rolandic spikes
- Juvenile myoclonic epilepsy
- Infantile spasms (West syndrome)
- Cherry-red-spot myoclonus (sialidase deficiency)
- Myoclonus epilepsy with ragged red fibers (MERRF)
- Ceroid lipofuscinosis (Kufs disease)
- Tay-Sachs disease
- Epilepsia partialis continua

Essential forms

Myoclonic dementias
- Creutzfeldt-Jakob disease
- Subacute sclerosing panencephalitis
- Familial progressive poliodystrophy
- Alzheimer, Lewy-body, and Wilson diseases (occasional in late stages)
- Whipple disease of the central nervous system
- Corticobasal ganglionic degeneration
- Dentatorubropallidoluysian atrophy
- AIDS dementia

Myoclonus with cerebellar disease (myoclonic ataxia)
- Opsoclonus-myoclonus syndrome (paraneoplastic [anti-Ri], neuroblastoma, post- and parainfectious)
- Postanoxic myoclonus (Lance Adams type)
- Ramsay-Hunt dyssynergia cerebellaris myoclonica (see Hunt JR)

Metabolic, immune, and toxic disorders
- Cerebral hypoxia (acute and severe)
- Uremia
- Hashimoto thyroiditis
- Lithium intoxication
- Haloperidol and sometimes phenothiazine intoxication
- Hepatic encephalopathy (rare)
- Cyclosporine toxicity
- Nicotinic acid deficiency encephalopathy
- Tetanus
- Other drug toxicities

Focal and spinal forms of myoclonus
- Herpes zoster myelitis
- Other unspecified viral myelitis
- Multiple sclerosis
- Traumatic spinal cord injury
- Arteriovenous malformation of spinal cord
- Subacute myoclonic spinal neuronitis
- Paraneoplastic spinal myoclonus

postanoxic action or intention myoclonus that emerges with recovery from cardiac arrest or asphyxiation (it is discussed below). The factor common to all these disorders, with the exception of acquired metabolic disorders and intoxications, is the presence of diffuse neuronal disease.

Myoclonus in association with signs of cerebellar incoordination and opsoclonus (rapid, irregular conjugate eye movements in all directions as described in Chap. 13) is another syndrome of both children and adults. Most cases run a chronic course, waxing and waning in severity. Many of the childhood cases are associated with occult neuroblastoma, and some have responded to the administration of corticosteroids. In adults, a similar syndrome is well known as an effect of specific circulating antibodies that are elaborated in response to the presence of some tumors ("paraneoplastic," mainly breast, and ovary as discussed in Chap. 30). The condition also occurs as a self-limited manifestation of a postinfectious (usually viral) illness (Baringer and colleagues).

As mentioned above, diffuse myoclonus is a prominent and often early feature of the prion illness, Creutzfeldt-Jakob disease, characterized by rapidly progressive dementia, disturbances of gait and coordination, and all manner of mental and visual aberrations (see Chap. 32). Initially the jerks are random but late in the disease they may attain an almost rhythmic and symmetric character. In addition, there is an exaggerated startle response, and violent myoclonus may be elicited by tactile, auditory, or visual stimuli in advanced stages of the disease. In yet another group of myoclonic dementias, the most prominent associated abnormality is a progressive deterioration of intellect. The myoclonic dementias may be sporadic or familial and may affect children or adults. A rare childhood type is subacute sclerosing panencephalitis (SSPE), which is an acquired subacute or chronic (occasionally remitting) disease related to a latent infection with the measles virus (see Chap. 32).

Postanoxic Intention (or Action) Myoclonus

This type of myoclonus was described by Lance and Adams in a group of patients who were recovering from hypoxic encephalopathy. When the patient is relaxed, the limb and other skeletal muscles are quiet (except in the most severe cases); only seldom does the myoclonus appear during slow, smooth (ramp) movements. Fast (ballistic) movements, however, especially when directed to a target elicit a series of irregular myoclonic jerks that differ from intention tremor. Only the limb that is moving is involved; hence it is a localized, stimulus-evoked myoclonus. Speech may be fragmented by the myoclonic jerks, and a syllable or word may be almost compulsively repeated, as in palilalia. Myoclonus of the axial muscles may make walking impossible.

Action myoclonus is almost always associated with cerebellar ataxia. The pathologic anatomy has not been entirely ascertained. Lance and Adams found the irregular discharges to be transmitted via the corticospinal tracts, preceded in some cases by a discharge from the motor cortex. Chadwick and coworkers postulated a reticular loop reflex mechanism, while others (Hallett and colleagues 1977) found that a cortical reflex mechanism was operative in some cases and a reticular reflex mechanism in others. Whether these are two aspects of one mechanism could not be decided.

Barbiturates and valproic acid have been helpful in some cases. Several clinical trials and case reports have suggested that the antiepileptic levetiracetam may be useful (Krauss et al, 2001). The use of 5-hydroxytryptophan alone or in combination with tryptophan or other drugs had been recommended in the past (van Woert et al). A combination of several of these medications is usually required to make the patient functional.

Pathophysiology of Myoclonus

It seems logical to assume that myoclonus is caused by abnormal discharges of aggregates of motor neurons or interneurons because of the enhanced excitability of these cells or the removal of some inhibitory mechanism. Sensory provocation may be a prominent feature of polymyoclonus, particularly those related to metabolic disorders. Flickering light, a loud sound, or an unexpected tactile stimulus to some part of the body initiates a jerk so quickly and consistently that it must utilize a direct sensorimotor pathway or the mechanism involved in the startle reaction. Repeated stimuli may recruit a series of incremental myoclonic jerks that culminate in a generalized convulsion, as often happens in the familial myoclonic syndrome of Unverricht-Lundborg.

Evidence implicating cortical hyperexcitability in myoclonus is indirect, being based mainly on the finding that the cortical components of the somatosensory evoked potential are exceedingly large and that in some instances, the myoclonic jerks have a strict time relationship ("timelocked") to preceding spikes in the contralateral rolandic area (Marsden et al; Brown et al). It is possible that these potentials originate from subcortical structures that project both to the descending motor pathways and upward to the cortex. There is an indication, for example, that postanoxic action myoclonus has its basis in reflex hyperactivity of the reticular formation. Furthermore, the only consistent damage in some disorders such as postanoxic myoclonus is in the cerebellum rather than in the cerebral cortex. As already noted, several types of myoclonus are closely coupled with other cerebellar degenerations.

Pathologic examinations have been of little help in determining the essential sites of this unstable neuronal discharge because in most cases, the disease is diffuse. Nonetheless, the most restricted lesions associated with myoclonus are in the cerebellum and rostral brainstem. Removal of the modulating influence of the cerebellum on the thalamocortical system of neurons has been postulated as a mechanism, but it is uncertain whether the disinhibited motor activity is then expressed through corticospinal or reticulospinal pathways. For example, pentylenetetrazol injections evoke myoclonus in animals, and the myoclonus persists despite transection of corticospinal and other descending tracts of the hemispheres and upper brainstem until the lower brainstem reticular structures are destroyed.

STARTLE SYNDROMES

To some degree, everyone startles or jumps in reaction to a totally unanticipated, potentially threatening stimulus. This normal startle reflex is probably a protective reaction, being also seen in animals, and its purpose seemingly is to prepare the organism for escape. In most ways, startle cannot be separated from myoclonus except for its generalized nature and an obligatory evocation by various stimuli. Any stimulus—most often an auditory one but also a flash of light, a tap on the neck, back, or nose, or even the presence of someone behind the patient—can normally evince a sudden contraction of the orbicularis, neck, and spinal musculature and even the legs. However, in the abnormal startle response that occurs in the diseases discussed below, the contraction is of greater amplitude and is more widespread, with less tendency to habituate. There may even be a jump and occasionally an involuntary shout and fall to the ground. It is these characteristics that distinguish pathologic startle.

Aside from exaggerated forms of the normal startle reflex, the commonest isolated syndrome is so-called startle disease, referred to as hyperexplexia or hyperekplexia (Gastaut and Villeneuve). This is a familial disease (e.g., the "jumping Frenchmen of Maine," and others, as described further on). The nature of the phenomenon displayed by the "jumping Frenchmen of Maine" has been disputed. The syndrome was described originally by James Beard in 1868 among small pockets of French-speaking lumberjacks in northern Maine. The subjects displayed a greatly exaggerated response to minimal stimuli, to which there was no adaptation. The reaction consisted of jumping, raising the arms, screaming, and flailing of limbs, sometimes with echolalia, echopraxia, and a forced obedience to commands, even if this entailed a risk of serious injury. A similar syndrome in Malaysia and Indonesia is known as latah and in Siberia as miryachit. This syndrome has been framed in psychologic terms as conditioned responses (Saint-Hilaire et al) or as culturally determined behavior (Simons). Possibly some of the complex secondary phenomena can be explained in this way, but the stereotyped onset with an uncontrollable startle and the familial occurrence attest to a biologic basis. The most common mutation is in the 1-subunit of the inhibitory glycine receptor GLRA1 (Shiang et al) but other glycine receptor–related genes have been implicated in other cases. As pointed out by Suhren and associates and by Kurczynski, the condition is transmitted in some families as an autosomal dominant trait. The subject has been reviewed by Wilkins and colleagues and by Ryan and associates.

Later in life, excessive startle must be distinguished from normal sleep starts, epileptic seizures, which may begin with a startle or massive myoclonic jerk (startle epilepsy), from the multiple tic disorder, Gilles de la Tourette syndrome, of which startle may be a prominent manifestation, and from cataplexy. With idiopathic startle disease, even with a fall, there is no loss of consciousness, and the manifestations of tic and other neurologic abnormalities are absent. Reflecting the clinical proximity to myoclonus, a stimulus-evoked startle response may be a manifestation of several myoclonic neurologic diseases including Tay-Sachs disease, SSPE, stiff person syndrome, lipid storage diseases, and Creutzfeldt-Jakob disease.

The mechanism of the startle response has been a matter of speculation. In animals, the origin of the phenomenon has been localized in the pontine reticular nuclei, with transmission to the lower brainstem and spinal motor neurons via the reticulospinal tracts. During the startle, the EEG may show a vertex or frontal spike–slow-wave complex, followed by a general desynchronization of the cortical rhythms; between startles, the EEG is normal. Some authors have postulated a disinhibition of certain brainstem centers. Others, based on testing by somatosensory evoked potentials, have suggested that hyperactive long-loop reflexes constitute the physiologic basis of startle disease (Markand et al). Wilkins and coworkers consider hyperexplexia to be an independent phenomenon (different from the normal startle reflex) and to fall within the spectrum of stimulus-sensitive myoclonic disorders. Presumably, the altered glycine receptor in startle disease is the source of some form of hyperexcitability in one or another of the motor or reticular alerting systems.

Treatment

Clonazepam controls the startle disorders to varying degrees. Levetiracetam has reportedly been helpful in some patients. Also, the act of flexing the neck and bringing the arms close to the torso may reduce the intensity of an attack (Vigevano maneuver).

FOCAL DYSTONIAS

The focal or segmental dystonias, in contrast to the generalized dystonic disorders, are intermittent, brief, or prolonged spasms or contractions of a group of adjacent muscles that places the body part in a forced and unnatural position. The most common type of focal dystonia is torticollis, a spasm that is limited to the neck muscles as detailed below. Other dystonias restricted to craniocervical muscle groups are spasms of the orbicularis oculi, causing forced closure of the eyelids (blepharospasm) and contraction of the muscles of the mouth and jaw, which may cause forceful opening or closure of the jaw and retraction or pursing of the lips (oromandibular dystonia). With the last of these conditions, the tongue may undergo forceful involuntary protrusion; the throat and neck muscles may be thrown into spasm when the patient attempts to speak, or the facial muscles may contract in a grimace. Another form of dystonia that occurs independently or in association with orofacial movements is spasmodic dysphonia, a dystonia of the laryngeal muscles that imparts a high-pitched, strained quality to the voice (sometimes incorrectly termed "spastic" dysphonia) as discussed in Chap. 22. Yet a different group of focal dystonias affects the limbs, particularly the hand in relation to overuse of a small skilled movement such as writing.

To give a perspective of the relative frequencies of these disorders, of the focal dystonias seen in the movement disorder clinic of Columbia Presbyterian Hospital, 44 percent were classified as torticollis, 26 percent as spasmodic dysphonia, 14 percent as blepharospasm, 10 percent as focal dystonia of the hand (writer's cramp), and 3 percent as oromandibular dystonia.

These movement disorders are involuntary and cannot be inhibited, thereby differing from habit spasms or tics. At one time, torticollis was thought to be a psychological disorder, but it is now considered a localized form of dystonia. It is characteristic of focal dystonias to display a simultaneous activation of agonist and antagonist muscles (co-contraction) and to have a tendency for the spasm to spread to adjacent muscle groups that are not normally activated in the movement (overflow), but these features tend not to be as prominent in focal dystonias as in the generalized varieties described earlier. Sometimes, focal dystonias include an arrhythmic intermixed tremor, which may be the prominent incipient feature. The tremor may cause difficulty in diagnosis if the slight degree of underlying dystonia is not appreciated by careful observation and by palpation of the involved muscles.

The pathogenesis of the idiopathic focal dystonias is uncertain, although there is evidence that some of them, like the generalized dystonias, are genetically determined. Authoritative neurologists, (Marsden), classified the apparently idiopathic adult-onset focal dystonias with genetically determined generalized torsion dystonia. This view is based on several lines of evidence: the recognition that each of the focal dystonias may appear as an early component of generalized syndrome in children, the occurrence of focal and segmental dystonias in family members of these children, as well as a tendency of the dystonia in some adult patients to spread to other body parts. Perhaps the most compelling observation in this regard has been the finding that there are families in which the only manifestation of the DYT1 mutation (the gene associated with generalized torsion dystonia) is a late-onset writer's cramp or other focal dystonia. Whether this explains most or even many of the cases of adult-onset focal dystonia is unclear, but it does emphasize the phenotypic variability associated with the DYT1 mutation. The genetics of primary torsion dystonia is more complex than portrayed here and is reviewed in Chap. 38, Degenerative Diseases of the Nervous System.

It is noteworthy that no consistent pathologic changes have been demonstrated in any of the idiopathic or genetically determined dystonias (Zeman). Most physiologists cast the disorder in terms of reduced cortical inhibition of unwanted muscle contractions (Berardelli and colleagues). Moreover, physiologic changes in the cortical sensory areas that are pertinent to the dystonias associated with overuse of body parts (occupational dystonias) are described further on.

Symptomatic Restricted Dystonias

A focal dystonia rarely emerges transiently after a stroke that involves the striatopallidal system, mainly the internal segment of the pallidum or the thalamus, but the varied locations of these infarctions make it difficult to draw conclusions about the mechanism of dystonia. It will be noticed that the same disturbances that cause chorea, as discussed in an earlier section, may produce focal dystonias (see Table 4-4). Focal dystonias may also occur in metabolic diseases such as Wilson disease and non-Wilsonian hepatolenticular degeneration. Any of the typical forms of restricted dystonia may represent a tardive dyskinesia; that is, they complicate treatment with high-potency dopamine antagonists and other medications that are used primarily for the treatment of psychosis and nausea (see further on under "Drug-Induced Dyskinesias"). Dystonias of the hand or foot often emerge as components of several degenerative diseases—Parkinson disease in particular but also corticobasal ganglionic degeneration, and progressive supranuclear palsy (described in Chap. 38). Such cases that fall into the category of symptomatic or secondary dystonias are described by Krystkowiak and colleagues and by Munchau and colleagues. Janavs and Aminoff have summarized several focal dystonias that are caused by acquired systemic disorders, such as drugs, and by autoantibodies, including from systemic lupus erythematosus. It is the last of these that we have encountered most often in clinical practice.

Spasmodic Torticollis (Idiopathic Cervical Dystonia)

Torticollis, the most frequent form of restricted dystonia, is localized to the neck and adjacent muscles. It usually begins as a subtle tilting or turning of the head that tends to worsen slowly, first evident in early to middle adult life, somewhat more commonly in women (peak incidence in the fifth decade) (extreme form shown in Fig. 4-8*A*). With the exception of the finding of DYT1 gene abnormality in a few patients, it is idiopathic. The quality of the neck and head movements varies greatly. Intermittent turning or tilting of the head may be deliberate and smooth, or jerky, but more typically there is a sustained deviation or tilting of the head to one side. Sometimes brief bursts of twitching or an irregular, high-frequency tremor accompanies deviation of the head, beating in the direction of the dystonic movement. At times the tremor is more dominant than is the dystonia, causing difficulty in diagnosis. The spasms are often worse when the patient stands or walks and are characteristically reduced or abolished by a contactual stimulus, such as placing a hand on the chin or neck; exerting mild but steady counterpressure on the side of the deviation or less often on the opposite side; or bringing the occiput in contact with the back of a high-backed chair. These maneuvers, termed gestes, or "sensory tricks" become less effective as the disease progresses. In many cases, the spasms are reduced when the patient lies down. In chronic cases, as the dystonic position typically becomes increasingly fixed in position, the affected muscles undergo hypertrophy. At that late stage, pain in the contracting muscles is common.

In a few patients, the condition disappears without therapy, an occurrence observed in 10 to 20 percent in the

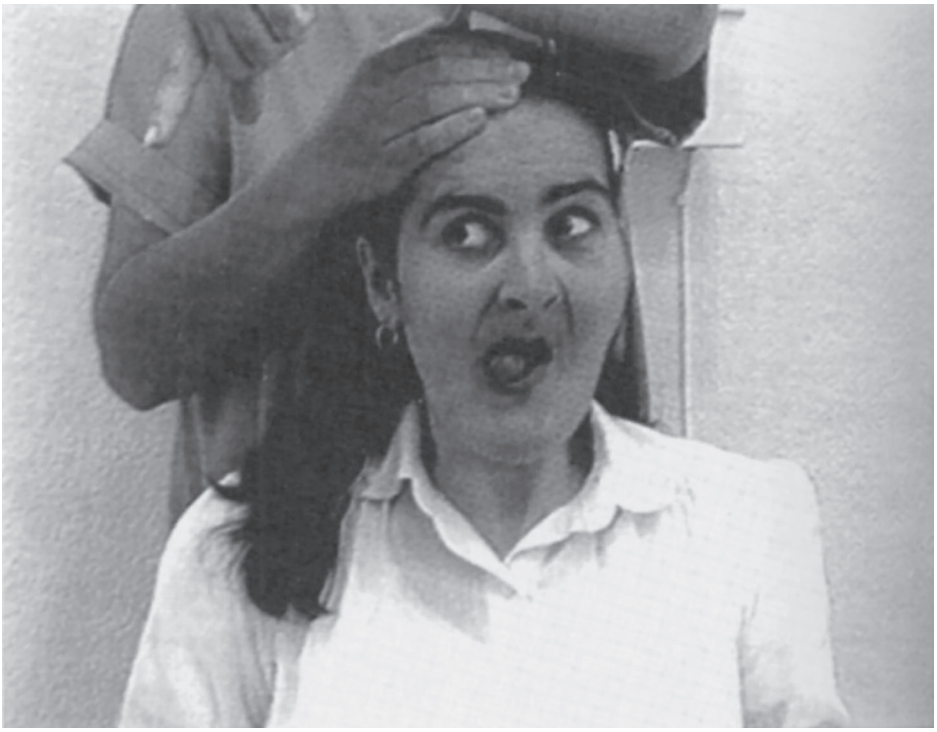

Figure 4-8. Acute facial dystonia. (Reproduced with permission from Ray L. Watts, David G. Standaert, José A. Obeso. *Movement Disorders*, 3rd edition. Copyright © 2012 by The McGraw-Hill Companies, Inc. All rights reserved.)

(Dauer et al). Remissions usually occur during the first few years after onset in patients whose disease began relatively early in life; however, nearly all these patients relapse within 5 years.

The most prominently affected muscles are the sternocleidomastoid, levator scapulae, and trapezius. EMG studies also show sustained or intermittent activity in the posterior cervical muscles on both sides of the neck. The levator spasm lifts the affected shoulder slightly, and tautness in this muscle is sometimes the earliest feature. As a general observation, we have been impressed with information gained from palpating the muscles of the neck and shoulder in order to establish which muscles are the predominant causes of the spasm and to direct treatment to them as noted further on. In most patients, the spasms remain confined to the neck muscles and persist in unmodified form, but in some, the spasms spread, involving muscles of the shoulder girdle and back or the face and limbs. The distinction between these patterns is not fundamental. About 15 percent of patients with torticollis also have oral, mandibular, or hand dystonia, 10 percent have blepharospasm, and a similarly small number have a family history of dystonia or tremor (Chan et al). As already noted, no neuropathologic changes have been found in case studies, for example, those reported by Tarlov and by Zweig and colleagues.

Treatment

Spasmodic torticollis is resistant to treatment with L-dopa and other antiparkinsonian agents, although occasionally they give slight relief. The drugs are, however, effective in those few instances in which dystonia is a prelude to Parkinson disease. Trihexyphenidyl or benztropine, used in the past in high doses for dystonia, may allow some amelioration but they are difficult to tolerate.

The most widely used form of treatment is the periodic (every 3–6 months) injection of small amounts of botulinum toxin directly into several sites in the affected muscles. The injections are best guided by palpation of muscles in spasm and by EMG analysis to determine which of the tonically contracted muscles are most responsible for the aberrant posture. About 90 percent of patients with torticollis have had some degree of relief from symptoms with this treatment. Adverse effects (excessive weakness of injected muscles, local pain, and dysphagia—the latter from a systemic effect of the toxin) are usually mild and transitory. Five to 10 percent of patients eventually become resistant to repeated injections because of the development of neutralizing antibodies to the toxin (Dauer et al).

More recently, the use of deep brain stimulation has found some success in the treatment of cases of idiopathic cervical dystonia that have been refractory to medications and botulinum injection. The internal segments of the globus pallidus and the subthalamic nuclei have been used as targets. This approach is certainly preferable to the former use of ablative lesions in these areas and in the thalami but, as in the randomized trial conducted by Volkmann and colleagues, adverse effects such as dysarthria, dyskinesias and worsening of dystonia occur in a proportion of cases. In the most severe cases of torticollis, a combined sectioning of the spinal accessory nerve and of the first

three cervical motor roots bilaterally has been successful in reducing spasm of the muscles without totally paralyzing them. Considerable relief has been achieved for as long as 6 years in one-third to one-half of cases treated in this way (Krauss et al; Ford et al).

Blepharospasm

Patients in mid and late adult life, predominantly women, may present with the complaint of excessive blinking and involuntary forced closure of the eyes, which is due to spasm of the orbicularis oculi muscles. Any attempt to look at a person or object is associated with a persistent tonic, symmetric spasm of the eyelids. During conversation, the patient struggles to overcome the spasms and is distracted by them. Reading and watching television are impossible at some times but surprisingly easy at others. In a survey of 250 such patients found that in the past, before effective treatment, 75 percent progressed in severity over the years to the point, in about 15 percent of cases, of making the patients functionally blind (Jankovic and Orman). Some instances of blepharospasm are a component of the Meige syndrome that includes jaw spasms (see next section) or are associated with spasmodic dysphonia, torticollis, and other dystonic fragments. Blepharospasm may also be a result of drug-induced tardive dyskinesia.

One's first inclination is to attribute this disorder to photophobia or a response to an ocular irritation or corneal dryness, and indeed, the patient may state that bright light is annoying. For example, ocular inflammation, especially of the iris, may produce severe reflex blepharospasm. However, the spasms persist in dim light and even after anesthesia of the corneas. Patients may hold the lid open with a finger and the eyebrow is seen to be displaced downward; in some forms, there is tonic contraction of the frontalis muscles in an apparent attempt to aid lid opening.

In the past, a psychiatric causation was proposed but, apart from a depressive reaction in some patients, psychiatric symptoms are lacking, and the use of psychotherapy, biofeedback, acupuncture, behavior modification therapy, and hypnosis has failed to help. No neuropathologic lesion or neurochemical profile has been established in any of these disorders (Marsden et al; see also Hallett). A genetic basis is possible although few cases seem to be inherited and there has been no association with the known dystonia genes.

Treatment

The most effective treatment consists of the injection of botulinum toxin into several sites in the orbicularis oculi and adjacent facial muscles. The benefit lasts for 3 to 6 months and repeated cycles of treatment are usually required. There appear to be few adverse systemic effects because of the low doses used. In the treatment of blepharospasm, a variety of antiparkinsonian, anticholinergic, and tranquilizing medications may be tried, but one should not be optimistic about the chances of success. A few patients have had temporary and partial relief from L-dopa. Sometimes the blepharospasm disappears spontaneously (in 13 percent of the cases in the series of Jankovic and Orman). Thermolytic destruction of part of the fibers in the branches of the facial nerves that innervate the orbicularis oculi muscles is reserved for the most resistant and disabling cases.

Other Causes of Blepharospasm

There are several clinical settings other than the one described above in which blepharospasm or a condition that simulates it may be observed. In the days following cerebral infarction or hemorrhage, the stimulus of lifting the patient's eyelids may lead to strong involuntary closure of the lids. Reflex blepharospasm, as Fisher has called this phenomenon, takes liberty with the term as it is more in the character of an apraxia of opening of the lids. It is more commonly associated with a left than a right hemiplegia. A homolateral blepharospasm has also been observed with a small thalamomesencephalic infarct. In patients with Parkinson disease, progressive supranuclear palsy, or Wilson disease and with other lesions in the rostral brainstem, light closure of the eyelids may induce blepharospasm and an inability to open the eyelids voluntarily.

We have seen an instance of blepharospasm as part of paraneoplastic midbrain encephalitis, and there have been several reports of it with autoimmune disease such as systemic lupus but the mechanism in these cases is as obscure as for the idiopathic variety. Myasthenia gravis and blepharospasm have been described by Roberts and colleagues; it is difficult to be certain whether this was evidence of a second disorder or simply an exaggerated response to keeping the eyes open. Eye closure with fluttering of the lids in patients with a suggestibility is usually indicative of a functional disorder. Blepharospasm induced by pain from ocular conditions such as iritis, blepharitis, and rosacea of the eyelids may also be responsible.

Lingual, Facial, and Oromandibular Spasms (Meige Syndrome)

These special varieties of involuntary movements appear in later adult life, with a peak age of onset in the sixth decade. Women are affected more frequently than men. The most common type is characterized by forceful opening of the jaw, retraction of the lips, spasm of the platysma, and protrusion of the tongue; or the jaw may be clamped shut and the lips may purse. Other patterns include lateral jaw deviation and bruxism. Common terms for this condition are Meige syndrome, after the French neurologist who gave an early description of it, and Brueghel syndrome, because of the similarity of the grotesque grimace to that of a subject in a Brueghel painting called De Gaper. Difficulty in speaking and swallowing (due in part to spasmodic dysphonia) and blepharospasm are also frequently conjoined, and occasionally patients with these disorders develop torticollis or dystonia of the trunk and limbs. A number have tremor of affected muscles or of the hands as well. All these prolonged, forceful spasms of facial, tongue, and neck muscles had in the past followed the administration of phenothiazine and butyrophenone drugs (tardive dyskinesia). More often, however, the dyskinetic disorder induced by neuroleptics is somewhat different, consisting

of choreoathetotic chewing, lip smacking, and licking movements (tardive orofacial dyskinesia, rabbit-mouth syndrome; see later).

Very few cases of the Meige syndrome have been studied neuropathologically. In most of them, no lesions were found. In one patient, there were foci of neuronal loss in the striatum (Altrocchi and Forno); another patient showed a loss of nerve cells and the presence of Lewy bodies in the substantia nigra and related nuclei (Kulisevsky et al); both are of uncertain significance.

A form of focal dystonia that affects only the jaw muscles has been described (masticatory spasm of Romberg); a similar dystonia may be a component of orofacial and generalized dystonias. In the cases described by Thompson and colleagues, the problem began with brief periods of spasm of the pterygoid or masseter muscle on one side. Early on, the differential diagnosis includes bruxism, hemifacial spasm, the odd rhythmic jaw movements associated with Whipple disease, and tetanus. As the illness progresses, forced opening of the mouth and lateral deviation of the jaw may last for days and adventitious lingual movements may be added. A form that occurs with hemifacial atrophy has been described by Kaufman. An intermittent spasm that is confined to one side of the face (hemifacial spasm) is not, strictly speaking, a dystonia and is considered with disorders of the facial nerve in Chap. 44.

Treatment

As with the other focal and regional dystonias, substantial success has been obtained with injections of botulinum toxin into the masseter, temporal, and medial pterygoid muscles. High doses of benztropine and related anticholinergic drugs may be helpful, but are not as effective as botulinum toxin treatment. Many other drugs have been used in the treatment of these craniocervical spasms, but none has effected persistent benefit.

Task-Specific Dystonias Including Writer's Cramp and Musician's Spasm

Occupational cramps or spasms are included in this chapter because the prevailing opinion is that they are acquired forms of regional or focal "task-specific" dystonias. In the most common form, writer's cramp, the patient experiences, upon attempting to write, that all the muscles of the thumb and fingers either go into spasm or are inhibited by a feeling of stiffness and pain or hampered in some other inexplicable way. The clinical descriptions of writer's cramp by Sheehy and Marsden are worth consulting. Men and women are equally affected, most often between the ages of 20 and 50 years. The spasm may be painful and can spread into the forearm or even the upper arm and shoulder. Sometimes the spasm fragments into a tremor that interferes with the execution of fluid, cursive movements. Immediately upon cessation of writing, the spasm disappears. At all other times and in the execution of grosser movements, the hand is normal, and there are no other neurologic abnormalities. Many patients learn to write in new ways or to use the other hand, though that, too, may become involved.

Other highly skilled motor acts performed over long periods of time, such as playing the piano or fingering the violin, may induce a similar highly task-dependent spasm ("musician's cramp," "musician's dystonia") or in the past, telegrapher's palsy. The "loss of lip" in trombonists and other brass and wind instrumentalists (embouchure dystonia) represents an analogous phenomenon, seen only in experienced musicians. In each case, a delicate motor skill, perfected by years of practice and performed almost automatically, suddenly comes to require a conscious and labored effort for its execution. Discrete movements are impaired by a spreading recruitment of unneeded muscles (intention spasm). Once developed, the disability persists in varying degrees of severity, even after long periods of inactivity of the affected part.

Regarding pathogenesis, Byl and colleagues, found that sustained, rapid, and repetitive highly stereotypical movements of the hand in monkeys greatly expand the area of hand cortical representation. These authors have hypothesized that degradation of sensory feedback to the motor cortex was responsible for excessive and persistent motor activity, including dystonia. Many patients with focal acquired dystonia demonstrate minor sensory abnormalities by way of impaired temporal and spatial detection of stimuli on careful examination. A similar enlargement of the area of cortical response to magnetic stimulation has been found by a number of investigators in patients with writer's cramp and the volume of gray matter was decreased in the sensorimotor cortex, thalamus, and cerebellum corresponding to the affected hand in the report by Delmaire and coworkers. There is a special category of dystonia following nerve injury, often with severe burning pain and autonomic changes that conforms to reflex sympathetic dystrophy. In these cases, it may be the injury that causes a reconfiguration of the sensory receptive fields. Berardelli et al have reviewed other theories pertaining to the physiology of the focal dystonias. More recent notions have included changes in synaptic plasticity as a result of overuse.

Treatment

A high degree of success has been obtained by injections of botulinum toxin into specifically involved muscles, such as those of the hand and forearm in cases of writer's cramp (Cohen et al; Rivest et al), and this is now widely used. The best results are obtained by guiding the injection from both palpation and EMG detection of the specific muscles that are active in the dystonic posture. Various forms of hand retraining are also said to be useful.

Transcutaneous electrical nerve stimulation (TENS) of the forearm in 20-minute sessions has a modest effect, according to a study by Tinazzi and colleagues. It had been claimed that the patient could be helped by a deconditioning procedure that delivers an electric shock whenever the spasm occurs or by biofeedback, but these forms of treatment have been largely abandoned in favor of botulinum treatments. There have been some preliminary investigations of thalamotomy and deep brain stimulation for resistant cases.

Drug-Induced Tardive (Delayed) Dyskinesias

Dyskinesia is a broadly encompassing term that is applied to many hyperkinetic involuntary movements including those taking the conventional forms of dystonia, chorea,

athetosis, and tremor and the less well-defined ones that are produced by L-dopa therapy in Parkinson disease. When modified by the adjective tardive, it refers specifically to movements induced by the use of neuroleptic drugs, often but not always phenothiazines, that are delayed in onset from the initiation of drug therapy and persist after the drugs are withdrawn. These movements are distinguished from acute dystonic reactions that occur in the first few days of exposure to medications, are aborted by anticholinergic drugs, and do not persist. At one time, tardive dyskinesia was a common problem in psychiatric and general medical practice, but it has been less prevalent with the newer classes of antipsychosis drugs. The problem is still easily recognized and familiar to physicians who treat psychiatric patients. The movements tend to lessen over a period of months or years and mild cases abate on their own or leave little residual effect; rarely have the symptoms worsened.

Tardive dyskinesias are intermittent or persistent and not subject to the will of the patient. The facial, lingual, eyelid, and bulbar muscles are most often involved but neck, shoulder, and spine muscles with arching of the back may be implicated in individual cases as noted below. There may be added blepharospasm and truncal, hand, or neck movements and akathisia of the legs, but these are not nearly so prominent as the orofacial and lingual dyskinesias. Longer exposure is more likely to cause the movements. If the drug is discontinued immediately after the movements appear, the problem may not persist. Oromandibular spasm and blepharospasm (Meige syndrome) and Huntington disease may cause difficulty in diagnosis.

In addition to the typical neuroleptic drugs, less familiar ones such as metoclopramide, pimozide, amoxapine, and clebopride, some of which are used for disorders other than psychosis, and newer agents such as risperidone may also be causative. Less often, the movements arise soon after cessation of one of these same drugs.

There are several other drug-induced tardive movement syndromes, mainly varieties of dystonias, some of which have been mentioned earlier, and akathisia (see further on). Often they begin focally in the neck and spread over time to the limbs. One highly characteristic pattern combines retrocollis, backward arching of the trunk, internal rotation of the arms, extension of the elbows, and flexion of the wrists simulating an opisthotonic posture. Other patients may have both orofacial and cervical dyskinesias. Many patients report that the dystonia abates during walking and other activities, quite unlike idiopathic torsion dystonia. These drug-induced dyskinesias are viewed as the result of changes in the concentration of dopamine receptors, five of which are currently known, as discussed earlier. Blockade and subsequent unmasking of the D2 receptor have been particularly linked to the development of the tardive syndromes.

Treatment

Little has been found to be consistently effective. If the movements follow withdrawal of one of the offending drugs, reinstitution of the medication in small doses often reduces the dyskinesias but may have the undesired side effects of causing parkinsonism and drowsiness. For this reason, most clinicians who are experienced in this field avoid using the known offending drugs if possible and choose one of the newer agents for the treatment of the underlying psychiatric condition. The newer "atypical" neuroleptic drugs have less of a propensity to cause tardive dyskinesia.

Dopamine and noradrenergic-depleting drugs such as reserpine and tetrabenazine have also been successful if used carefully but the more effective of the two, tetrabenazine, may be more difficult to obtain. The dystonias also respond to anticholinergic drugs (trihexyphenidyl 2.5 mg once or twice daily, increased by small increments weekly up to 12.5 mg) if high enough doses can be tolerated.

Further discussion of the side effects of the antipsychosis drugs is found in later chapters.

TICS AND HABIT SPASMS

When idle, almost all individuals display a variety of fidgeting types of small amplitude movement, gestures, and mannerisms. They are slower and more complex than tics and spasms. Others, throughout their lives, are given to odder and more intrusive but benign habitual movements. These range from simple, highly idiosyncratic mannerisms (e.g., of the lips and tongue) to repetitive actions such as sniffing, clearing the throat, protruding the chin, or blinking whenever these individuals become tense. Stereotypy and irresistibility are the main identifying features of these phenomena. The patient admits to making the movements and feels compelled to do so in order to relieve perceived tension. Such movements can be suppressed for a short time by an effort of will, but they reappear as soon as the subject's attention is diverted. In certain cases, the tics become so ingrained that the person is unaware of them and seems unable to control them. An interesting feature of many tics is that they correspond to coordinated acts that normally serve some purpose to the organism. It is only their incessant repetition when uncalled for that marks them as habit spasms or tics. The condition varies widely in its expression from a single isolated movement (e.g., blinking, sniffing, throat clearing, tongue clicking, or stretching the neck) to a complex of movements.

Children between 5 and 10 years of age are especially likely to develop these habit spasms. These consist of blinking, hitching up one shoulder, sniffing, throat clearing, jerking the head or eyes to one side, grimacing, etc. If ignored, such spasms seldom persist for longer than a few weeks or months and tend to diminish on their own. In adults, relief of nervous tension by sedative or tranquilizing drugs may be helpful, but the disposition to tics persists. A putative relationship to streptococcal infection is discussed below.

Special types of rocking, head bobbing, hand waving (in autism) or hand wringing (typical of Rett syndrome), and other movements, particularly self-stimulating

movements, are disorders of motility frequent in the developmentally delayed child or adult. These "rhythmias" have no known pathologic anatomy in the basal ganglia or elsewhere in the brain. Apparently, they represent a persistence of some of the rhythmic, repetitive movements of normal infants. In some cases of impaired vision and photic epilepsy, eye rubbing or moving the fingers rhythmically across the field of vision is observed, especially again in developmentally delayed children.

Gilles de la Tourette Syndrome

Multiple tics—sniffing, snorting, involuntary vocalization, and troublesome compulsive and aggressive impulses—constitute the rarest and most severe tic syndrome—Gilles de la Tourette syndrome (his complete surname). The problem begins in childhood, in boys three times more often than in girls, usually as a simple tic. As the condition progresses, new tics are added to the repertoire. It is the multiplicity of tics and the combination of motor and vocal tics that distinguish the disorder from the more benign, restricted tic disorders. The modern definition has expanded to include an attention deficit disorder that may not reach a severity appropriate for that diagnosis independently as summarized by Kurlan.

Vocal tics, sometimes loud and irritating in pitch, are characteristic. Some patients display repetitive motor behavior, such as jumping, squatting, or turning in a circle. Other common types of repetitive behavior include the touching of other persons and repeating one's own words (palilalia) and the words or movements of others. Explosive and involuntary cursing and the compulsive utterance of obscenities (coprolalia) are perhaps the most dramatic manifestations. Interestingly, the latter phenomenon is reportedly uncommon in Japanese patients, whose decorous culture and language contain few obscenities. The full repertoire of tics and compulsions comprised by Gilles de la Tourette syndrome has been described by Tolosa and Bayes and in the reviews by Jankovic and by Leckman, which are recommended.

Some clinicians have noted the occurrence of blepharospasm, torticollis, and other dystonic fragments in a small number of patients (Stone and Jankovic). Isometric contractions of isolated muscle groups (tonic tics) may also occur. As in other tic disorders, there is a premonitory sensation of tightness, discomfort or paresthesia, or a psychic sensation or urge that is relieved by the movement. A fair proportion stutters or displays a mild dysfluency of speech. So-called *soft neurologic signs* are noted in half of the patients. Feinberg and associates have described 4 patients with arrhythmic myoclonus and vocalization, but it is not clear whether these symptoms represent an unusual variant of the disease or a new syndrome. A degree of cyclicality of symptoms has been noted by several authors; tics tend to happen in groups over minutes or hours and they are clustered over weeks and months. This gives the appearance of a waxing and waning process.

The course of the illness is unpredictable. In half of the adolescents the tics subside spontaneously by early adulthood and those that persist become milder with time. Others undergo long remissions only to have tics recur, but in other patients, the motor disorder persists throughout life. This variability emphasizes the difficulty in separating transient habit spasms from the Gilles de la Tourette chronic multiple tic syndrome. Isolated and mild but lifelong motor tics probably represent a variant of Tourette syndrome insofar as they display the same predominantly male heredofamilial pattern and similar responses to medication.

An attention-deficit hyperactivity disorder, obsessive–compulsive traits, or both are said to be evident at some time in the course of the illness, and these interfere with progress in school to a greater degree than do the tics. Poor control of temper, impulsiveness, self-injurious behavior, and certain sociopathic traits are seen in a few but by no means all affected children. Evidence of cognitive impairment by psychometric tests was found in 40 to 60 percent of patients in the series reported by Shapiro and colleagues, but intelligence did not deteriorate. Nonspecific abnormalities of the EEG have occurred in more than half of the patients but are not consistent enough to be considered a feature of the disease.

In one-third of the cases, isolated tics were observed in other members of the family (Shapiro and colleagues). Several other studies have reported a familial clustering of cases in which the pattern of transmission appears to be autosomal dominant with incomplete penetrance (Pauls and Leckman) but this has been disputed and several predisposing genes have been found. In any biologic explanation, the marked predominance of males must be explained. Now, Gilles de la Tourette syndrome cannot be attributed to a single genetic locus. Nonetheless, support its genetic nature derives from twin studies, which have revealed higher concordance rates in monozygotic twin pairs than in dizygotic pairs. An ethnic propensity has been reported in Ashkenazi Jews, but this has not been borne out in other large series (Lees et al).

As to causation, little is known. There is no consistent association with infection, trauma, or other disease except the putative connection to streptococcal infections discussed further on. Hyperactive children who have been treated with stimulants appear to be at increased risk of developing or exacerbating tics (Price et al) but a causal relationship has not been established (see comments regarding treatment below). MRI has shown no uniform abnormalities; functional imaging has demonstrated numerous but inconsistent abnormalities. Histopathologic changes have not been discerned in the few brains examined by the usual methods. However, analysis of pre- and postsynaptic dopamine markers in postmortem striatal tissue, found a alteration of dopamine uptake mechanisms (Singer and coworkers 1991); and the differences in D2 dopamine receptor binding in the head of the caudate nucleus reflect differences in the phenotypic severity of Gilles de la Tourette syndrome (Wolf and colleagues). These observations, coupled with the facts that L-dopa exacerbates the symptoms of the syndrome and that haloperidol, which blocks dopamine (particularly D2) receptors, is an effective treatment, support a dopaminergic

abnormality in the basal ganglia, more specifically in the caudate. In this respect, instances of compulsive behavior in relation to lesions in the head of the caudate nucleus and its projections from orbitofrontal and cingulate cortices may be pertinent.

Treatment

For delimited and benign tics, treatment is generally not necessary. Reassurance of the parents can be very helpful. Isolated or infrequent nonintrusive, motor tics in males beyond adolescence, generally an inherited trait, is often aided by clonazepam but may require some of the more potent medications named above.

Two classes of drugs are used in treatment of intractable and multiple tics; alpha agonists and antipsychosis medications. The alpha-2-adrenergic agonists, clonidine and guanfacine, have been useful in several studies. These are not as potent as treatment with neuroleptic drugs, but their side effects are less severe, and they are recommended as the first treatment. Guanfacine has the advantage over clonidine of daily dosing and less sedating effect. The initial dose is 0.5 to 1 mg given at bedtime and gradually increased as needed to a total dose of 4 mg. Clonidine is started as a bedtime dose of 0.05 mg and increased every several days by 0.05 mg until a total dose of about 0.1 mg three times daily. The neuroleptics haloperidol and pimozide (and less frequently used sulpiride and tiapride) have proved to be effective therapeutic agents but should be used only in severely affected patients and usually after the adrenergic agents have been tried. Haloperidol is instituted in small doses (0.25 mg initially, increasing the dosage gradually to 2 to 10 mg daily). The atypical neuroleptics, such as risperidone, have also been used with some success. Pimozide, which has a more specific antidopaminergic action than haloperidol, may be more effective than haloperidol; it should be given in small amounts (0.5 mg daily) to begin with and increased gradually to 8 to 9 mg daily. The addition of benztropine mesylate (0.5 mg daily) at the outset of treatment may help to prevent the adverse motor effects of haloperidol. The potent agent tetrabenazine, a drug that depletes monoamines and blocks dopamine receptors, may be useful if high doses can be tolerated. Further details of the use of these drugs can be found in reviews (Leckman and by Kurlan). According to a trial conducted by the Tourette's Syndrome Study Group, the hyperactivity component of Tourette syndrome can be treated safely with methylphenidate or clonidine without fear of worsening the tics.

Another interesting approach has been to inject botulinum toxin in muscles affected by prominent focal tics, including the vocal ones as described by Scott and colleagues; curiously, this treatment is said to relieve the premonitory sensory urge. Deep brain stimulation of thalamic and other nuclei has shown promise in a few small series of drug-resistant cases.

PANDAS Syndrome

Using the model of Sydenham chorea, a recent line of investigation has implicated streptococcal infection in the genesis of abruptly appearing Gilles de la Tourette syndrome and of less-generalized tics in children. This association has been extended by some authors to explain obsessive-compulsive behavior of sudden and unexplained onset. These putative poststreptococcal disorders were summarized by Swedo and colleagues under the acronym PANDAS (pediatric autoimmune neuropsychiatric disorders associated with streptococcal infection). In a few cases, there has been a relapsing course that is like that seen in Sydenham chorea. Two health database studies have suggested a modest association between tic disorder, obsessive-compulsive disorder, and streptococcal infection. These observations taken together are intriguing but not confirmed and several groups have been unable to differentiate patients with PANDAS and Gilles de la Tourette syndrome from controls based on epidemiologic factors or serum autoantibodies to streptococcus (Singer et al, 2005; Schrag et al).

Akathisia

This term was coined by Haskovec in 1904 to describe an inner feeling of restlessness, an inability to sit still, and a compulsion to move about. When sitting, the patient constantly shifts his body and legs, crosses and uncrosses his legs, and swings the free leg. Running in place and persistent pacing are also characteristics. This abnormality of movement is most prominent in the lower extremities and may not be accompanied, at least in mild forms of akathisia, by perceptible rigidity or other neurologic abnormalities. In its advanced form, patients complain of difficulty in concentration, distracted, no doubt, by the constant urge to move.

First noted in patients with Parkinson disease and Alzheimer disease, akathisia is now observed most often in patients receiving neuroleptic drugs as a component of tardive dyskinesia or independently. However, this disorder may be observed in psychiatric patients who are receiving no medication. It occurs in both medicated and unmedicated patients with Parkinson disease.

The main diagnostic considerations are an agitated depression, particularly in patients already on neuroleptic medications, and the "restless legs" syndrome—a sleep disorder that may be evident during wakefulness in severe cases (see Chap. 18). Patients with the restless leg syndrome describe a crawling or drawing sensation in the legs rather than an inner restlessness, although both disorders create an irresistible desire for movement. At times these distinctions are blurred.

Many of the medications used for the restless legs syndrome, such as clonazepam, may be tried for akathisia or, if the symptom is a component tardive dyskinesia, selecting a less potent neuroleptic, an anticholinergic medication, amantadine, or a beta-adrenergic–blocking drug.

Ataxia and Disorders of Cerebellar Function

The cerebellum, containing half of the brain's neurons, is primarily responsible for the coordination of movements, especially skilled voluntary ones, the control of posture and gait, and participation in the regulation of muscular tone. In addition, the cerebellum may play a role in the modulation of the emotional state and in special aspects of cognition. The mechanisms by which these functions are accomplished have been the subject of intense investigation by anatomists and physiologists for over 100 years. Their studies have yielded a mass of data, testimony to the complexity of the organization of the cerebellum and its afferent and efferent connections. A reasonably coherent picture of cerebellar function has emerged, and it is possible to relate certain of the symptoms and signs of cerebellar disease to discrete anatomic and functional units.

Knowledge of cerebellar function has been derived mainly from the study of natural and experimental ablative lesions and to a lesser extent from stimulation of the cerebellum, which actually produces little in the way of alteration of movement. None of the motor activities of the cerebellum reaches conscious kinesthetic perception; its main role is instead to modulate willed movements. A fuller account of cerebellar anatomy, physiology, and functioning can be found in monographs and early writings on the subject (Jansen and Brodal, of Gilman, Thach and colleagues) and modern atlases, (Schmahmann and colleagues).

ANATOMIC AND PHYSIOLOGIC CONSIDERATIONS

Early studies of the comparative anatomy and fiber connections of the cerebellum led to its subdivision into three parts (Fig. 5-1 and Table 5-1): (1) The flocculonodular lobe, located inferiorly, is phylogenetically the oldest (hence its former designation as archicerebellum). It is separated from the main mass of the cerebellum, the cerebellar hemispheres, by the posterior fissure. (2) The anterior lobe, or paleocerebellum, which is the portion rostral to the primary fissure. In lower animals, the anterior lobe constitutes most of the cerebellum, but in humans it is relatively small, consisting of the anterosuperior vermis and the contiguous paravermian cortex. (3) The posterior lobe, or neocerebellum, consisting of the middle divisions of the vermis and their large lateral extensions. The major portion of the cerebellum, the cerebellar hemispheres, falls into this subdivision.

The cerebellum is connected to the brain through three paired peduncles: the *superior*, which is efferent with the exception of the ventral spinocerebellar and tectocerebellar tracts; the *middle*, which contains the main input to the cerebellum from the pons; and the *inferior*, through which the vestibular and spinal input enters the cerebellum. The posterolateral walls of the fourth ventricle are bounded by these peduncles (Fig. 5-2 and Table 5-2).

The anatomic subdivision of the cerebellum corresponds roughly with its functional organization and with the arrangement of its afferent fiber connections. The flocculonodular lobe receives special proprioceptive impulses from the vestibular nuclei and is therefore also referred to as the vestibulocerebellum; it is concerned essentially with equilibrium and stability of eye movements. The anterior vermis and part of the posterior vermis are referred to as the spinocerebellum, since the afferent projections to these parts derive mostly from the proprioceptors of muscles and tendons in the limbs, conveyed to the cerebellum in the dorsal spinocerebellar tract (from the lower limbs) and the ventral spinocerebellar tract (upper limbs). The main Influences of the spinocerebellum appear to be on posture and muscle tone. The neocerebellum derives its afferent fibers indirectly from the cerebral cortex via the pontine nuclei and through the middle cerebellar peduncles (brachium pontis). This portion of the cerebellum is concerned primarily with the coordination of skilled movements including articulation that are initiated at a cerebral cortical level.

Largely based on ablation experiments in animals, three characteristic physiologic patterns corresponding to these major divisions of the cerebellum have been delineated. Lesions of the nodulus and flocculus (flocculonodular lobe) in animals produce a disturbance of equilibrium and frequently with nystagmus and related eye movement disorders; individual movements of the limbs are not affected. Anterior lobe ablation in primates results in increased shortening and lengthening reactions (the reactions of the muscle to passive flexion or extension at a joint), somewhat increased tendon reflexes, and an exaggeration of the postural reflexes, particularly

the "positive supporting reflex," which consists of extension of an animal's limb in response to light pressure on the animal's foot pad. Ablation of a cerebellar hemisphere in cats and dogs yields inconsistent results, but in monkeys it causes hypotonia and clumsiness of the ipsilateral limbs; if the dentate nucleus is included in the ablation, these abnormalities are more enduring and the limbs also show an ataxic, or "intention" tremor, which is a characteristic feature of lesions of a cerebellar hemisphere.

The cerebellum is organized into longitudinal (sagittal) rather than transverse zones. The three longitudinal zones are—the vermian, paravermian or intermediate, and lateral—but there is considerable overlap between them. Based on investigations in cats, the vermian zone coordinates movements of the eyes and body with respect to gravity, and movement of the head in space (Sprague and Chambers). The intermediate zone, which receives both peripheral and central projections (from motor cortex), influences postural tone and individual movements of the ipsilateral limbs. The lateral zone is concerned mainly with coordination of movements of the ipsilateral limbs but is also involved in other functions.

Table 5-2

THE CEREBELLAR PEDUNCLES

CEREBELLAR PEDUNCLE	AFFERENT PATHWAYS (INTO CEREBELLUM)	EFFERENT PATHWAYS (FROM CEREBELLUM)
Superior	Ventral spinocerebellar tract[a] and tectocerebellar tract[a]	Cerebellothalamic, cerebellorubral, cerebelloreticular, and cerebellovestibular fibers
Middle	Pontocerebellar fibers[a]	None
Inferior	Dorsal and cuneo spinocerebellar tract[a] Contralateral inferior olive[b]	None

[a]Via mossy fibers.
[b]Via climbing fibers.

Cerebellar connections to the main motor pathways

A major circuit comprising direct connections from cerebellar cortex to dentate nucleus to ventral thalamus to cerebral motor cortex brings cerebellar function into direct relation to voluntary movement of the ipsilateral limbs, a cardinal feature of cerebellar function. The efferent fibers of the cerebellar cortex, which consist essentially of the axons of Purkinje cells in both humans and animals, project onto the deep cerebellar nuclei (see later). The projections from Purkinje cells are inhibitory whereas those from the nuclei are excitatory on other parts of the motor nervous system. Cells of the vermis project mainly to the fastigial nucleus; those of the intermediate zone, to the globose and emboliform nuclei (that are combined in humans as the interpositus, or "interposed" nucleus); and those of the lateral zone, to the dentate nucleus (Jansen and Brodal).

The deep cerebellar nuclei, in turn, send project excitatory fibers to thalamic and brainstem nuclei via two main pathways: fibers from the dentate and interposed nuclei form the superior cerebellar peduncle, enter the upper pontine tegmentum as the brachium conjunctivum, decussate at the level of the inferior colliculus, and ascend to the ventrolateral nucleus of the thalamus and, to a lesser extent, to the intralaminar thalamic nuclei (Fig. 5-3). Some of the ascending fibers, soon after their decussation, synapse in the red nucleus, but most of them traverse this nucleus without terminating, and pass on to the thalamus. Ventral thalamic nuclear groups that receive these ascending efferent fibers project to the supplementary motor cortex of that side. Since the pathway from the cerebellar nuclei to the thalamus and then on to the motor cortex is crossed, and the connection from the motor cortex through the corticospinal tract is again crossed, a fundamental feature of cerebellar function is that a lesion in one cerebellar

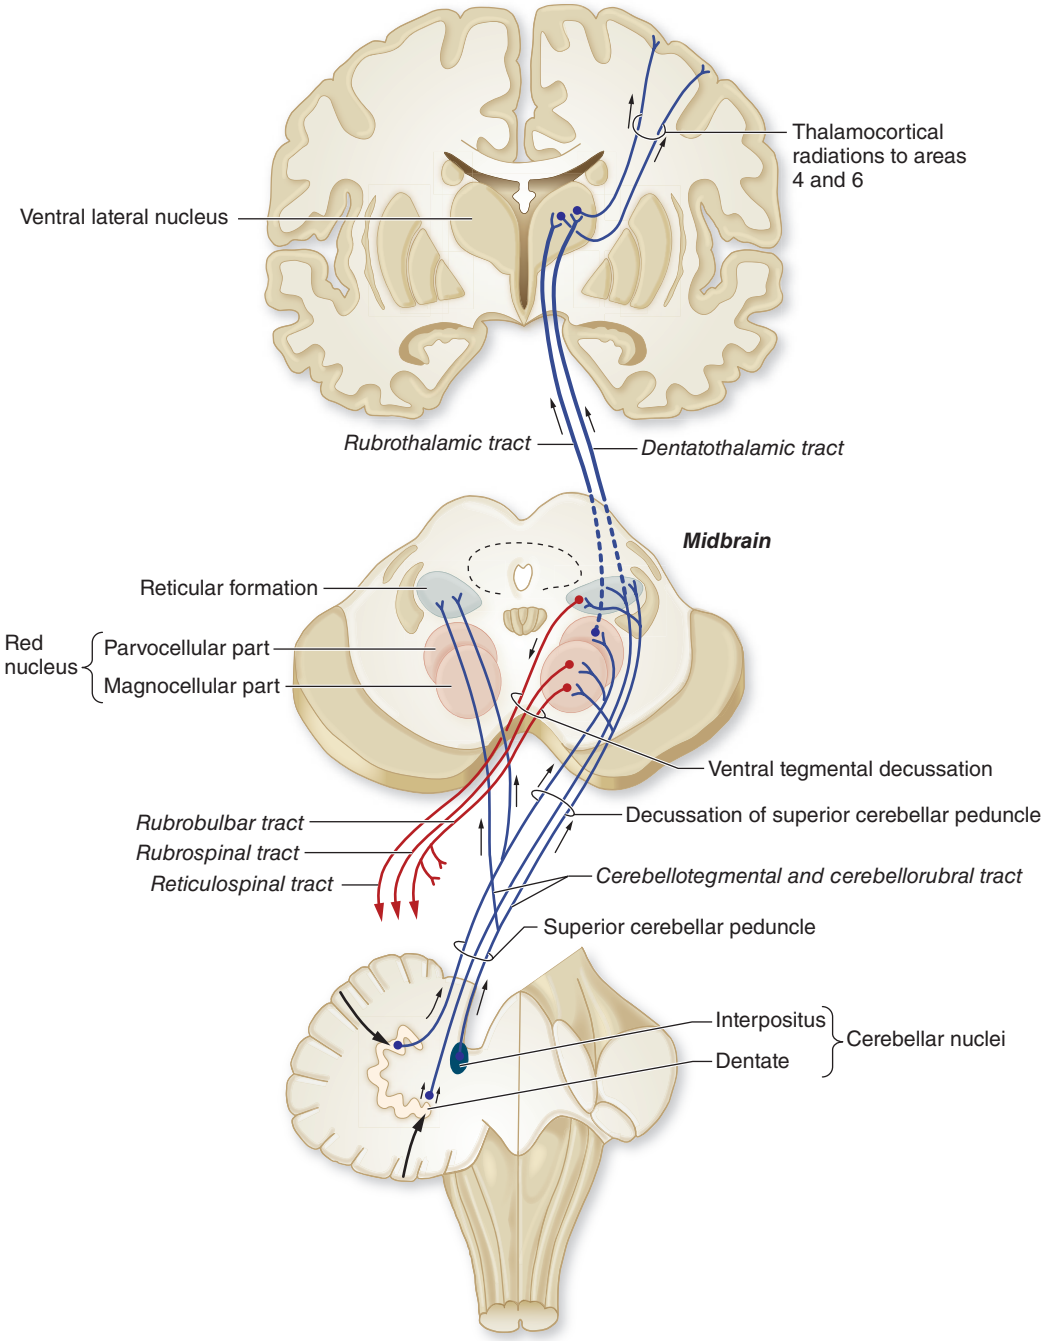

Figure 5-3. Cerebellar projections to the red nucleus, thalamus, and cerebral cortex. Ascending tracts are red and descending tracts are blue. Note that all efferent fibers leaving the cerebellum exit through the superior cerebellar peduncle. (Reproduced with permission from House EL et al: *A Systematic Approach to Neuroscience,* 3rd ed. New York: McGraw-Hill, 1979.)

hemisphere cause incoordination on the ipsilateral side of the body.

Another loop, called the Guillain-Mollaret, or Mollaret, triangle, is of clinical interest. A small group of fibers of the superior cerebellar peduncle, following their decussation, synapse in the red nucleus and then descend via the central tegmental fasciculus in the ventromedial tegmentum of the brainstem, terminating in the inferior olivary nuclei of the medulla. The olivary nuclei, in turn, project via the opposite inferior cerebellar peduncle back to the cerebellum, mainly the anterior lobe, thus completing a cerebellar–reticular–cerebellar feedback system (Fig. 5-4). The clinical syndrome of oculopalatal tremor (see later) results from lesions in the central tegmental fasciculus component of this circuit. Another result of interrupting this circuit, particularly of the central tegmental fasciculus is peculiar hypertrophy of the inferior olivary nucleus on the same side.

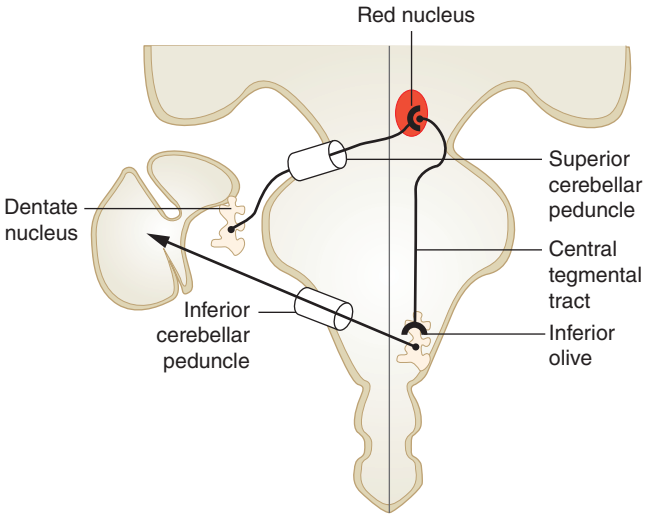

Figure 5-4. The Guillain-Mollaret triangle connecting the red nucleus, inferior olive, and contralateral dentate nucleus.

The fastigial nucleus sends fibers to the vestibular nuclei of both sides and, to a lesser extent, to other nuclei of the reticular formation of the pons and medulla. There are also direct fiber connections with the alpha and gamma motor neurons of the spinal cord. The inferior olivary nuclei, as mentioned, project via the restiform body (inferior cerebellar peduncle) to the contralateral cerebellar cortex and corresponding parts of the deep cerebellar nuclei.

In summary, the cerebellum influences motor activity through its connections with the motor cortex and brainstem nuclei and their descending motor pathways (Evarts and Thach). Chapter 4 details the integration of basal ganglionic influences with those of the cerebellum by their confluence in the anterior thalamic nuclei.

Somatotopic organization of the cerebellum Experimental observations suggest that the cerebellar cortex is somatotopically organized, but not in the same manner as the motor cortices of the cerebral hemispheres. Curiously, stimulation of the cerebellar cortex does not produce movement of body parts. Moreover, modulation of movement of body parts is not represented in a continuous fashion in the cerebellar cortex and instead corresponds to small discontinuous patches. There is an approximate motor specificity in that the legs, trunk, and gait are affected in a restricted fashion with lesions of the vermis and coordination of limb movements is affected by lesions of the cerebellar hemispheres, but this does not simulate the refined organization observed in the cerebrum that is represented as a homunculus distributed over the primary motor cortices. However, there is a somatotopic organization of sensory representation of sorts in the cortex of the cerebellar hemispheres that maps peripheral sensory stimuli to corresponding sites of the cerebellar cortex in animals and probably in humans. Published diagrams of the cerebellum with an overlaid homunculus therefore reflect sensory, not motor, topographic organization (Manni and Petrosini).

Deep Cerebellar Nuclei The physiologic role of the deep cerebellar nuclei has been studied by focal cooling of each structure during a projected movement in the macaque. These observations, coupled with established anatomic data, permit several conclusions. The dentate nucleus receives information indirectly from the premotor and supplementary motor cortices via the pontocerebellar system and helps to initiate volitional movements. These movements are accomplished via efferent projections from the dentate nucleus to the ventrolateral thalamus and motor cortex through the circuit described earlier. The dentatal neurons have been shown to fire just before the onset of volitional movements and inactivating these neurons delays the initiation of such movements. The interpositus nucleus also receives projections from the cortex via the crossed pontocerebellar fibers; in addition, it receives spinocerebellar projections via the intermediate zone of the cerebellar cortex. The spinocerebellar projections convey information from Golgi tendon organs, muscle spindles, cutaneous afferents, and spinal cord interneurons involved in the movement. The interpositus nucleus fires in relation to a movement once it has started. Also, the interpositus nucleus appears to be responsible for making volitional oscillations (alternating movements). Its cells fire in tandem with these actions and the regularity and amplitude of movements become impaired when these cells are inactivated. In addition, the nucleus interpositus normally damps physiologic tremor and plays a part in the genesis of intention tremor. The fastigial nucleus receives projections from the spinocerebellar fibers and, like the interpositus, projects to the vestibular nuclei. It controls antigravity and other muscle synergies in standing and walking; ablation of this nucleus greatly impairs these motor activities.

There are complex physiologic relationships among the deep nuclei. Cerebellar cortical regions generally have inhibitory influences on the deep nuclei as already mentioned. The flocculonodular lobe has among the most complex influences, being inhibitory to the fastigial nucleus but also projecting directly in an inhibitory manner to the lateral vestibular (Deiters) nucleus. The vestibular nuclei, and in particular the lateral one, may be considered the equivalent of a deep cerebellar nucleus.

Neuronal Organization of the Cerebellar Cortex

Coordinated and fluid movements of the limbs and trunk result from a neuronal organization within the cerebellum that permits ongoing and almost instantaneous comparison between desired and actual movements while the movements are being carried out. An enormous number of neurons are committed to these tasks, as attested by the fact that the cerebellum contributes only 10 percent to the total weight and volume of the brain but contains half of the brain's neurons. It has been correspondingly estimated that there are 40 times more afferent axons than efferent axons in the various cerebellar pathways—a reflection of the enormous amount of incoming (sensory) information that is required for the control of motor function.

The cerebellar cortex is configured as a stereotyped three-layered structure, the molecular, Purkinje, and granular layers, that together contain five types of

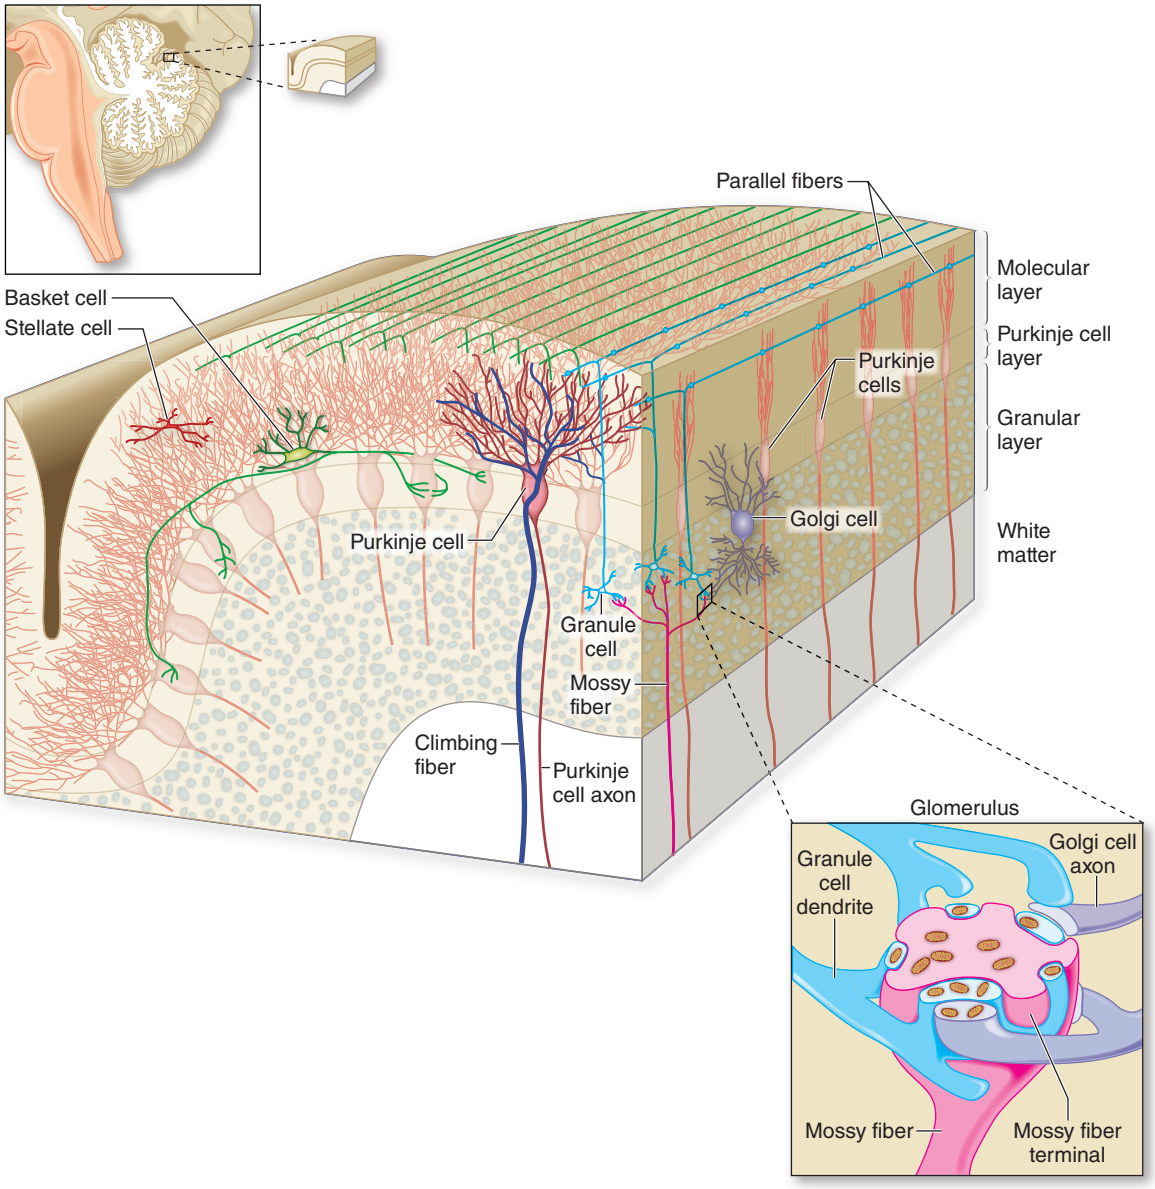

Figure 5-5. Anatomic organization of the cerebellar cortex in a longitudinal and transverse section of a folium. Shown are the relationships between (a) climbing fibers and Purkinje cells, (b) mossy fibers and both granule cells and Golgi cells, and (c) the parallel fibers that course longitudinally and connect these three main cell types. (Reproduced with permission from Kandel ER, Schwartz JH, Jessel TM. *Principles of Neural Science*, 5th ed. New York: McGraw-Hill; 2013.)

neurons (Fig. 5-5). In its relatively regular geometry, the cerebellar cortex is similar to the columnar architecture of the cerebral cortex but it differs in having a much greater degree of intracortical feedback between neurons and input fibers. The outermost molecular layer of the cerebellum contains two types of inhibitory neurons, the stellate cells and the basket cells. They are interspersed among the dendrites of the Purkinje cells, the cell bodies of which lie in the underlying layer. The Purkinje cell axons constitute the main output of the cerebellar cortex, which is directed at the deep cerebellar and vestibular nuclei described above. Purkinje cells are, as mentioned earlier, entirely inhibitory and utilize the neurotransmitter gamma-aminobutyric acid (GABA). The innermost granular layer contains an enormous number of densely packed granule cells and a few larger Golgi interneurons. Axons of the granule cells travel long distances as parallel fibers, which are oriented along the long axis of the folia and form excitatory synapses with Purkinje cells. Each Purkinje cell is influenced by as many as a million granule cells to produce what has been termed physiologically a "simple spike," in contrast to the complex spike noted below.

Cerebellar input pathways The predominant afferent inputs to the cerebellum are via mossy fibers, which comprise the axons of the spinocerebellar tracts, and via the projections from pontine, vestibular, and reticular nuclei.

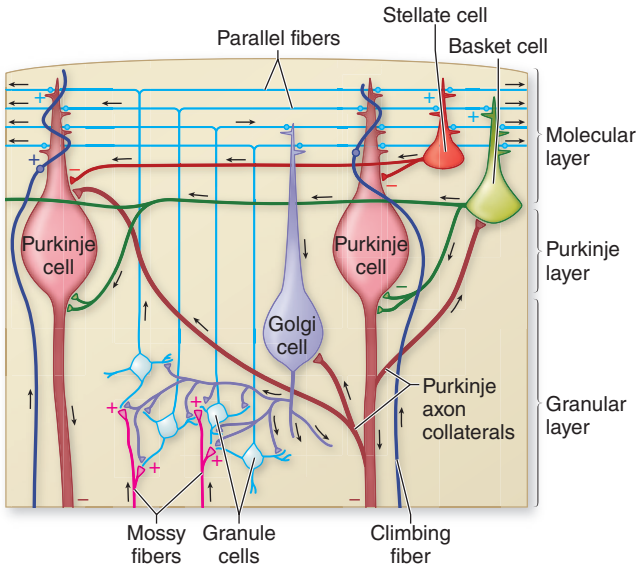

Figure 5-6. The physiologic organization of the cerebellum. The main input into the cerebellum is via mossy fibers from various sources and via climbing fibers from the contralateral inferior olive. Both are excitatory. Mossy fibers synapse on granule cells, whose axons form the parallel fibers in the molecular layer. These axons synapse with Purkinje cells and also with stellate and basket cells that inhibit nearby Purkinje cells. Further modulation occurs via a recurrent loop made by Golgi cells, whose dendrites lie in the molecular layer and whose axons synapse on granule cells. Output from the cerebellar cortex has an inhibitory effect on the deep cerebellar nuclei. This output is modulated by climbing fibers that synapse directly on Purkinje cell dendrites. (Reprinted by permission from Springer Nature: Nature. Experimental Brain Research. Intracellularly recorded responses of the cerebellar Purkinje cells, Prof. Sir J. C. Eccles et al. © 1966.)

They enter through all three cerebellar peduncles, but mainly the middle (pontine input) and inferior (vestibulocerebellar) ones. Mossy fibers ramify in the granule layer and excite Golgi and granule neurons through special synapses termed cerebellar glomeruli. The other main afferent input is via the climbing fibers, which originate in the inferior olivary nuclei (olives) and communicate somatosensory, visual, and cerebral cortical signals (Figs. 5-5 and 5-6). The climbing fibers, so named because of their vinelike configuration around Purkinje cells and their axons, preserve a topographic arrangement from olivary neuronal groups; a similar topographic arrangement is maintained in the Purkinje cell projections. The climbing fibers have specific excitatory effects on Purkinje cells that result in prolonged "complex spike" depolarizations. The firing of stellate and basket cells is facilitated by the same fibers that excite Purkinje cells, and these smaller cells, in turn, inhibit the Purkinje cells. These reciprocal relationships form the feedback loops that permit the exquisitely delicate inhibitory smoothing of limb movements that are lost when there is cerebellar injury.

The uniform cortical structure of the cerebellum could reasonably lead to the notion that the organ has similar effects on all parts of the cerebrum to which it projects (cortex, basal ganglia, thalamus, etc.). It would follow that the activities of these cerebral structures (motor, cognitive, sensory) may be modulated in similar ways by cerebellar activity but this is only partly true as the picture is more complex and not entirely elucidated in humans.

Neurochemical Considerations

A number of biochemical aspects of cerebellar function are of interest. Four of the five cell types of the cerebellar cortex (Purkinje, stellate, basket, Golgi) are inhibitory; the granule cells are an exception and are excitatory. Afferent fibers to the cerebellum are of three types, two of which have been mentioned above: (1) Mossy fibers, which are the main afferent input to the cerebellum, utilize aspartate; (2) Climbing fibers, which are the axons of cells in the inferior olivary nucleus and project to the Purkinje cells of the opposite cerebellar hemisphere. The neurotransmitter of the climbing fibers is probably glutamate, which acts on amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors; (3) Aminergic fibers, which project through the superior cerebellar peduncle and terminate on the Purkinje and granule cells in all parts of the cerebellar cortex. They are of two types: dopaminergic fibers, which arise in the ventral mesencephalic tegmentum and project to the interpositus and dentate nuclei and to the granule and Purkinje cells throughout the cortex, and serotonergic neurons, which are located in the raphe nuclei of the brainstem and project diffusely to the granule cell and molecular layer. The granule cell axons elaborate the excitatory transmitter glutamate. All the inhibitory cerebellar cortical neurons appear to utilize GABA. The neurotransmitters of the deep nuclei have not been fully elucidated.

CLINICAL FEATURES OF CEREBELLAR DISEASE

The disturbances of movement and posture that result from lesions of the cerebellum are part of the canon clinical neurology. Trying to capture the role of the cerebellum attracted the attention of many great neurologists of the past, who resorted to metaphorical and sometimes colorful, descriptions. For Babinski, the essential function of the cerebellum was the orchestration of muscle synergies in the performance of voluntary movement. A loss or impairment of this function—that is, asynergia or dyssynergia—resulted in irregularity or fragmentation of the normal motor sequences involved in any given act. This deficit, most apparent in the execution of rapid alternating movements, was referred to by Babinski as dys- or adiadochokinesis, as discussed below. He also pointed out that this was accompanied by certain maladjustments of stance and by catalepsy (perseveration of a posture), features that are no longer considered prominent by modern observers.

Holmes summarized the effects of cerebellar disease as being in the acceleration and deceleration of movement. We are attracted to his summary of these as defects in the *rate, range*, and *force* of movement, resulting in an undershooting or overshooting of the target. He used the term "decomposition" to describe the fragmentation of a smooth movement into a series of irregular, jerky components. The terminal tremor of cerebellar disease,

traditionally called intention tremor, and the inability to check the displacement of an outstretched limb, elegantly described by Holmes, he attributed to hypotonia, a mechanism no longer accepted.

Parts of the hypotheses of both Babinski and Holmes have been sustained by modern physiologic and clinical studies. In an analysis of rapid (ballistic) movements, Hallett and colleagues have demonstrated that with cerebellar lesions, there is a prolongation of the interval between the commanded act and the onset of movement. More prominently, there is a failure of the normal ballistic, triphasic agonist–antagonist–agonist motor sequence of voluntary movements, referred to in Chaps. 3 and 4. The agonist burst may be too long, too short, or continue into the antagonist burst, resulting in excessive agonist–antagonist cocontraction at the onset of movement. These findings may explain what was described by Babinski and Holmes as asynergia, decomposition of movement, but they more certainly explain dysmetria. These fundamental abnormalities in the timing and amplitude of reciprocal inhibition and of cocontraction of agonist–antagonist muscles are particularly evident in pluriarticular movements (Diener and Dichgans).

As mentioned, the symptoms produced in animals by ablation of discrete anatomic or functional zones of the cerebellum bear only an imperfect relationship to the symptoms of cerebellar disease in humans. This is understandable for several reasons. Most of the lesions that occur in humans do not respect the boundaries established by anatomists. Even with lesions that are more or less confined to discrete functional zones (e.g., flocculonodular lobe, anterior lobe), it is difficult to identify the resultant clinical syndromes with those produced by ablation of analogous zones in cats, dogs, and even monkeys, indicating that the functional organization of these parts varies from species to species.

Clinical observations affirm what was stated above—that lesions of the cerebellum in humans give rise to the following abnormalities: (1) incoordination (ataxia) of volitional movement; (2) a characteristic tremor ("intention," or ataxic tremor, by which is meant a side-to-side oscillation as movement approaches a target), described in detail in Chap. 4; (3) disorders of equilibrium and gait; (4) diminished muscle tone, particularly with acute lesions; (5) dysarthria, which is probably predicated on incoordination of the muscles of articulation that is analogous to derangements of limb movement; (6) impaired ocular pursuit, inaccurate saccades, and nystagmus.

Extensive lesions of one cerebellar hemisphere, especially of the anterior lobe, cause ataxia of the ipsilateral arm and leg for reasons discussed earlier in relation to the double-crossing of cerebellar cortical to cerebral cortical pathways. Lesions of the deep nuclei and cerebellar peduncles have the same effects as extensive hemispheric lesions. If the lesion involves a limited portion of the cerebellar cortex and subcortical white matter, there may be surprisingly little disturbance of function, or the abnormality may attenuate with the passage of time. For example, a congenital developmental defect or an early life cortical atrophy of half of the cerebellum may produce no clinical abnormalities. Lesions involving the superior cerebellar peduncle or the dentate nucleus cause the most severe and enduring cerebellar symptoms, which manifest mostly as ataxia in the ipsilateral limbs. Disorders of stance and gait depend more on vermian than on hemispheral or peduncular involvement. Damage in the inferior cerebellum causes vestibulocerebellar symptoms—namely dizziness, vertigo, vomiting, and nystagmus—in varying proportions. These symptoms often share with disturbances of the vestibular system the feature of worsening of symptoms with changes in head position.

Ataxic Incoordination

The most prominent manifestation of cerebellar disease is ataxia, the incoordination of intended (volitional) movement. The terms dyssynergia, dysmetria, and dysdiadochokinesis have come into common usage to describe these abnormalities of movement. Holmes's characterization of abnormalities in the rate, range, and force of movement, as mentioned earlier, is less confusing. These signs are brought out by standard neurologic tests, including finger-to-nose and toe-to-finger movement, running the heel down the opposite shin, or tracing a square in the air with a hand or foot. In performing these maneuvers, the patient should be asked to move the limb to the target accurately and rapidly.

The speed of initiating movement and force of movement are impaired in cerebellar disease. But the most arresting feature is irregularity of the movement itself, in both acceleration and deceleration that become particularly prominent as the finger or toe approaches a target. All the foregoing defects in volitional movement are also evident in acts that require alternation or rapid change in direction of movement, such as pronation–supination of the forearm or successive touching of each fingertip to the thumb. The normal rhythm of these movements is interrupted by irregularities of force and speed. Even a simple movement may be fragmented ("decomposition" of movement), each component being executed with greater or lesser force than is required. These abnormalities together impart a highly characteristic clumsiness to the cerebellar syndromes, an appearance that is not simulated by the weakness of upper or lower motor neuron disorders or by diseases of the basal ganglia.

The excursion of the limb may be arrested prematurely, and the target is then reached by a series of jerky movements. In contrast, the limb may overshoot the mark (hypermetria) because of delayed activation and diminished contraction of antagonist muscles; then the error is corrected by a series of secondary movements in which the finger or toe sways around the target before coming to rest, or moves from side to side a few times on the target itself. This side-to- side movement of the finger as it approaches its mark tends to assume a rhythmic quality and has traditionally been referred to as intention tremor, or ataxic tremor. The tremor is mainly perpendicular to the trajectory of movement and mostly in the horizontal plane. The term "intention" as applied to cerebellar tremor, while embedded in neurologic parlance, does not fully capture the necessity for the limb to be in action rather

than for the patient to "intend" a movement for the tremor to be manifest. "Action tremor," however, has been used for an entirely different category of oscillations, as discussed in Chap. 4. "Ataxic tremor" may be the preferable term.

In addition to intention tremor, there may be a separate coarse, irregular, wide-range tremor that may be present whenever the patient activates limb muscles, either to sustain a posture or to effect a large amplitude proximal movement. It is traditionally elicited by having the patient hold the arms out to the sides with elbows bent (causing a "wing-beating tremor"). Holmes called it rubral tremor; although the red nucleus may be the site of the lesion, the nucleus itself is not necessarily involved. Instead, it is a result of interruption of the fibers of the superior cerebellar peduncle as they traverse the red nucleus, for which reason a better description may be cerebellar outflow tremor." Lesions anywhere along bundle of fibers in the superior cerebellar peduncle cause the same tremor and, if unilateral, involve only the ipsilateral limbs. Also, with certain sustained postures (e.g., with arms extended or hands on knees), the patient with cerebellar disease may develop a rhythmic oscillation of the fingers having much the same tempo as a parkinsonian tremor. A rhythmic tremor of the head or upper trunk (3 to 4 per second) called titubation, mainly in the anteroposterior plane, often accompanies midline (vermian) cerebellar disease, but may also be a manifestation of essential tremor.

Cerebellar Dysarthria

Cerebellar lesions commonly give rise to a disorder of articulation, which may take one of two forms: either a slow, slurring dysarthria or a scanning dysarthria with variable intonation, so-called because words are broken up into syllables that are irregularly and over-forcefully issued, as when a line of poetry is scanned for meter. Typical cerebellar speech simulates the abnormality of limb movements in that the rhythm and amplitude of phonation and articulation are irregular, imparting a pattern that is distinguishable from spastic and extrapyramidal speech and may be so severe as to be incomprehensible. The scanning pattern of speech disorder is uniquely cerebellar. In addition to its scanning quality, scanning speech is slow, and each syllable, after an involuntary interruption, may be uttered with less force or more force ("explosive speech") than is natural. The scanning and slurred patterns may be combined. It has been deduced from cases of cerebellar infarction that the articulatory muscles are controlled from the rostral paravermian area of the anterior lobe, and this area is affected in most cases with dysarthria (Urban et al).

Cerebellar Eye Movement Abnormalities

Ocular movement may be altered as a result of cerebellar disease, specifically if vestibular connections are involved (Thach and Montgomery). The essential abnormality of eye movements in disease of the cerebellar hemispheres is what might be termed ataxia of eye movements. Patients with cerebellar lesions are unable to hold eccentric positions of gaze, resulting in nystagmus. Smooth pursuit movements are slower than normal and require that the patient make small "catch-up" saccades in an attempt to keep the moving target near the fovea. Saccades are also inaccurate, with the eyes often overshooting the target and making a corrective movement, sometimes oscillating through several corrective cycles until fixation is attained. These nystagmoid abnormalities, similar to those of speech, resemble the abnormalities of ataxic movements of the limbs. Skew deviation (supranuclear vertical misalignment of the eyes), vertical nystagmus, ocular flutter, and ocular myoclonus (opsoclonus) may also be the result of cerebellar disease; these abnormalities and other effects of cerebellar lesions on ocular movement are discussed in Chap. 13.

Disorders of Equilibrium and Gait

The patient with cerebellar disease has variable degrees of difficulty in standing and walking, as described more fully in Chap. 6. Standing with feet together may be impossible or maintained only briefly before the patient pitches to one side or backward. Closing the eyes may worsen this difficulty, but the Romberg sign (which signifies impaired proprioceptive input) is not dramatically evident in cerebellar disease if the patient is allowed to steady himself before closing his eyes. In walking, the patient's steps are uneven and placement of each foot is inconsistent, resulting in unexpected lurching, usually most apparent during turns. Walking with feet in tandem that is, on a straight line, becomes impossible as the patient falls off to one side or the other and makes forceful footfalls to steady himself. Yet, there is minimal complaint of dizziness.

The disequilibrium syndrome with normal movements of the limbs corresponds more closely with lesions of the anterior vermis than with those of the flocculus and nodulus (essentially, the posterior vermis). This statement is based in part on the study of vermian atrophy in cerebellar degeneration in alcoholics (see Chap. 41). In more severely affected patients, who also manifest impaired coordination of the limbs, the changes extend laterally from the vermis, involving the anterior portions of the anterior lobes when the legs are affected and more posterior portions of the anterior lobes when the arms are affected.

The point to be made is that midline anterior cerebellar lesions may produce solely a disorder of stance and gait, that is, nystagmus, dysarthria, and limb ataxia are absent. The entire problem may be missed if the examination does not include an assessment of the patient's ability to stand and walk.

Hypotonia

This refers to a decrease in the normal resistance that is offered by muscles to passive manipulation. It is the least conspicuous of the cerebellar signs of disease but may explain certain clinical features of the ataxic syndrome. As mentioned earlier, Holmes believed that hypotonia was a fundamental defect in cerebellar disease, accounting not only for the defects in postural fixation but also for certain elements of ataxia and the tremor.

Hypotonia is much more apparent with acute than with chronic cerebellar lesions and may be demonstrated

in a number of ways but admittedly, these are no longer incorporated into the standard neurologic examination. A conventional test is to tap the wrists of the outstretched arms and to detect a displacement through a wider range than normal in the affected limb (or both limbs in diffuse cerebellar disease), sometimes causing the limb to oscillate; this is presumably the result of a failure of the hypotonic muscles to fixate the arm at the shoulder. Another test for hypotonia is to shake the affected limb and demonstrate that the flapping movements of the hand are of wider excursion than normal. If the patient places his elbows on the table with the arms flexed and the hands are allowed to hang limply, the hand of the hypotonic limb will sag. If the standing patient is rotated to and fro at the shoulders, the hypotonic arm will be seen to continue to swing after the other has come to rest. Holmes also attributed pendular knee jerks to hypotonia. Babinski also was impressed with gross alterations of posture related to hypotonia. These take the form of extension of the neck and involuntary bending of the knees, which are apparent when the patient first stands or by slight slumping of the shoulder on the affected side.

Failure to check a movement is probably a related phenomenon. After strongly flexing one arm against a resistance that is suddenly released, the patient may be unable to check the flexion movement, to the point where the arm may strike the face. Patients with these abnormalities of tone may show little or no impairment of motor power, indicating that the maintenance of posture involves more than the voluntary contraction of muscles. It has been stated by some authors that there is a slight loss of muscular power and fatigability of muscle (asthenia) with acute cerebellar lesions. Insofar as these symptoms cannot be explained by other disturbances of motor function, they may be regarded as primary manifestations of cerebellar disease, but they are never severe or persistent and are of little clinical importance; anything approaching a hemiparesis in distribution or severity is not attributable to cerebellar disease.

Myoclonic movements—that is, brief (50 to 100 ms), random contractions of muscles or groups of muscles—are, in some disease processes, combined with cerebellar ataxia. When multiple myoclonic jerks mar a volitional movement, they may be mistaken for an ataxic tremor. Action myoclonus may be the principal residual sign of postanoxic encephalopathy, referred to as the Lance-Adams syndrome and discussed further in Chap. 39. It has been proposed that this condition has a cerebellar origin. Myoclonus is described more fully in Chap. 4, where it is pointed out that it more often has its origin in diseases of the cerebral cortex.

Cognitive Features of Cerebellar Disease

In addition to its motor functions, it has been established that the cerebellum participates in certain aspects of cognitive function and behavior (see the reviews by Schmahmann and Sherman and by Leiner et al). A wide range of alterations of memory and cognition, language function, and behavior has been described in patients with disease limited to the cerebellum as determined by CT and MRI. It is not entirely clear if there is a uniform clinical pathologic syndrome in which a distinctive group of cognitive–behavioral deficits are related to cerebellar lesions. Our impression is that the most common ones have elements of a frontal lobe dysexecutive syndrome (Chap. 21) Investigations into the cerebral influences of the cerebellum are novel contributions to neurology but may be subtle in the bedside neurologic examination.

Noncerebellar Sources of Ataxia

Several clinical abnormalities simulate the incoordination of cerebellar ataxia, among them myoclonus, spasticity, convulsions, tics, tremors of various types, and psychogenic movement disorders.

Furthermore, diseases other than those of the cerebellum can cause ataxia that closely simulates the cerebellar type. The ataxia of severe sensory neuropathy and neuronopathy, discussed in Chap. 43, and of posterior column or posterior spinal root disease very much simulate cerebellar ataxia. Presumably this is a result of involvement of the large peripheral spinocerebellar afferent fibers that provide rapid feedback of limb position and posture to the cerebellum, but the explanation may be more complex and has been little studied. Tabes dorsalis and sensory ganglionopathy are prime examples of sensory ataxia. While the two forms of ataxia look almost or entirely identical with conventional finger-to-nose and heel-to-shin tests, sensory ataxia can usually be distinguished from cerebellar ataxia by noting of the loss of distal joint position sense, absence of dysarthria or nystagmus, loss of tendon reflexes, and the partial corrective effects of vision on sensory ataxia. In peripheral neuropathy and in spinal cord disease with ataxia, the Romberg sign is invariably present, reflecting parallel dysfunction of large afferent fibers in the posterior columns as in the spinocerebellar tracts; Romberg's sign is not found in lesions of the cerebellar hemispheres except that the patient may initially sway with eyes open, and a bit more with eyes closed.

Similarly, a cerebellar type of tremor reaches an extreme form in the large-fiber polyneuropathy related to antibodies against myelin-associated glycoprotein (anti-MAG), as discussed in Chap. 43. In the Miller Fisher syndrome, which is considered to be a version of acute Guillain-Barré polyneuropathy, sensation is often intact or affected only slightly and the severe ataxia and intention tremor are presumably a result of a selective peripheral disorder of spinocerebellar nerve fibers. Disorders of these same fibers in the spinocerebellar tracts of the spinal cord may produce similar sensory-ataxic effects; subacute compressive lesions such as thoracic meningioma or demyelinating (multiple sclerosis) lesions are the usual causes. Again, there is a prominent Romberg sign. Occasionally, a cerebellar-like tremor in one limb results from a lesion in the dorsolateral cord or roots that presumably interrupts afferent fibers selectively in the spinocerebellar tracts.

Intense vertigo produces a special ataxia of gait and that is distinguished by reeling from side to side and listing to one side, past pointing, and torsional-rotatory nystagmus, as discussed in Chap. 14. The nonvertiginous ataxia

of gait caused by vestibular paresis (e.g., aminoglycoside toxicity) has special qualities, which are described in Chap. 6. Vertigo and cerebellar ataxia may be concurrent, as in some patients with a paraneoplastic disease and in those with infarction of the lateral medulla and inferior cerebellum, in which case it is difficult to determine which of the two structures is at fault. An unusual and transient ataxia of the contralateral limbs occurs acutely after infarction or hemorrhage in the anterior thalamus (thalamic ataxia); in addition to characteristic signs of thalamic damage, there may be an asterixis on the affected side. A lesion of the superior parietal lobule (areas 5 and 7 of Brodmann) rarely results in mild ataxia of the contralateral limbs, a phenomenon that may be attributed to loss of position sense. Finally, there are numerous genetic forms of spinocerebellar ataxia, the archetype being Friedreich's ataxia, in which the spinocerebellar fibers in the cord are atrophied and severe gait and lesser limb ataxia result.

Differential Diagnosis of Cerebellar Disease

In the diagnosis of disorders characterized by generalized cerebellar ataxia affecting limbs, gait, and speech, the mode of onset, rate of development, and degree of permanence of the ataxia are of particular importance, as summarized in Table 5-3. Unilateral ataxia without accompanying signs is most often caused by infarction or tumor in the ipsilateral cerebellar hemisphere or by demyelinating disease affecting cerebellar connections to the brainstem, mainly the superior cerebellar peduncle. Each of the major causes is discussed in an appropriate chapter. In adults, toxic effects of medications, paraneoplastic, and demyelinating cases account for the largest proportion of cases of subacute onset, and hereditary forms are the usual cause of very slowly progressive and chronic ones, particularly if gait is predominantly affected. The last category of genetic ataxias constitutes a large and heterogeneous group for which the mutation has been established in many cases; they are described in Chap. 38.

Table 5-3

DIAGNOSIS OF CEREBELLAR DISEASE

PACE	CAUSES
Acute and transitory	Intoxication with alcohol, sedatives, lithium, phenytoin, or other antiepileptics (Chap. 41) Diamox-responsive episodic ataxia (Chap. 36) Childhood hyperammonemias (Chap. 36) Cytarabine (Ara-C) chemotherapy
Acute and usually reversible	Postinfectious (Chap. 35) Viral cerebellitis (Chap. 32) Myxedema
Acute and enduring	Infarction or hemorrhage Postanoxic cerebellar degeneration Extreme hyperthermia (Chap. 16) Intoxication with mercury compounds or toluene (glue sniffing; spray painting; Chap. 41) Adulterated heroin ("chasing the dragon")
Subacute (over days to weeks)	Paraneoplastic cerebellar degeneration (Chap. 30) Posterior fossa tumors such as medulloblastoma, astrocytoma, hemangioblastoma, and metastasis (Chap. 30) Multiple sclerosis (Chap. 35) Alcoholic–nutritional (Chaps. 40 and 41) Autoimmune damage such as from anti-GAD and anti-VGKC antibody Creutzfeldt-Jakob (prion) disease (Chap. 32) Cerebellar abscess (Chap. 31) Whipple disease (Chap. 31) Celiac disease (gluten enteropathy)
Chronic (over months to years)	Multiple system atrophy (Chap. 38) Friedreich ataxia and other spinocerebellar degenerations (Chap. 38) Hereditary cerebellar degenerations (olivopontocerebellar degenerations; cerebellar cortical degenerations [Chap. 38]) Adult form of fragile X premutation syndrome (Chaps. 37 and 38) Hereditary metabolic diseases (Chap. 36) Childhood ataxias, including ataxia telangiectasia, cerebellar agenesis

Disorders of Stance and Gait

It is interesting to consider that the human bipedal gait is unique among animals. The transition from quadrupedal to bipedal gait created challenges for the nervous system in maintaining upright posture, stability when standing, and a complex righting reflex to avoid falls. A considerable amount of the cerebra is devoted to integrating the visual, proprioceptive, and vestibular information that drive the cortical, spinal, cerebellar, and basal ganglionic motor activities of gait.

The analysis of stance, carriage, and gait is a rewarding exercise; with some experience, the examiner can sometimes reach a neurologic diagnosis merely by noting the manner in which the patient enters the office. Considering the frequency of falls that result from gait disorders and their consequences such as hip fracture and the resultant need for hospital and nursing home care, gait abnormalities are an important subject for all physicians. The substantial dimensions of the social and economic problem of falls and the elderly have been described by Tinetti and Williams.

Certain diseases that affect motor and sensory function manifest themselves most clearly as impairments of stance and locomotion; their evaluation depends on knowledge of the neural mechanisms underlying the uniquely human function of standing and bipedal walking. As important in neurology are the myriad ways that gait can be disordered without implicating any of the elemental aspects of neurologic function; in these, the integrative mechanisms for stable walking and avoidance of falls are affected. Moreover, especially in the elderly, problems with gait and balance are due to two or more disorders and even to aging itself.

NORMAL GAIT

Gait varies considerably from one person to another, and it is a commonplace observation that a person may be identified by the sound of their footsteps, notably by the pace and the lightness or heaviness of tread, and their carriage at a distance, even before the person is recognizable by face. The gaits of men and women differ, a woman's steps being quicker and shorter. Sherlock Holmes expressed pride in his talent for deducing from the manner of gait, an individual's personality and occupation. It is said that Jean-Martin Charcot could often make the correct diagnosis, even before seeing the patient, based on the sound of patient walking down the hallway on the way to the examining room. The changes in stance and gait that accompany aging—the slightly stooped posture and slow, stiff tread as described in Chap. 28—are so familiar that they are not perceived as abnormalities.

The normal gait seldom attracts attention, but it should be observed with care if slight deviations from normal are to be appreciated. The body is erect, the head is straight, and the arms hang loosely and gracefully at the sides, each moving rhythmically forward with the opposite leg. The feet are slightly externally rotated, the steps are approximately equal in length, and the medial malleoli almost touch as each foot passes the other. The medial edges of the heels, as they strike the ground with each step, lie almost along a straight line. As each leg moves forward, there is coordinated flexion of the hip and knee, dorsiflexion of the foot, and a barely perceptible elevation of the hip, so that the foot clears the ground. Also, with each step, the thorax advances slightly on the side opposite the swinging lower limb. The heel strikes the ground first, and inspection of the shoes will show that this part is most subject to wear.

The normal gait cycle, defined as the period between successive points at which the heel of the same foot strikes the ground, is illustrated in Fig. 6-1 (Murray and colleagues, and Olsson). In this figure, the cycle is initiated by the heel strike of the right foot. The stance phase, during which one foot is in contact with the ground, occupies 60 to 65 percent of the cycle. The swing phase begins when the left toes leave the ground. For 20 to 25 percent of the walking cycle, both feet are in contact with the ground (double-limb support). In later life, when the steps shorten and the cadence (the rhythm and number of steps per minute) decreases, the proportion of double-limb support increases (see further on). Surface electromyograms show an alternating pattern of activity in the legs, predominating in the flexors during the swing phase and in the extensors during the stance phase.

When analyzed in greater detail, the requirements for locomotion in an upright, bipedal position may be reduced to the following elements: (1) antigravity support of the body, (2) stepping, (3) the maintenance of equilibrium, and (4) a means of propulsion. Locomotion is impaired

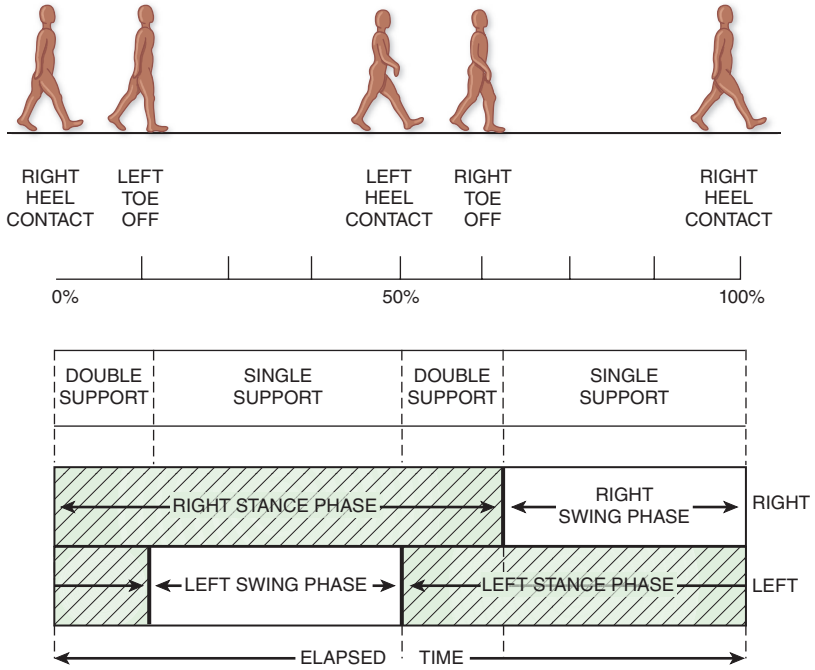

Figure 6-1. The normal gait cycle, based on the studies of Olsson and of Murray and colleagues. See text for details.

in the course of neurologic disease when one or more of these mechanical principles are prevented from operating normally.

The muscles of greatest importance in maintaining the erect posture are the erector spinae and the extensors of the hips and knees. The upright support of the body is provided by righting and antigravity reflexes, which allow a person to arise from a lying or sitting position to an upright bipedal stance and to maintain firm extension of the knees, hips, and back, modifiable by the position of the head and neck. These postural reflexes depend on the afferent vestibular, somatosensory (proprioceptive and tactile), and visual impulses, which are integrated in the spinal cord, brainstem, and basal ganglia. Transection of the neuraxis between the red and vestibular nuclei leads to exaggeration of these antigravity reflexes—decerebrate rigidity.

Stepping, the second element of the gait cycle, is a basic movement pattern present at birth and integrated at the spinal, midbrain, and diencephalic levels. It is elicited by contact of the sole with a flat surface and a shifting of the center of gravity—first laterally onto one foot, allowing the other to be raised, and then forward, allowing the body to move onto the advancing foot. Rhythmic stepping movements can be initiated and sustained in decerebrate or "spinal" cats and dogs. This is accomplished in animals through the activity of interneurons that are organized as rhythmic "locomotor generators," akin to the pattern generators that permit the rhythmic movement of wings or fins. There is no clear evidence for a similar system of locomotor control in primates including humans. There are poorly localized spinal mechanisms for walking in humans, but they cannot produce the act of walking, and they require descending control from vaguely defined higher centers. These higher areas are located in the caudal midbrain tegmentum and pontine reticular formation (in or near the pedunculopontine nucleus); they control the spinal gait mechanisms through the reticulospinal, vestibulospinal, and tectospinal pathways in the ventral cord (Eidelberg and colleagues and Lawrence and Kuypers).

Moreover, these brainstem locomotor regions are activated by frontal cortical areas that are absolutely integral to initiating and engaging the gait cycle. Although a discrete "gait center" cannot be found in the cerebrum, frontal lobe lesions can devastate gait, as discussed further on. Often, the supplementary motor areas relating to the legs (superior frontal gyri) or periventricular white matter are implicated. In all likelihood, the medial frontal lobes embody automatic programs for walking that are intimately tied to adjacent networks in the striatum.

Equilibrium involves the maintenance of balance in relation to gravity and to the direction of movement in order to retain a vertical posture. The unstable center of gravity that prevails in walking must shift within narrow limits from side to side and forward as the weight is borne first on one foot, then on the other. This is accomplished through the activity of highly sensitive postural and righting reflexes that have both peripheral (stretch reflexes) and central (vestibulocerebellar reflexes) components. These reflexes are activated within 100 ms of each shift in the support surface and depend on reliable afferent information from the visual, vestibular, and proprioceptive systems.

Propulsion is provided by leaning forward and slightly to one side and permitting the body to fall a certain distance before being checked by the support of the leg. Here, both forward and alternating lateral movements must occur. In contrast to walking, running requires that both feet are momentarily off the ground, necessitating a forward drive or thrust by the trailing leg.

TESTING OF GAIT

General Comments

Because normal body posture and locomotion require intact vestibular function, proprioception, and vision (we see where we are going and adjust our steps), the effects of deficits in these senses are worth noting. A blind person—or a normal one who is blindfolded or walks in the dark—moves cautiously, with arms slightly forward to avoid collisions, and shortens his step slightly on a smooth surface; there is less rocking of the body and the gait is unnaturally stiff and cautious.

Pain in the hips or knees can lead to a disorder (antalgic gait) that can be challenging to distinguish from neurological causes of gait problems. Slowness of the swing phase and reduction in the amount of time spent with the painful limb in contact with the ground may be clues to recognizing rheumatological and orthopedic causes of a gait disorder. Of course, the patient's description of pain in certain positions or actions makes the problem self-evident, and maneuvers, such as passive movement of the leg about the hip, further expose the source of gait disruption. At times, musculoskeletal disorders produce little pain but alter the gait pattern as a result of protective and compensatory responses. Weakness of one or a group of adjacent muscles imparts a peculiar but identifiable appearance to walking, some aspects of which are detailed further on.

Examination of the Patient with Abnormal Gait

When confronted with a disorder of gait, the examiner should observe the patient's stance and the positions of the legs, trunk, and arms and their interrelationships. It is good practice to watch patients as they enter the examining room when they are apt to walk more naturally than during the performance of commanded tasks. Walking without the support of a cane or the arm of a companion brings out a certain stiffness of the legs and firmness of the muscles.

The patient should be asked to walk, noting, in particular, any hesitation in starting and negotiating turns, width of base, length of stride, foot clearance, arm swing, and cadence. More delicate tests of gait are walking a straight line heel to toe ("tandem walking test"), walking backward, and having the patient arise quickly from a chair, walk briskly, stop and turn suddenly, walk back, and sit down again. A tendency to veer to one side, as occurs with unilateral cerebellar or vestibular disease, can be elicited by having the patient walk around a chair; when the affected side is toward the chair, the patient tends to walk into it, and when it is away from the chair, there is a veering outward in ever-widening circles. Turning the patient three full revolutions with eyes open, first right and then left, each time followed by asking the patient to walk naturally, allows the examiner to stress the vestibular apparatus and to compare the two sides. The patient affected by a vestibular or cerebellar process will veer to the side of a lesion. Marching in place with eyes closed (Unterberger or Fukada stepping tests) also reveals a rotation in the yaw plane (rotation around the vertical axis), indicating an asymmetrical disorder in the plane of the horizontal semicircular ducts or their connections. Spasticity of one or both legs can be detected as stiffness and delay in moving the leg forward and a tendency to trace an arc with the toe, which gives rise to a scraping sound on the floor and wearing of the toe of the shoe.

The patient should be asked to stand with feet together and head erect, with eyes open and then closed (Romberg test). A normal person can stand with feet together and eyes closed while moving the head from side to side, a test that blocks both visual and vestibular cues and induces certain compensatory trunk and leg movements that depend solely on proprioceptive afferent mechanisms (Ropper). As mentioned in Chap. 5, the Romberg sign—marked swaying or falling with the eyes closed but not with the eyes open—usually indicates a loss of postural sense, not of cerebellar function, although with vestibular or cerebellar disease there may be an exaggeration of swaying. Swaying due to psychological causes may be uncovered by noting that balance is improved when distracting the patient, for example, by asking him to look at the ceiling or follow the examiner's finger, or to touch the tip of his nose alternately with the forefinger of one hand and then the other.

It is then instructive to observe the patient's postural reaction to a sudden push or tug at the shoulders, backward and forward, or to the side. With postural instability of any type, there is a delay or inadequacy of corrective actions. The patient may be asked to hop on one leg and to jog. Finally, it may be useful to have the patients simulate walking while seated or in bed. A dissociation between the inability to walk and the retained ability to simulate walking when not erect may reveal a disorder of the integrative mechanisms for gait in the frontal lobe or other regions.

Together, these tests serve to distinguish whether a disordered gait is due to a proprioceptive, labyrinthine-vestibular, basal ganglionic, corticospinal, cerebellar, or orthopedic-rheumatologic mechanism. It is then necessary to determine which of several other disturbances of function is responsible for the patient's disorder of gait, for example, the antalgic gait referred to earlier.

The following types of abnormal gait (Table 6-1) are distinctive enough that, with experience, they can be readily identified.

TYPES OF ABNORMAL GAIT

Cerebellar Gait (See Also Chap. 5)

The main features are a wide base (separation of legs), unsteadiness, irregularity or arrhythmicity of steps, and lateral veering. Steps are uncertain, some are shorter and others longer than intended and the patient may compensate for these abnormalities by shortening his steps or even keeping both feet on the ground simultaneously. Cerebellar gait is sometimes referred to as "reeling" or "drunken," but these terms are not entirely correct and are characteristic instead of intoxication and of certain types of labyrinthine disease, as explained further on.

Table 6-1

FEATURES OF GAIT ABNORMALITIES

	CADENCE	STEP LENGTH	BASE	OTHER ASSOCIATED SIGNS
Cerebellar	Irregular	Slightly short	Wide	Erratic shifting of weight and step
Sensory ataxic (tabetic)	Normal	Short	Slightly wide	Excessive force in step resulting in stamping of feet; Romberg sign
Steppage	Normal	Normal	Normal	Overlifting and slapping of feet
Plegic	Slow	Short	Narrow	Circumduction and scraping of affected leg(s)
Dystonic	Slow	Normal	Erratic	Twisting athetoid movements interrupt walking
Parkinsonian-festinating	Slow until festination	Short	Normal	Quickening step, forward leaning, shuffling, may have trouble with gait initiation
Waddling-myopathic	Normal	Normal	Slightly wide	Overlifting of hip(s)
Toppling	Slow until fall	Short	Widened (protective)	Sudden loss of balance
Normal pressure hydrocephalus	Slow	Short	Slightly wide	Numerous problems with axial body movement
Frontal lobe	Slow	Greatly shortened	Slightly wide (protective)	Difficulty starting and stopping; tendency for feet to "stick" to floor
Aging and marche à petit pas	Slow	Slightly shortened	Slightly widened	Cautious, slight forward lean

With cerebellar ataxia, the unsteadiness and irregular swaying of the trunk are prominent when the patient arises from a chair or turns suddenly while walking and may be evident when they have to stop walking abruptly and sit down; they may find it necessary to grasp the chair for support. Cerebellar ataxia may be so severe that the patient cannot sit without swaying. If it is less severe, standing with feet together and head erect is difficult with open eyes and only slightly more so with eyes closed. In its mildest form, ataxia is best demonstrated by having the patient walk a line heel to toe; after a step or two, they lose their balance and find it necessary to place one foot to the side to avoid falling. Elderly individuals may have some difficulty with the task.

As just stated, the patient with cerebellar ataxia who sways perceptibly when standing with feet together and eyes open will sway somewhat more with eyes closed. This slight increase in swaying may be misattributed to the loss of proprioceptive input to the cerebellum. By contrast, the removal of visual clues from a patient with proprioceptive loss causes a marked increase in swaying or falling (the Romberg sign). Thus, the defect in cerebellar disease is primarily in the coordination of the sensory input from proprioceptive, labyrinthine, and visual information with reflex movements, particularly those that are required to make rapid adjustments to changes in posture and position. This integrative deficiency is also reflected in the stepping test, in which the patient is asked to march in place with eyes closed. Those with vestibular and sometimes unilateral cerebellar disease have difficulty remaining stable and have a tendency to turn to the left or right or to move forward (occasionally backward) after a few steps.

Cerebellar abnormalities of stance and gait are usually accompanied by signs of incoordination of the legs, but they need not be. The presence of ataxia of the legs depends on the involvement of the cerebellar hemispheres as distinct from the antero-superior (vermian) midline structures that dominate the control of gait as described in Chap. 5. This emphasizes the value of having the patient get out of bed and walk rather than depending solely on an examination for ataxia of the legs while the patient remains in bed. If the cerebellar lesions are bilateral, there is often titubation (tremor) of the head and trunk in addition to the abnormality of gait.

Cerebellar gait is seen most commonly in patients with multiple sclerosis, cerebellar tumors (particularly those affecting the vermis—e.g., medulloblastoma), cerebellar stroke, paraneoplastic cerebellar syndrome, and prominently, in the large group of cerebellar degenerations.

Reeling Gait of Intoxication

This is characteristic of inebriation with alcohol, sedative drugs, and antiepileptic drugs. The drunken patient totters, reels, tips forward and then backward, appearing each moment to be on the verge of losing his balance and falling. Control over the trunk and legs is greatly impaired. The steps are irregular and uncertain. Such patients may appear indifferent to the quality of their performance, but under certain circumstances, they can momentarily correct the defect. As indicated above, the adjectives drunken and reeling are used frequently to describe the gait of cerebellar disease, but the similarities between them are only superficial. The severely intoxicated patient reels or sways in many different directions and seemingly makes little or no effort to correct the staggering by watching his legs or the ground, as occurs in cerebellar or sensory ataxia. Also, the variability of the drunken gait is noteworthy. Despite wide excursions of the body and deviation from the line of march, the drunken patient may, for short distances, be able to walk on a narrow base and maintain their balance. In contrast, the patient with cerebellar gait has great difficulty in correcting their balance if they sway or lurch too far to one side. Milder degrees of the drunken gait resemble

the gait disorder that follows loss of labyrinthine function discussed below.

Gait Disorder of Vestibulopathy

Patients with a chronic vestibulopathy show unsteadiness in standing and walking, often without widening their base, and an inability to descend stairs without holding onto the banister. They complain of a particular type of imbalance, usually with movement but at times when standing still—a sensation that may be likened to being on the deck of a rolling ship (*mal de debarquement*). Running and turning quickly are even more impaired, with lurching in all directions. The patient has great difficulty focusing their vision on a fixed target when moving or on a moving target when either stationary or moving. When the body is in motion or the head is moved suddenly, objects in the environment may appear momentarily blurred or actually jiggle up and down or from side to side (oscillopsia). Driving a car or reading on a train is difficult or impossible; even when walking, the patient may need to stop in order to read a sign. These abnormalities indicate a loss of stabilization of ocular fixation by the vestibular system during body movements (the *vestibulo-ocular reflex*, or VOR). An elderly person has difficulty compensating for these abnormalities. Proof that the gait of such persons with vestibulopathy is dependent on visual clues comes from their performance blindfolded or in the dark when their unsteadiness and staggering increase to the point of falling. When standing with eyes closed, they sway more than normal but generally do not fall over (i.e., they do not have a Romberg sign). The diagnosis is confirmed by testing labyrinthine function (caloric and rotational testing, electronystagmography, and posture platform testing).

Chronic disorders of vestibular function in relation to gait disorders are most often the result of prolonged administration of aminoglycoside antibiotics or other toxic medications, which destroy the hair cells of the vestibular labyrinth. Vestibular suppressants, such as meclizine and similar medications, mostly anticholinergic and antihistaminic that are available over the counter, can lead to decreased function of the vestibular system and a persistent gait disorder if used for more than a few weeks consecutively. This also occurs in some patients in the late stages of Ménière disease and, infrequently, for no definable reason. A colorful essay by a physician depicting the effects of the loss of the vestibular apparatus can be found by the author "JC" in the *New England Journal of Medicine*.

The literature is also replete with references to a "multimodal" gait disorder in the elderly that is the result of an ostensible aging of the vestibular organ, together with impaired proprioceptive function caused by distal neuropathy in the elderly and impaired vision.

Toppling Gait

Toppling, meaning tottering and falling, occurs with brainstem and cerebellar lesions, especially in the older person following a stroke. In a related defect caused by a vestibular disorder, the patient may describe a sense of being pushed (pulsion) rather than of imbalance.

With midbrain strokes, toppling falls tend to be backward (retropulsion). In patients with progressive supranuclear palsy (discussed in Chap. 38), where dystonia of the neck is combined with paralysis of vertical gaze and pseudobulbar features, unexplained unanticipated toppling is an early and prominent feature. The falls of progressive supranuclear palsy may derive from a disorder of the righting mechanism. In midbrain disease, including progressive supranuclear palsy, a remarkable feature is the lack of appreciation of a sense of imbalance. Toppling to one side is a feature of the lateral medullary syndrome.

In the advanced stages of Parkinson disease, falling of a similar type may be a serious problem, but it is more surprising how relatively infrequently it occurs. The cause of the toppling phenomenon is unclear; it does not have its basis in weakness, ataxia, or loss of sensation. It appears to be a disorder of balance that is occasioned by precipitant action or the wrong placement of a foot and by a failure of the righting reflexes. Slowness of motor response is another factor.

Sensory (Tabetic, or Proprioceptive) Gait Ataxia

A loss of proprioception—as occurs in patients with severe large-fiber polyneuropathy, posterior nerve root lesions (e.g., tabes dorsalis, lumbosacral root compression), or interruption of the posterior columns in the spinal cord (multiple sclerosis, vitamin B_{12} deficiency, spondylotic, or tumor compression)—abolishes or seriously impairs the capacity for independent locomotion. After years of training, such patients still have difficulty in initiating gait and in forward propulsion. As J. Purdon Martin described in the severe form of the disorder, they hold their hands slightly in front of the body, bend the body and head forward, walk with a wide base and irregular uneven steps, but still rock the body. If they are tilted to one side, they fail to compensate for their abnormal posture. If they fall, they cannot rise without help; they are sometimes unable to crawl or to get into an "all fours" posture. They have difficulty in getting up from a chair. When standing, if instructed to close their eyes, they sway markedly and fall (Romberg sign).

The principal observable features of sensory-ataxic gait are the brusqueness of movement of the legs, and in its extreme, stamping of the feet as the foot is forcibly brought down onto the floor (apparently to detect the location of the foot as a substitute for proprioception). The feet are placed far apart to correct the instability, and patients carefully watch both the ground and their legs. As they step out, their legs are flung abruptly forward and outward in irregular steps of variable length and height. The body is held in a slightly flexed position, and some of the weight is supported on the cane that the severely ataxic patient usually carries. To use Ramsay Hunt's characterization, the patient with this gait disorder is recognized by his "stamp and stick." As mentioned, the most specific feature is that the ataxia is markedly exaggerated when the patient is deprived of visual cues, as in walking in the dark. Such patients, when asked to stand with feet together and eyes closed, show greatly increased swaying and usually, the fully expressed Romberg sign with falling off to one side. It is said that in cases of sensory ataxia, the shoes do not

show wear in any one place because the entire sole strikes the ground at once. Examination usually discloses a loss of position sense in the feet and legs and usually of vibratory sense as well. The peripheral or central location of the sensory lesions can be further determined by the state of the tendon reflexes.

Whatever the location of the lesion, its effect is to deprive the patient of perception of the position of his limbs and, more relevant to gait, to interfere with a large amount of afferent proprioceptive and related information that does not attain conscious perception. A sense of imbalance is usually present, but these patients do not describe dizziness. They are aware that the trouble is in the legs and not in the head, that foot placement is awkward, and that the ability to recover quickly from a misstep is impaired. The resulting disorder is characterized by varying degrees of difficulty in standing and walking; in advanced cases, there is a complete failure of locomotion, although muscular power is retained.

Formerly, a disordered gait of this type was observed most frequently with tabes dorsalis, hence the term tabetic gait; but it is also seen in Friedreich ataxia and related forms of spinocerebellar degeneration, subacute combined degeneration of the spinal cord (vitamin B_{12} deficiency), a large number of sensory polyneuropathies, sensory ganglionopathies of various causes, and those cases of multiple sclerosis or compression of the spinal cord in which the posterior columns are involved.

Steppage or Equine Gait (Foot-Drop Gait)

This gait pattern is caused by paralysis of the pretibial and peroneal muscles, with resultant inability to dorsiflex the foot (foot drop). The steps are regular and even, but the advancing foot hangs with the toes pointing toward the ground. In its purest form, it is the result of peroneal nerve or fifth lumbar root damage. Walking is accomplished by excessive flexion at the hip, the leg being lifted abnormally high in order for the foot to clear the ground. There is a slapping noise as the foot strikes the floor. Thus, there is a superficial similarity to the tabetic gait described just above, especially in cases of severe polyneuropathy, where the features of steppage and sensory ataxia may be combined. However, patients with steppage gait alone are not troubled by a perception of imbalance; they fall from tripping on carpet edges and curbstones.

Foot drop may be unilateral or bilateral and occurs in diseases that affect the peripheral nerves of the legs or motor neurons in the spinal cord, lumbar roots, such as chronic acquired neuropathies (diabetic, inflammatory, toxic, and nutritional), Charcot-Marie-Tooth disease (peroneal muscular atrophy), progressive spinal muscular atrophy, and poliomyelitis. It may also be observed in certain types of muscular dystrophy in which the distal musculature of the limbs is involved.

"Burning Foot" Gait

A particular disorder of gait, also of peripheral origin and resembling steppage gait, may be observed in patients with painful dysesthesias of the soles of the feet. Because of the exquisite pain evoked by tactile stimulation of the feet, the patient treads gingerly, as though walking barefoot on hot sand or pavement, with the feet rotated in such a way as to limit contact with their most painful portions. The usual cause is one of the painful peripheral neuropathies (most often alcoholic-nutritional but also toxic and amyloid types), causalgia, or erythromelalgia.

Hemiplegic and Paraplegic (Spastic) Gaits

The patient with hemiplegia or hemiparesis holds the affected leg stiffly and does not flex it freely at the hip, knee, and ankle. The leg tends to rotate outward to describe a semicircle, first away from and then toward the trunk (*circumduction*). The foot scrapes the floor, contact being made by the toe and outer heel of the foot. One can recognize a spastic gait by the sound of slow, rhythmic scuffing of the foot and wearing of the medial toe of the shoe. With a cerebral or cervical lesion, the arm on the affected side is weak and stiff to a variable degree; it is carried in a flexed position and does not swing naturally (Fig. 6-2*A*). In the hemiparetic child, the arm tends to abduct as he steps forward. This type of gait disorder is most often a sequela of stroke or trauma but may result from any condition that damages the corticospinal pathway on one side.

The spastic paraplegic or paraparetic gait is, in effect, a bilateral hemiplegic gait. Each leg is advanced slowly and stiffly, with restricted motion at the hips and knees. The legs are extended or slightly bent at the knees, and the thighs may be strongly adducted, causing the legs almost to cross as the patient walks (*scissor-like gait*; Fig. 6-2*B*). The steps are regular and short, and the patient advances only with great effort as though wading waist-deep in water. The defect is in stiffness of the stepping mechanism and in propulsion, not in support or equilibrium.

A spastic paraparetic gait is the major manifestation of cerebral diplegia (Little disease, a type of cerebral palsy), the result of anoxic or other damage to the brain in the perinatal period. This disorder of gait is also seen in a variety of chronic spinal cord diseases involving the dorsolateral and ventral tracts, most often multiple sclerosis, but also including syringomyelia, any type of chronic meningomyelitis, subacute combined system disease of both the pernicious anemia and non-pernicious anemia types, spinal cord compression or traumatic injury, adrenomyeloneuropathy, and familial forms of spastic paraplegia. Frequently in these diseases, the effects of posterior column disease are added, giving rise to a mixed gait disturbance—a spinal spastic ataxia, characteristic of multiple sclerosis and certain spinal cord degenerations such as Friedreich ataxia.

Parkinsonian and Festinating Gait (See Also Chap. 38)

With disorders of the basal ganglia, the posture of the body and the postural responses to perturbations in equilibrium are faulty. There is difficulty in taking the first step; once it is taken, and in extreme cases, the body pitches forward and a fall can be prevented only by catch-up stepping (propulsive festination). Similarly, a step backward may induce

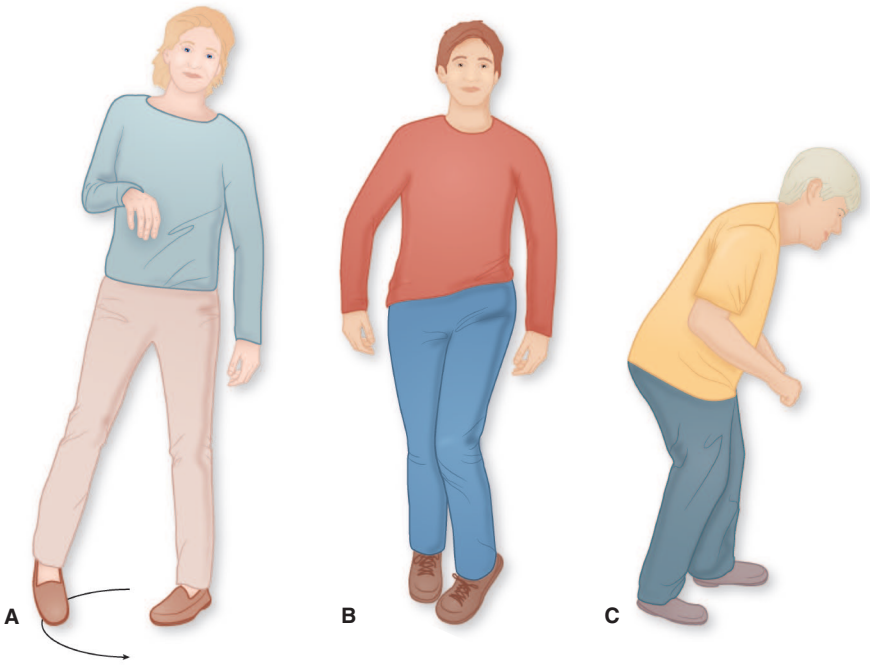

Figure 6-2. Schematic depiction of three of the main disorders of gait, described further in the text. *A*. Gait of right hemiplegia with flexed arm and circumduction of foot. *B*. Spastic gait on the left with close approximation of the feet and legs and flexion at the knees. *C*. Parkinsonian gait with forward position of the upper torso, flexion of the neck and elbows, and short-stepped gait. This may be contrasted with the similar but distinctive gait of aging (Fig. 6-3).

a series of quickening steps in that direction (retropulsive festination). Corrective righting reflexes are clearly faulty when the patient is pushed off balance (Denny-Brown).

Diminished or absent arm swing, forward bent torso, short or shuffling steps, turning en bloc, hesitation in starting to walk, shuffling, or "freezing" when encountering doorways or other obstacles are the features of the parkinsonian gait. When they are joined to the typical tremor, unblinking and mask-like facial expression, general attitude of flexion, and poverty of movement, there can be little doubt as to the diagnosis (Fig. 6-2*C*). The arms are carried slightly flexed and ahead of the body and do not swing. The legs are stiff and bent at the knees and hips. The steps are short, and the feet barely clear the ground as the patient shuffles along.

Once walking has started, the upper part of the body advances ahead of the lower part, and the patient is impelled to take increasingly short and rapid steps as though trying to catch up to their center of gravity. The steps become more and more rapid, and the patient could easily break into a trot and collide with an obstacle or fall if not assisted. The term *festination* derives from the Latin *festinare*, "to hasten," and appropriately describes the involuntary acceleration or hastening that characterizes the gait of patients with Parkinson disease. Festination may be apparent when the patient is walking forward or backward. The defects are in rocking the body from side to side so that the feet can clear the floor, and in moving the legs quickly enough to overtake the center of gravity. The problem is compounded by the inadequacy of postural support reflexes, demonstrable in the standing patient by falling in response to a push against the sternum or a tug backward on the shoulder. A normal person readily retains his stability or adjusts to modest displacement of the trunk with a single step, but the parkinsonian patient may lean backward with the upper torso and then stagger or fall unless someone stands by to prevent it.

Quite often, one encounters an elderly patient with only the instability and freezing components of the parkinsonian gait disorder, so-called *lower-half parkinsonism*. Usually, this is not a manifestation of idiopathic Parkinson disease although a few patients are responsive to levodopa for a brief period. It may be an early manifestation of progressive supranuclear palsy, a basal ganglionic degeneration, normal pressure hydrocephalus (NPH), or widespread and frontal subcortical vascular damage, but it also occurs as a virtually isolated phenomenon that progresses independently of other movement disorders or of dementia. The basis is then probably a particular isolated frontal lobe degeneration (see further on). Within a few years, as pointed out by Factor and colleagues in their two papers, the patient is usually reduced to a chair-bound state.

Other very unusual gaits are sometimes observed in Parkinson disease and were particularly prominent in the postencephalitic form, which is now practically extinct. For example, such a patient may be unable to take a step forward or does so only after he takes a few hops or one or two steps backward (aptly mimicked by the Monty Python troupe in their skit, "Ministry of Silly Walks"). Or walking may be initiated by a series of short steps or a series of steps of increasing size. Occasionally such a patient may run better than he walks or walk backward better than forward. Often, walking so preoccupies the patient that talking simultaneously is impossible and requires that the individual must stop to answer a question.

Choreoathetotic and Dystonic Gaits

Diseases characterized by involuntary movements and dystonic postures seriously affect gait. In fact, a disturbance of gait may be the initial and dominant manifestation of such diseases, and the testing of gait often brings out abnormalities of movement of the limbs and posture that are otherwise not conspicuous.

As the patient with congenital athetosis or Huntington chorea stands or walks, there is a continuous play of irregular movements affecting the face, neck, hands, and, in the advanced stages, the large proximal joints and trunk. The position of the arms and upper parts of the body varies with each step, at times giving the impression of a puppet. There are jerks of the head, grimacing, squirming, and twisting movements of the trunk and limbs, and peculiar respiratory noises. One arm may be thrust aloft and the other held behind the body, with wrist and fingers undergoing alternate nonrhythmic flexion and extension, supination, and pronation. The head may incline in one direction or the other, the lips alternately retract and purse, and the tongue intermittently protrudes from the mouth. The legs advance slowly and awkwardly, the result of superimposed involuntary movements and postures. Sometimes the foot is plantarflexed at the ankle and the weight is carried on the toes; or the foot may be dorsiflexed or inverted. An involuntary movement may cause the leg to be suspended in the air momentarily, imparting a lilting or waltzing character to the gait, or it may twist the trunk so violently that the patient may fall.

In dystonia musculorum deformans and focal dystonias, the first symptom may be a limp caused by inversion or plantarflexion of the foot or a distortion of the pelvis, as discussed in Chap. 4. One leg may be rigidly extended or one shoulder elevated, and the trunk may assume a position of exaggerated flexion, lordosis, or scoliosis. Because of the muscle spasms that deform the body in this manner, the patient may have to walk with knees flexed. The gait may seem normal as the first steps are taken, the abnormal postures asserting themselves as the patient continues to walk. Prominence of the buttocks owing to a lumbar lordosis, combined with flexion of one or both legs at the hip, gives rise to the so-called dromedary gait of Oppenheim. In the more advanced stages, walking becomes impossible owing to torsion of the trunk or the continuous flexion of the legs.

Stiff-person syndrome, an unusual non-dystonic disorder causing severe axial muscle spasm, causes stiffness of the legs and buttock muscles, slow propulsion, and lumbar lordosis; there is sometimes a mild superimposed ataxic disturbance of gait (see Chap. 46). Another unusual disorder affecting body position during walking is *camptocormia*, a severe forward bending of the trunk at the waist that is symptomatic of either a dystonia, Parkinson disease, or one of several muscle diseases that focally weakens the extensors of the spine. Kyphosis due to spinal deformities does the same and all of these conditions cause the patient to walk while looking at the ground beneath the feet, but they rarely cause falling.

Waddling (Gluteal, or Trendelenburg) Gait

This gait is characteristic of the gluteal muscle weakness that is seen in the progressive muscular dystrophies, but it occurs as well in chronic forms of spinal muscular atrophy, in certain inflammatory myopathies, lumbosacral nerve root compression, and with congenital dislocation of the hips.

In normal walking, as weight is placed alternately on each leg, the hip is fixated by the gluteal muscles, particularly the gluteus medius, allowing for a slight rise of the opposite hip and tilt of the trunk to the weight-bearing side. With weakness of the glutei, however, there is a failure to stabilize the weight-bearing hip, causing it to bulge outward and the opposite side of the pelvis to drop, with inclination of the trunk to that side. The alternation in lateral trunk movements results in the roll or waddle. With unilateral gluteal weakness, often the result of damage to the first sacral nerve root, tilting, and dropping of the pelvis ("pelvic ptosis") is apparent on only one side as the patient overlifts the leg when walking.

In several of the muscular dystrophies, an accentuation of lumbar lordosis is often seen. Also, childhood cases may be complicated by muscular contractures, leading to an equinovarus position of the foot so that the waddle is combined with walking on the toes ("toe walking").

Primary Orthostatic Tremor

This unusual fast tremor of the legs may devastate gait. As discussed in Chap. 4, "Disorders of Movement and Posture," it is present only when the patient stands or exerts force with the legs while seated. The tremor ceases upon walking. In reaction to a perception of severe imbalance, which is characteristic of the disorder, the patient assumes a widened and often stiff-legged stance.

Gait Disorder in Normal Pressure Hydrocephalus (See Also Chap. 29)

Progressive difficulty in walking is typically the initial and most prominent symptom of NPH. However, the gait disturbance in NPH has few specific features. Certainly, it cannot be categorized as ataxic or spastic or what has been described as "apraxic" gait; nor does it have more than a superficial resemblance to parkinsonian gait. Its main early features—slowness in lifting the feet from the floor, reduced cadence, widened base, and short steps—may be misconstrued as compensations observed in patients with all manner of gait disorders. Patients with the gait disorder of NPH may complain of a sense of imbalance or vague dizziness, but most have difficulty in articulating the exact problem.

Like patients with disorders of frontal lobe function, they are better able to carry out the motions of stepping and cycling with the legs while supine or sitting but have difficulty in taking steps when upright or attempting to walk. They are helped by marching to a cadence or in step with the examiner and by maintaining contact with the arm of another person. Turning may be impeded, performed in multiple steps, and have the appearance of a foot

remaining stuck to the ground. If observed getting on and off an examining table and in and out of bed, they display poor management of the entire axial musculature, moving their bodies without shifting the center of gravity (en bloc turning) or adjusting their limbs appropriately. Changes in posture, even rolling over in bed, are made en bloc as well. The erect posture is assumed in an awkward manner—with hips and knees only slightly flexed and stiff and a delay in swinging the legs over the side of the bed.

Tone in the leg muscles of the NPH patient is often slightly increased, with a tendency toward co-contraction of flexor and extensor muscle groups. Walking is perceptibly slower than normal, the body is held stiffly, arm swing is diminished, and there is a tendency to fall backward—features that are reminiscent of Parkinson and related diseases, although the lack of arm swing, a tendency to festination, and the stooped posture are more prominent in Parkinson disease than in NPH. We have been impressed that NPH causes parkinsonian shuffling only when the hydrocephalus is very advanced. In patients with untreated NPH, one observes a progressive deterioration of stance and gait—from an inability to walk to an inability to stand, sit, and rise from or turn over in bed. The neurologist is aided in diagnosis by the presence of incontinence and mental deterioration that are components of advancing NPH and are not early components of Parkinson and related diseases.

There is no hint of ataxia, but a study of the mechanics of the gait in NPH described a widened base and slight outward rotation of the feet (Stolze and colleagues). These defects were quantified using high-speed cameras and computer analysis and a reduction in height of step, increase in sway, and decrease in rotation of the pelvis and counter-rotation of the torso were reported (Sudarsky and Simon). Unlike patients with the antalgic gait of hip or leg pain, the upper body in NPH is held stiffly and there is no avoidance of weight bearing.

Frontal Lobe Disorders of Gait

Standing and walking may be severely disturbed by diseases that affect the frontal lobes, particularly their medial parts and their connections with the basal ganglia. This disorder is sometimes spoken of as a frontal lobe "apraxia of gait" among numerous other labels because the difficulty in walking cannot be accounted for by weakness, loss of sensation, cerebellar incoordination, or basal ganglionic abnormality. The disorder should probably not be designated as an apraxia in the sense of the original concept of loss of ability to perform a learned act, as walking is instinctual and not learned. Patients with the so-called apraxia of gait do not have apraxia of individual limbs; conversely, patients with apraxia of the limbs usually walk normally. More likely, the frontal gait disorder represents a loss of integration, at the cortical and basal ganglionic levels, of the essential elements of stance and locomotion that are acquired in infancy and often lost in old age.

Patients typically assume a posture of slight flexion with the feet placed farther apart than normal. They advance slowly, with small, shuffling, hesitant steps. At times they halt, unable to advance without great effort, although they improve if escorted or if instructed to walk in step with the examiner or to a cadence. Walking and turning are accomplished by a series of tiny, uncertain steps that are made with one foot, the other foot being planted on the floor as a pivot.

"Lower-half parkinsonism," as mentioned earlier, has been applied to a pattern of slowed, sometimes shuffling gait in the absence of any abnormalities of the upper extremities, but the cause is rarely idiopathic Parkinson disease. The term "*marche à petit pas*" (gait with little steps) is also used as a description for an advanced form of the frontal lobe gait disorder and has been particularly associated with vascular damage to the white matter.

In frontal lobe disorders of gait, there is a need to seek support from a companion's arm or nearby furniture. The initiation of walking becomes progressively more difficult; in advanced cases, the patient makes only feeble, abortive stepping movements in place, unable to move the feet and legs forward; eventually, the patient can make no stepping movements whatsoever, as though their feet are glued to the floor. These late phenomena have been referred to as "*magnetic gait*" and the difficulty initiating gait as "slipping clutch" syndrome (Denny-Brown) or "gait ignition failure" (Atchison and colleagues). In some patients, difficulty in the initiation of gait may be an early and apparently isolated phenomenon, but invariably, with the passage of time, the other features of the frontal lobe gait disorder become evident. Finally, the resemblance to NPH is notable and these patients become unable to stand or even to sit; without support, they fall helplessly backward or to one side.

Until the late stages of the process, these patients, while seated or supine, are able to make complex movements with their legs such as drawing imaginary figures or pedaling a bicycle, and, quite remarkably, to simulate the motions of walking, all at a time when their gait is seriously impaired. Eventually, however, all movements of the legs become slow and awkward, and the limbs, when passively moved, offer variable counter-resistance (paratonia or *gegenhalten*). As with Parkinson disease, difficulty in turning over in bed may eventually become impossible.

These advanced motor disabilities are usually associated with dementia, but the gait and mental disorders need not evolve in parallel. Thus, some patients with Alzheimer disease may show a severe degree of dementia for several years before a gait disorder becomes apparent; in other conditions, such as NPH and Binswanger disease, the opposite pertains. Or, both the dementia and gait disorder may progress more or less together. Grasping, groping, hyperactive tendon reflexes, and Babinski signs may or may not be present. The end result in some cases is a "cerebral paraplegia in flexion," in which the patient lies curled up in bed, immobile and mute, with the limbs fixed by contractures in an attitude of flexion (Yakovlev).

On the basis of bilateral but isolated frontal lobe infarction in the territory of the anterior cerebral artery (medial frontal lobes), the existence of a "gait center" has been proposed, as mentioned in the introduction (Della Sala and colleagues). In the most severe and localized instance of complete gait failure from a frontal lobe stroke

we have observed, the lesion was situated in the left pericallosal, medial supplementary motor area. An analysis of MRIs from a selected group of patients with stroke showed that periventricular frontal and occipitoparietal ischemic lesions in the deep white matter are associated with deterioration of gait (Benson and colleagues). Isolated pontine ischemic changes were associated with gait disequilibrium in another study (Kwa and colleagues). The clinical validity of all of these observations in regard to localization is uncertain but generally converges on the notion that ischemic damage at any of the aforementioned sites in the white matter can alter walking.

In addition to NPH and Alzheimer disease, the causes of the frontal lobe gait disorder include large neoplasms (meningioma, infiltrating glioma, and lymphoma), subcortical arteriosclerotic encephalopathy (Binswanger disease; see Thompson and Marsden), progressive leukoencephalopathy associated with exposure to radiation therapy, frontotemporal lobar degeneration, and frontal lobe damage from trauma, stroke, or the residual of a ruptured anterior communicating aneurysm.

Gait of the Aged (See Also Chap. 28)

An alteration of gait unrelated to overt cerebral disease is an almost universal accompaniment of aging and probably a variant of frontal lobe gait deterioration (Fig. 6-3). Lost with aging are speed, balance, and many of the quick and graceful adaptive movements that characterize the gait of younger individuals. The main objective characteristics are a slightly stooped posture, varying degrees of slowness and stiffness of walking, shortening of the stride, slight widening of the base, and a tendency to turn en bloc. The shortening of stride and widening of the base provides the support that enables the elderly individual to more confidently maintain balance, but together they result in a somewhat guarded gait, like that of a person walking on a slippery surface or in the dark.

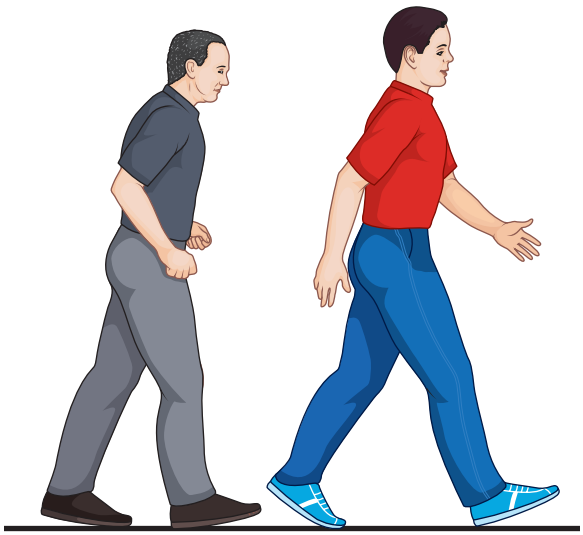

Figure 6-3. Changes in posture and gait that accompany aging ("senile gait"). The normal upright posture of youth (left) slowly acquires decreased length of stride and reduced hip excursion, less toe elevation in the forward foot and less elevation of the heel of the trailing foot, as well as a tendency to flexion at the shoulders on forward arm swing and flexion of the elbow on backward arm swing (right).

Also lacking to a varying degree in the elderly is the ability to make the rapid compensatory postural changes ("rescue responses") that are necessary to cushion or prevent a fall. A slight misstep, a failure to elevate the foot sufficiently, or tipping of the center of gravity to one side often cannot be corrected—features that no doubt account for the frequency of falls and fear of falling among the elderly. Most persons with this type of gait disturbance are aware of impaired balance and their need for caution to avoid falls. As such, this gait lacks specificity, being combined with a general adaptive or defensive pattern of walking. Added to this, knee buckling that is attributable to quadriceps weakness from muscle loss of aging contributes to the problem (Felson and colleagues). Furthermore, osteoarthritis, the almost inevitable accompaniment of aging, contributes to the disruption of gait as a result of pain and a reduced range of motion and is a component of many gait disorders in the elderly.

The nature of the elderly gait disorder is not fully understood. It may simply represent cerebral neuronal loss attributable to aging itself, which in a severe form is the frontal lobe disorder of gait discussed above. Inadequate proprioception, slowness in making corrective postural responses, diminished vestibular function, and weakness of pelvic and thigh muscles are, as mentioned, probably contributing factors. However, Baloh and colleagues found that changes in sensory function do not correlate well with deterioration in gait. Fisher remarked on the similarity of the senile gait to that of NPH and suggested that hydrocephalus underlies the gait disorder of some elderly. Cobalamin deficiency caused by gastric atrophy may contribute as well. The multiple contributors to gait deterioration, including vestibulopathy in the aged, are reflected in the survey by Fife and Baloh.

We emphasize here the common and vexing problem encountered so often of an elderly person with gait disturbance but minimal dementia and without an obvious etiology. Factor and colleagues identify this as a primary freezing gait disorder of many etiologies, and it conforms to "lower-half Parkinson" pattern as discussed earlier. Walking deteriorates over a period of months or years in an elderly individual. The gait disturbance has most of the features of NPH or of a frontal gait disorder, but frontal atrophy is not marked, the ventricles are not enlarged, there is no response to drainage of CSF, and cervical spondylosis or neuropathy is not found. Sometimes, a functional imaging study such as positron emission tomography (PET) shows hypometabolism in the frontal lobes, and there is a high incidence of subsequent dementia (Verghese and colleagues). Presumably, this reflects a degenerative process, perhaps of the frontotemporal variety. The changes in gait due to aging are nicely summarized in the text by Masdeu and colleagues and the review by Sudarsky.

Gaits of the Developmentally Delayed

The array of abnormal gaits in individuals with developmental delay defies easy analysis. An ungainly stance with

the head too far forward or the neck extended and arms held in odd positions, a wide-based gait with awkward lurches or feet stomping the floor—each with its own ungraceful style—these are but a few of the patterns that are commonly encountered. One tries, generally in vain, to relate them to a disorder of proprioception, cerebellar deficit, or pyramidal or extrapyramidal disease.

The only plausible explanation that comes to mind is that these variants of gait are based on a change in the natural developmental sequence of cerebral and spinal mechanisms involved in bipedal locomotion, posture, and righting. The acquisition of the developmental refinements of locomotion—such as running, hopping, jumping, dancing, balancing on one foot, kicking a ball—is also disrupted or delayed. The rhythmic rocking movements and hand clapping, odd mannerisms, waving of the arms, and other stereotyped patterns mentioned in the chapter on development, make gait even more maladroit. The Lincoln-Oseretsky scale is an attempt to quantitate these maturational delays in the locomotor sphere.

Functional Gait Disorders

This may take several forms, often dramatic in appearance, such as walking on stilts, extreme dystonic postures, or lurching wildly in all directions or collapsing legs without falling to the ground, actually demonstrating by their gyrations a normal ability to make rapid and appropriate postural adjustments (Keane). The functional gait disorder may be accompanied by similarly exaggerated movements of the arms, as though to impress the observer with the great effort required to walk and maintain balance; indeed, a high frequency of coincident psychogenic movement and gait disorders has been documented (Baik and Lang).

Astasia-abasia was a term used to describe a psychogenic gait disorder in which patients, although unable to either stand or walk, display more or less normal use of their legs while in bed and have an otherwise normal neurologic examination and body carriage. When such patients are placed on their feet, they may take a few steps and then become unable to advance their legs; they lurch in all directions and crumple to the floor if not assisted. As noted below, astasia-abasia has causes other than psychogenic and the use of the term has been expanded to describe other forms of complete inability to stand and walk.

Also included in this category are hysterical monoplegias, hemiplegias, or paraplegias. In walking, the patient may hesitate and advance the leg in a grossly ataxic or tremulous manner. Typically, patients with a hysterical paralysis of the leg do not lift the foot from the floor while walking; instead, they tend to drag the leg as a useless member or push it ahead of them as though it were on a skate. In hysterical hemiparesis, the characteristic circumduction seen in bona fide spastic paresis of the leg is absent, as are hemiparetic postures, hyperactive tendon reflexes, and Babinski sign. The hysterical paraplegic cannot very well drag both legs and usually depends on canes or crutches or remains helpless in bed or in a wheelchair; after months or longer of immobilization, the muscles may be flaccid or rigid from shortening, with development of contractures. Leg movements in bed may be unimpaired, or the patient may display a Hoover sign (described in Chap. 3), which belies genuine leg weakness. Some of the patients exhibit additional abnormalities of the voice and visual fields, tremors, and asthenic weakness of muscle contraction.

On the other hand, one should not assume that a patient who manifests a disorder of gait or inability to walk but no other neurologic abnormality necessarily has a functional gait disorder. Lesions that are restricted to the anterosuperior cerebellar vermis may cause an ataxia or severe instability that becomes manifest only when the patient attempts to stand and walk; this is also true of advanced NPH, frontal lobe disease, and various intoxications such as with alcohol or antiepileptic medications. Cases of severe peripheral neuropathy, particularly if there is prominent sensory loss, may also greatly impair the ability to stand or walk, and the unusual condition of orthostatic leg tremor that may produce buckling of the legs when the patient stands for some period of time, a situation often mistaken for a psychogenic etiology. Similarly, the combination of ataxia and stiffness of the legs and buttocks that characterizes stiff-person syndrome may too be mistaken for a psychogenic disorder.

Rehabilitative Measures

Once the gait abnormality has been characterized, one should explore the possibility of rehabilitation by a combination of medical therapy and other corrective measures. The anti-spasticity agents baclofen and tizanidine are somewhat helpful when stiffness of the limbs exceeds weakness. They may reduce spasticity of the legs, but sometimes at the expense of exposing, to a greater degree than before, a loss of muscle power—the net effect being to the patient's disadvantage. In extreme cases, an intrathecal pump infusion of baclofen may be effective for spasticity.

Hypofunction of the labyrinths, as in drug-induced or idiopathic vestibulopathy, has greatly challenged physiatrists. Balance training and attention to postural correction and vision have helped some patients to be more steady and better able to function. Vestibular sedatives (e.g., meclizine) should be discontinued. Exercises to strengthen leg muscles can be beneficial in many circumstances, as can weight loss. Likewise, gait ataxia from proprioceptive defects can probably be corrected to some extent by careful attention to visual control and proper placement of the feet. Once dementia becomes conjoined with any of the gait disorders that occur in advanced age or with frontal lobe disease, rehabilitation stands less chance of success since the ability to attend to small changes in terrain and posture is lost. Many patients have found exercises that emphasize balance, such as tai chi and yoga, to be helpful. Progression from the use of a cane to a pronged cane and finally to a four-posted walker allows patients with all types of gait disorders to maintain some mobility. The optimal use of these orthoses is best directed by experienced physical therapists and physiatrists.

Gait training with encouragement has been a useful maneuver to improve psychogenic gait disorders, but some prove resistant.

SECTION 2

Pain and Disorders of Somatic Sensation

CHAPTER 7 **Pain**
CHAPTER 8 **Disorders of Non-Painful Somatic Sensation**
CHAPTER 9 **Headache and Other Craniofacial Pains**
CHAPTER 10 **Pain in the Back, Neck, and Extremities**

This section deals with pain and somatic sensations, all derived mainly from afferent impulses that arise in the organs, skin, blood vessels, connective tissues, muscles, and joints. Because of its overriding clinical importance, pain has been accorded a chapter of its own. The special senses—vision, hearing, taste, and smell—are considered in the next section, and visceral sensation, most of which does not reach consciousness, is considered with the disorders of the autonomic nervous system.

Pain is an important sign of illness and it stands preeminent among all the sensory experiences by which humans judge the existence of a disease. Relatively few medical diseases do not have a painful phase. Moreover, the diagnosis of certain diseases rests heavily on a characteristic absence of pain. Headache and the pain derived from disorders of the spinal column and roots occupy a distinctive place in clinical practice and are elaborated in their own chapters.

To deal effectively with problems of pain and altered sensation requires familiarity with the anatomy of sensory pathways and the sensory innervation of body segments as well as insight into the psychological factors that influence the perception of and reaction to pain. Two major systems, designated by their tracts in the spinal cord, subserve these functions: spinothalamic pathways for pain and the posterior column-medial lemniscal pathways for touch, joint position, deep pressure, and vibration senses.

The spinothalamic system originates in free nerve endings that coalesce into lightly myelinated axons. These fibers represent the peripheral projections of neurons contained in the dorsal root ganglia. Their central projections are contained in the dorsal (posterior) roots that enter the spinal cord and synapse in the dorsal horns onto neurons. The axons of these neurons decussate and ascend as the spinothalamic tract, terminating in the thalamus. An analogous pathway called the spinal trigeminal tract subserves pain sensation in the face.

The posterior column-medial lemniscal system originates in several distinctive specialized receptors that give rise to heavily myelinated axons whose cell bodies are also contained in the dorsal root ganglia. Their central projections enter the dorsal roots and then the dorsal horn of the spinal cord, and without synapsing or decussating, ascend as the posterior columns. An analogous anterior trigeminothalamic tract subserves somatic sensation in the face.

7

Pain

The ambiguity with which the term pain is used reflects some of our difficulty in understanding it. One aspect, the easier to comprehend, is nociception—the transmission of impulses in response to potentially tissue-damaging stimuli. More abstruse are the aspects of pain as a mental state intimately linked to emotion, the quality of anguish or suffering that defies definition and quantification, or "a passion of the soul," in the words of Aristotle. This duality (nociception and suffering) is of tremendous practical importance in terms of selecting appropriate comprehensive treatment approaches for an individual patient. Further complexities are that the symptom of pain may persist despite interruption of neural pathways that abolish all sensation (i.e., denervation dysesthesia or anesthesia dolorosa), or that pain may continue to be perceived from the absent part of an amputated limb ("phantom pain"). Finally, pain can be evoked by almost any sensory modality, such as touch, pressure, heat, or cold, if it is intense enough.

Although much has been learned about the anatomy of pain pathways, their physiologic mechanisms, and which structures to ablate to produce analgesia, the effective management of pain by medical and surgical means remains a considerable clinical challenge. The practice of pain medicine challenges every thoughtful physician, often requiring a high degree of skill. It can be particularly challenging to address the needs of patients who seek treatment for pain that appears to have little or no structural basis; further inquiry may disclose that fear of serious disease, worry, or depression has aggravated a relatively minor ache or that the complaint of pain has become the means of seeking attention, drugs, or monetary compensation. Further complicating almost all aspects of pain medicine is concern about narcotic dependence, tolerance, and addiction, which may be informed by societal and political forces. Finally, the physician must be prepared to manage patients who require palliative relief from intractable pain caused by established and incurable disease.

ANATOMY OF PAIN

Historical Perspective

For more than a century, views on the nature of pain sensation have been dominated by two major theories. The first theory, the *specificity theory*, was put forth by von Frey, who asserted that the skin consisted of a mosaic of discrete sensory spots that, when stimulated, each gave rise to one sensation—either pain, pressure, warmth, or cold. In his view, each of these sensations had a distinctive end organ in the skin that was connected by its own discrete pathway to the brain. A second theory was that of Goldscheider, who argued that there were no distinctive pain receptors, but that the sensation of pain resulted from the summation of intense pressure or thermal stimuli applied to the skin. Originally called the intensity theory, this later became known as the *pattern* or *summation theory*.

In an effort to conciliate the specificity and pattern theories, in 1905 Henry Head formulated a concept of pain sensation based on observations that followed the purposeful sectioning of the cutaneous branch of the radial nerve in his own forearm. The zone of impaired sensation contained an innermost area in which superficial sensation was completely abolished. This was surrounded by a narrower ("intermediate") zone, in which pain sensation was preserved but poorly localized. Extreme degrees of temperature were recognized in the intermediate zone but perception of touch, lesser differences of temperature, and two-point discrimination were abolished. To explain these findings, Head postulated the existence of two systems of cutaneous receptors and conducting fibers: (1) an ancient *protopathic* system, subserving pain and extreme differences in temperature and yielding ungraded, diffuse all-or-none responses; and (2) a more recently evolved *epicritic* system, which mediated touch, two-point discrimination, lesser differences in temperature, and localized pain. The pain and hyperesthesia that followed damage to a peripheral nerve were attributed to a loss of inhibition that was normally exerted by the epicritic on the protopathic system. This theory was used for many years to explain the sensory alterations that occur with both peripheral and central (thalamic) lesions. It lost credibility for several reasons but mainly because certain aspects of Head's original observations and deductions could not be confirmed (Trotter and Davies; also Walshe). Nevertheless, both fast and slow forms of pain conduction were later corroborated (see below).

A later refinement of the pattern and specificity concepts of pain was made in 1965 when Melzack and Wall articulated their "gate-control" theory. They observed,

in decerebrate and spinal cats, that peripheral stimulation of large myelinated fibers produced a negative dorsal root potential, while stimulation of small unmyelinated C (pain) fibers caused a positive dorsal root potential. They postulated that these potentials, which represented presynaptic inhibition or excitation, modulated the activity of secondary transmitting neurons (T cells) in the dorsal horn and that this modulation was mediated through inhibitory (I) cells. The essence of this theory was that the large-diameter fibers excited the I cells, which, in turn, caused a presynaptic inhibition of the T cells; conversely, the small pain afferents inhibited the I cells, leaving the T cells in an excitatory state. Wall and Melzack emphasized that pain impulses from the dorsal horn must also be under the control of a descending system of fibers from the brainstem, thalamus, and limbic lobes.

At first the gate-control mechanisms seemed to offer an explanation of the pain of conditions such as ruptured disc and neuropathies (particularly those with large fiber involvement), prompting attempts to relieve pain by subjecting the peripheral nerves and dorsal columns (presumably their large myelinated fibers) to sustained transcutaneous electrical stimulation. Such selective stimulation would theoretically "close" the gate. In some clinical situations these procedures have indeed given relief from pain, but not necessarily as a result of stimulation of large myelinated fibers alone (Taub and Campbell). In a number of other instances relating to pain in large and small-fiber neuropathies, however, the gate-control mechanism has not yielded a sound pathophysiologic understanding of clinical phenomena (Nathan). As with preceding theories, weaknesses have been exposed in the physiologic observations on which the theory is based.

During the last few decades there has been a significant accrual of information on refined aspects of cutaneous sensation, demanding modification of earlier anatomic–physiologic and clinical concepts. Interestingly, however, much of this information is still best described and rationalized in the general framework of some of the older theories.

Pain Receptors and Peripheral Afferent Pathways

Peripheral pain conducting nerve fibers demonstrate a degree of specificity, and have been classified according to their size and function (Table 7-1). There are two main types of afferent fibers that respond maximally to nociceptive (i.e., potentially tissue-damaging) stimuli. One type is the very fine, unmyelinated, slowly conducting C fiber (0.3 to 1.1 μ in diameter); the other is the thinly myelinated, more rapidly conducting A-δ fiber (2 to 5 μ in diameter). The peripheral terminations of both of these primary pain afferents are free, profusely branched nerve endings in the skin and other organs; these receptors are covered by Schwann cell cytoplasm but with little or no myelin.

Three categories of free endings or receptors are recognized, demonstrating a degree of subspecialization: mechanoreceptors, thermoreceptors, and polymodal nociceptors. Each ending transduces stimulus energy into an action potential in the distal nerve membranes. Mechanical effects are transmitted by both A-δ and C fibers and the thermal effects mostly by C fibers. The majority of C-fiber endings are polymodal and are most effectively excited by noxious stimuli, but they can also respond to mechanical or thermal stimuli and to chemical mediators such as those associated with inflammation. Although less prominent, some A-δ fibers respond to light touch, temperature, and pressure as well as to pain stimuli and are capable of discharging in proportion to the intensity of the stimulus. The stimulation of single fibers by intraneural electrodes indicates that they can also convey information concerning the nature and location of the stimulus. These observations on the polymodal functions of A-δ and C fibers would explain the observation that modes of sensation other than pain can be evoked from structures such as the cornea, which is innervated solely by free nerve endings (Lele and Weddell; Weddell).

Painful stimuli are translated into electrical depolarizations in nerve endings when specialized molecules, activated by noxious stimuli, open cationic channels in membranes of the nerve ending (Benarroch). Opening of these channels activates voltage-gated sodium channels and generates an action potential in the sensory axon. It is of interest that numerous unique, specialized ion channels are expressed only on certain nociceptive nerve cells and their processes, but not in the brain or spinal cord; these include specific sodium, potassium, calcium channels, and other cation channels such as TRP (transient receptor potential) and ASIC (acid-sensing ion channel). Particular pain syndromes arise from mutations in these channels

Table 7-1

CLASSIFICATION AND FUNCTION OF SENSORY PERIPHERAL NERVE FIBER TYPES AND SYMPTOMS ASSOCIATED WITH THEIR DYSFUNCTION (SEE ALSO TABLE 8-1)

FIBER TYPE	ALTERNATIVE DESIGNATION	FIBER DIAMETER (mm)	CONDUCTION VELOCITY (m/s)	FUNCTION AND SYMPTOMS OF DYSFUNCTION
Large, heavily myelinated				
A-α and -β	II	5–20	30–70	Touch, pressure
Small, thinly myelinated				
A-γ	Ia	3–6	15–30	Spindle afferents
A-δ	III	2–5	12–30	Pain and temperature, somatic touch (sharp, lancinating, prickly pain)
B		1–3	3–15	Visceral and autonomic afferents
Small, unmyelinated				
C	IV	0.3–1.1	0.5–2	Slow pain and temperature (dull, burning, poorly localized pain)

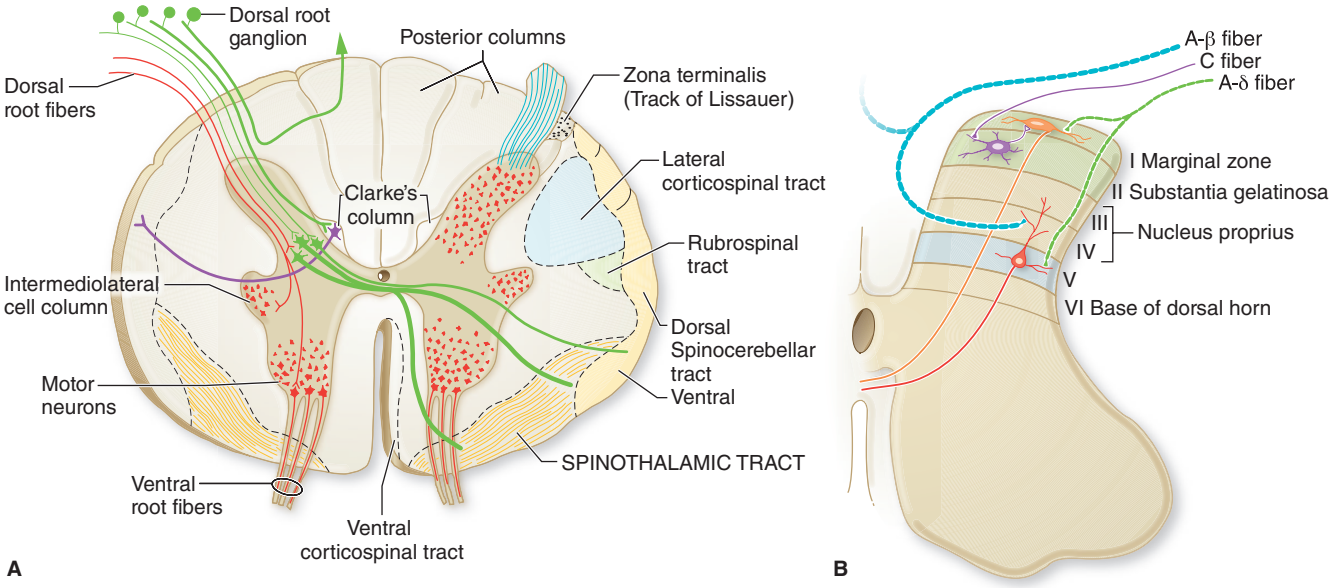

Figure 7-1. *A*. Spinal cord in transverse section illustrating the course of the afferent fibers and the major ascending pathways. Fast-conducting pain fibers are not confined to the spinothalamic tract but are scattered diffusely in the anterolateral funiculus (see also Fig. 7-3). (Adapted from Martin JH: *Neuroanatomy: Text and Atlas*. New York, McGraw-Hill, 2003.) *B*. and from autoimmune diseases that interfere with their function.

The peripheral afferent pain fibers of both A-δ and C types have their cell bodies in the dorsal root ganglia; central extensions of these nerve cells project to the spinal cord via the dorsal root. The posterior spinal nerve root can be considered to have a lateral division, which contains small pain fibers, and a medial division, which contains large myelinated fibers, but the separation into discrete functional bundles is not complete, and in humans the two groups of fibers cannot be differentially interrupted by selective rhizotomy. Within the spinal cord, many of the thinnest fibers (C fibers) form a discrete bundle, the tract of Lissauer (Fig. 7-1*A*). Transection of the tract of Lissauer produces ipsilateral segmental analgesia, demonstrating that it is predominantly a pain pathway, but it does contain deep sensory and propriospinal fibers as well.

Dermatomal Distribution of Pain Fibers

The *sensory unit* consists of the sensory nerve cell in the dorsal root ganglion, its central and peripheral extensions, and its cutaneous and visceral endings. The topography of the units maintains a consistent distribution from the periphery to the sensory cortex. The discrete segmental distribution of the sensory units permits the construction of clinically useful sensory maps (see Fig. 8-1). This aspect of sensory anatomy is elaborated in the next chapter, which includes maps of the sensory dermatomes and cutaneous nerves. However, as a means of quick orientation to the topography of peripheral pain pathways, it is useful to remember that the facial structures and anterior cranium lie in the fields of the trigeminal nerves; the back of the head, second cervical; the neck, third cervical; the epaulet area, fourth cervical; the deltoid area, fifth cervical; the radial forearm and thumb, sixth cervical; the index and middle fingers, seventh cervical; the little finger and ulnar border of hand and forearm, eighth cervical–first thoracic; the nipple, fourth to fifth thoracic; the umbilicus, tenth thoracic; the groin, first lumbar; the medial side of the knee, third lumbar; the medial malleolus, the fourth lumbar; the great toe, fifth lumbar; the little toe, first sacral; the back of the thigh and lateral foot, second sacral; and the genitoanal zones, third, fourth, and fifth sacral segments.

The distribution of pain fibers from deep structures, although not fully corresponding to those from the skin, also follows a roughly segmental pattern. Neurologically relevant maps of pain projection from the bones, ligaments, and adjacent musculoskeletal structures have been termed *sclerotomes*. The first to fourth thoracic nerve roots are the important sensory pathways for the heart and lungs; the sixth to eighth thoracic, for the upper abdominal organs; the lower thoracic and upper lumbar, for the lower abdominal viscera; and lower pelvic organs such as the bladder and rectum, the second through fourth sacral roots. These areas of pain projection from visceral structures roughly correspond to the areas of skin innervation by the same roots, with some exceptions, such as the testicles, because of the routing of sensory nerves to organs that migrate caudally with development. A further discussion of referred pain and a figure comparing sclerotomes and dermatomes is given later in the chapter.

The Dorsal Horn

The afferent pain fibers, after traversing the tract of Lissauer, terminate in the posterior gray matter or dorsal

horn, predominantly in the marginal zone. Most of the fibers terminate within the segment of their entry into the cord; some extend ipsilaterally to one or two adjacent rostral and caudal segments; and some project, via the anterior commissure, to the contralateral dorsal horn. The cytoarchitectonic studies performed by Rexed in the cat (the same organization pertains in primates and probably in humans) have shown that the second-order neurons on which the afferent sensory fibers synapse in the dorsal horn are arranged in a series of six layers or laminae (Fig. 7-1*B*). Thinly myelinated (A-δ) fibers terminate principally in lamina I of Rexed (also referred to as the marginal cell layer of Waldeyer) and in the outermost part of lamina II; some A-δ pain fibers penetrate the dorsal gray matter and terminate in the lateral part of lamina V. Lamina I is considered to be the origin of the majority of spinothalamic fibers, discussed below. Unmyelinated (C) fibers also terminate in lamina II (substantia gelatinosa). Yet other cells that respond to painful cutaneous stimulation are located in ventral horn laminae VII and VIII; these neurons are responsive to descending impulses from brainstem nuclei as well as segmental sensory impulses. From the cells of termination in the dorsal horn, axons connect with ventral and lateral horn cells in the same and adjacent spinal segments to subserve both somatic and autonomic reflexes. The main bundle of secondary neurons subserving pain sensation ascend contralateral (and to a lesser extent ipsilateral) to the point of entry into the cord, constituting the *spinothalamic tract,* discussed below.

A number of important observations have been made concerning the mode of transmission and modulation of pain impulses in the dorsal horn and brainstem. Excitatory amino acids (glutamate, aspartate) and nucleotides such as adenosine triphosphate (ATP) are the putative transmitters at terminals of primary A-δ sensory afferents. Also, A-δ pain afferents, when stimulated, release several neuromodulators that play a role in the transmission of pain sensation. Slower neurotransmission by C neurons involves other substances, of which the most important is the 11-amino-acid peptide known as substance P ("P" for powder extracted from animal tissue and urine by von Euler and Gaddum in 1931). In animals, substance P excites nociceptive dorsal root ganglion and dorsal horn neurons; furthermore, destruction of substance P fibers produces analgesia. In patients with the rare condition of congenital neuropathy and insensitivity to pain, there is a marked depletion of dorsal horn substance P.

The term "opiate" is used to describe naturally occurring exogenous substances such as morphine that resemble the endogenous "opioids," which are modulators of pain impulses as they are relayed through the dorsal horn and the nuclei in the medulla and midbrain. Administration of opiates has been noted to decrease substance P; at the same time, flexor spinal reflexes, which are evoked by segmental pain, are reduced. Opioid receptors of three types are found on both presynaptic primary afferent terminals and postsynaptic dendrites of small neurons in lamina II. Moreover, lamina II neurons, when activated, release enkephalins, endorphins, and dynorphins—all of which are endogenous, morphine-like peptides that bind specifically to opiate receptors and inhibit pain transmission at the dorsal horn level.

Spinal Afferent Tracts for Pain (The Anterolateral System)

The Spinothalamic Tract

The majority of axons originating from dorsal horn neurons that subserve pain sensation, in laminae I, II, V, VII, and VIII, decussate in the anterior spinal commissure and ascend in the anterolateral fasciculus of the opposite side of the cord as the *spinothalamic tract* to terminate in brainstem and thalamic structures (Fig. 7-2). As they decussate, these axons carrying pain impulses from each dermatome ascend one to three segments rostral to the level of root entry. For this reason, a discrete lesion of the lateral spinal cord creates a loss of pain and thermal sensation of the contralateral trunk at a dermatomal level beginning two to three segments below that of the spinal cord lesion. As the ascending fibers cross the cord, they are added to the medial side of the spinothalamic tract, so that the longest fibers from the sacral segments come to lie most superficially and fibers from successively more rostral levels occupy progressively deeper positions (Fig. 7-3). This somatotopic arrangement provides an explanation of the pattern of "sacral sparing" of pain and thermal sensation created by centrally placed lesions of the spinal cord.

Other Ascending Tracts Conveying Pain

In addition to the spinothalamic tract—a fast-conducting pathway that projects directly to the thalamus and subserves the sensory-discriminative aspects of noxious stimuli including its location, quality, and possibly intensity—the anterolateral fasciculus of the cord also contains several more slowly conducting systems of fibers. These fibers are placed medial to the spinothalamic tract. One such group, referred to as the spinoreticulothalamic or paleospinothalamic pathway, projects directly to the reticular core of the medulla and midbrain and then to the medial and intralaminar nuclei of the thalamus. At the level of the medulla, these fibers synapse in the nucleus gigantocellularis; more rostrally, they connect with nuclei of the parabrachial region, midbrain reticular formation, periaqueductal gray matter, and hypothalamus. A second, more medially placed pathway in the anterolateral cord ascends to the brainstem reticular core via a series of short interneuronal links. It is not clear whether these spinoreticular fibers are collaterals of the spinothalamic tracts, as Cajal originally stated, or whether they represent an independent system, as more recent data seem to indicate. There is also a third, direct spinohypothalamic pathway in the anterolateral fasciculus.

The conduction of diffuse, poorly localized pain arising from deep and visceral structures (such as the gut, peritoneum, or periosteum) has been ascribed to these slow-conducting, indirect pathways of the anterolateral system. Melzack and Casey have proposed that this fiber system, with its diffuse projections via brainstem and thalamus to the limbic and frontal lobes, subserves the affective aspects, that is, the associated unpleasant feelings,

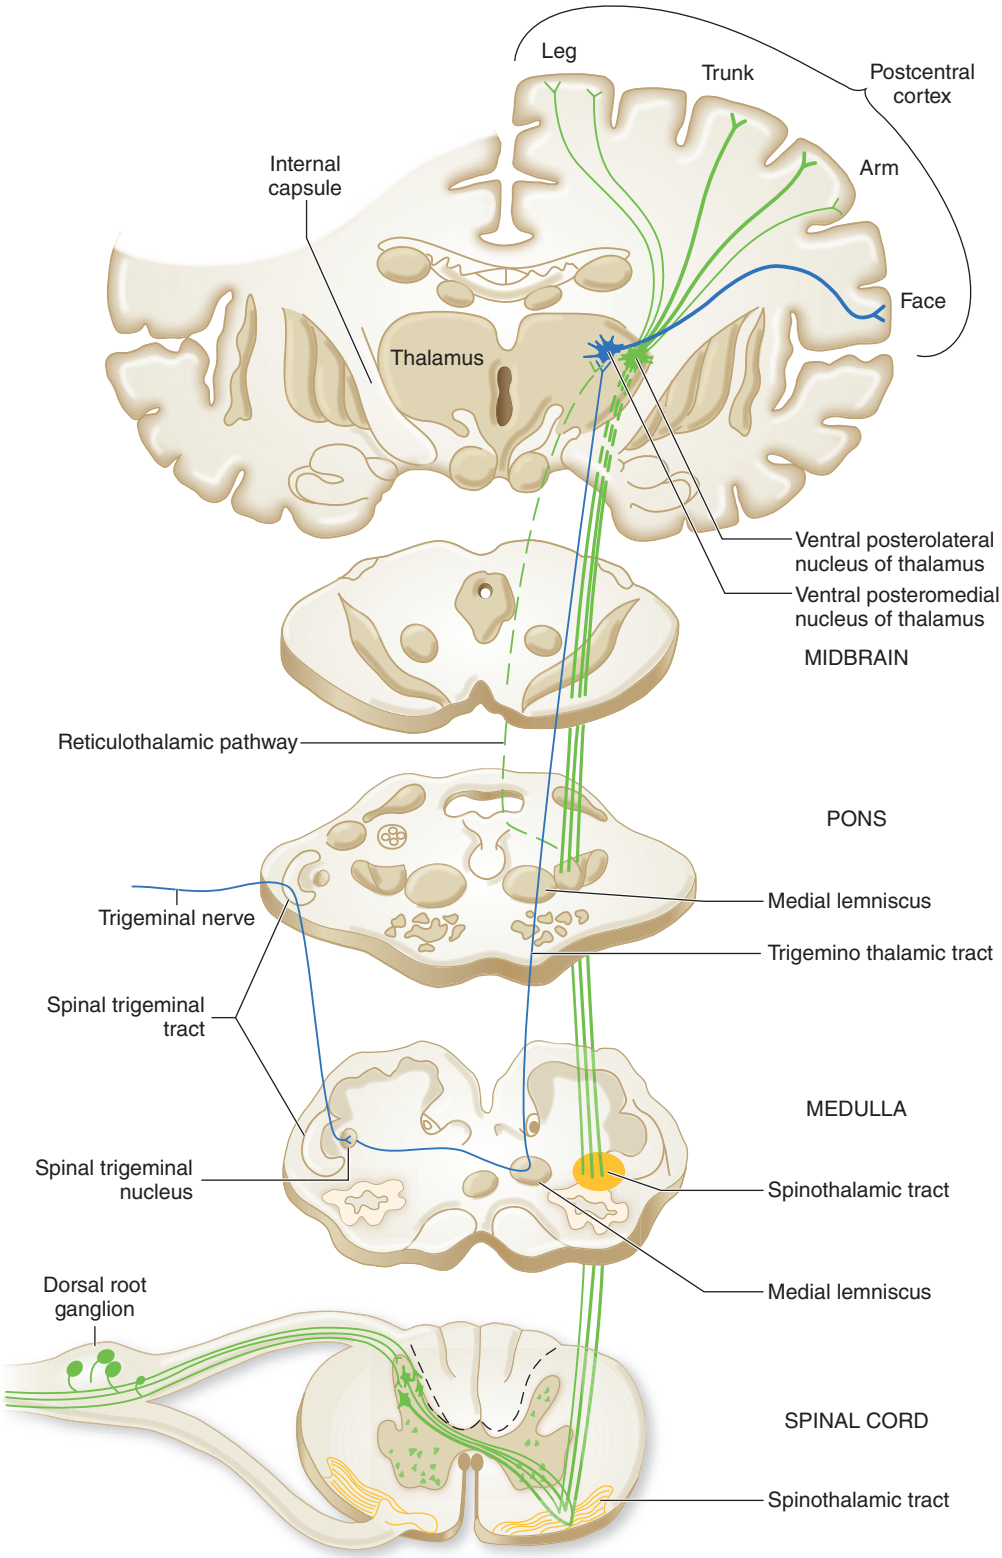

Figure 7-2. The spinothalamic and trigeminothalamic tracts (pain, thermal sense) are shown. In the bottom section, the fibers that form the spinothalamic tract cross over two or three segment rostral to their entry into the cord, not at the same level as depicted. Offshoots from the ascending anterolateral fasciculus (spinothalamic tract) to nuclei in the medulla, pons, and mesencephalon and nuclear terminations of the tract are indicated. The cortical representation of sensation is shown grossly; it is shown more explicitly in Fig. 8-6 and discussed in Chap. 8. The lemniscal (posterior column) system is shown in Fig. 8-5.

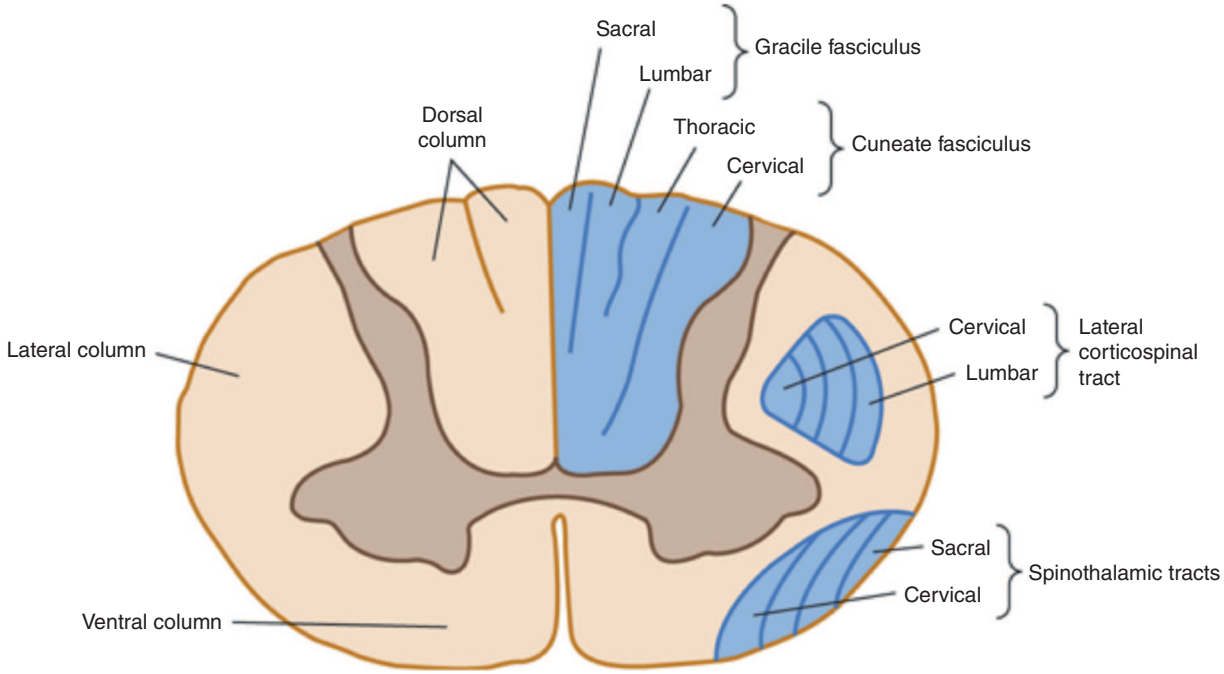

Figure 7-3. Somatotopic organization (segmental arrangement) in the spinal cord. (Reproduced with permission from Waxman SG. *Clinical Neuroanatomy*, 29e, New York: McGraw-Hill, 2020.)

of pain. It is evident that these spinoreticulothalamic pathways continue to evoke the psychic experience of pain even when the direct spinothalamic pathways have been interrupted. Also, the pathways for visceral pain from the esophagus, stomach, small bowel, and proximal colon are carried largely in the vagus nerve and terminate in the nucleus of the solitary tract (nucleus tractus solitarius [NTS]) before projecting to the thalamus, as described below. Other abdominal viscera still activate the NTS when the vagus is severed in animals, probably transmitting impulses through the splanchnic plexus.

It should be emphasized that the foregoing data concerning the cells of termination of cutaneous nociceptive stimuli and the cells of origin of ascending spinal afferent pathways have all been obtained from studies in animals (including monkeys). In humans, the specific cells of origin of the direct spinothalamic tract fibers have not been fully identified. Information about this pathway in humans has been derived from the study of postmortem material and from the examination of patients subjected to anterolateral cordotomy for intractable pain.

Unilateral section of the anterolateral funiculus produces a relatively complete loss of pain and thermal sense on the opposite side of the body, extending to a level two or three segments below the lesion as noted earlier. After a variable period of time, partial sensibility for pain usually returns, probably being conducted by pathways that lie outside the anterolateral quadrants of the spinal cord that gradually increase their capacity to conduct pain impulses. These pathways include a longitudinal polysynaptic bundle of small myelinated fibers in the center of the dorsal horn (the dorsal intracornual tract); and axons of lamina I cells that travel in the dorsal part of the lateral funiculus.

Thalamic Terminus of Pain Fibers

The spinothalamic fibers terminate in the ventral posterior nuclei, the most important of which are the ventroposterolateral (VPL) and ventroposteromedial (VPM) nuclei. These are the nuclei that project to the parietal and other areas of the cortex and subserve discriminative functions relating to pain. A contingent of medially projecting direct spinothalamic fibers terminates in the intralaminar complex of nuclei and in the nucleus submedius. These pertain to less-specific aspects of pain such as alerting and arousal. The indirect spinoreticulothalamic fibers also project onto the intralaminar thalamic nuclei and overlap with the terminations of the direct spinothalamic pathway. Projections from the dorsal column nuclei, which have a modulating influence on pain transmission, are mainly to the ventroposterior group of thalamic nuclei. Each of the thalamic nuclear groups has a distinct cortical projection and each is thought to play a different role in pain sensation.

One practical conclusion to be reached from anatomic and physiologic studies is that, in general, as one ascends from peripheral nerve to spinal, medullary, mesencephalic, thalamic, and limbic levels, the predictability of neuron responsivity to noxious stimuli diminishes. Thus it comes as no surprise that neurosurgical lesions that interrupt afferent pathways at progressively higher levels of the brainstem and thalamus become decreasingly successful, with results that are harder to predict.

Thalamocortical Projections

The ventroposterolateral (VPL) and ventroposteromedial (VPM) nuclei mainly project to two cortical areas: the primary sensory cortex and the upper bank of the sylvian fissure. A small number terminates in the precentral cortex. The thalamic projection to the primary sensory cortex that is distributed mainly along the postcentral gyrus of the anterior parietal lobe is described more fully in Chap. 8 and is shown in Fig. 8-6 (the "sensory homunculus"). This cortical representation is concerned mainly with the reception of tactile and proprioceptive stimuli and with all discriminative sensory functions, including the accurate localization of the site of origin of pain. However, stimulation of these (or any other) cortical areas in a normal, alert human being does not produce pain.

The intralaminar nuclei, which also project to the hypothalamus, amygdaloid nuclei, and limbic cortex, probably mediate the arousal and affective aspects of pain and autonomic responses. Thalamic and cerebral cortical localization of visceral sensation is not well known. However, cerebral-evoked potentials and increased cerebral blood flow (by positron emission tomography [PET] studies) have been demonstrated in the thalamus and pre- and post-central gyri of patients undergoing rectal balloon distention (Silverman et al; Rothstein et al).

Descending Pain-Modulating Systems

The discovery of a system of descending fibers and way stations that modulate activity in nociceptive pathways has proved to be a major addition to our knowledge of pain. The endogenous pain control system that has been studied most extensively emanates from the frontal cortex and hypothalamus and projects to cells in the periaqueductal region of the midbrain and then passes to the ventromedial medulla. From there it descends in the dorsal part of the lateral fasciculus of the spinal cord to the posterior horns (laminae I, II, and V; see further discussion under "Endogenous Pain-Control Mechanisms"). Several other noradrenergic and serotonergic descending pathways, which arise in the locus ceruleus, dorsal raphe nucleus, and nucleus reticularis gigantocellularis, are also important modifiers of the nociceptive response. The clinical significance of these pain-modulating pathways, still under study, is discussed further on.

PHYSIOLOGY OF PAIN

The stimuli that activate pain receptors vary from one tissue to another. The adequate stimulus for skin is one that has the potential to injure tissue, that is, pricking, cutting, crushing, burning, and freezing. These stimuli are ineffective when applied to the stomach and intestine, where pain is produced by an engorged or inflamed mucosa, distention or spasm of smooth muscle, and traction on the mesenteric attachment. In skeletal muscle, pain is caused by ischemia (the basis of intermittent claudication), necrosis, hemorrhage, injection of irritating substances, and by injuries of connective tissue sheaths. Prolonged contraction of skeletal muscle evokes an aching type of pain. Ischemia is also the most important cause of pain in cardiac muscle. Joints are insensitive to pricking, cutting, and cautery, but pain can be produced in the synovial membrane by inflammation and by exposure to hypertonic saline. The stretching and tearing of ligaments around a joint can evoke severe pain. Injuries to the periosteum give rise to pain but probably not to other sensations. Blood vessels are a source of pain when pierced by a needle or involved in an inflammatory process. Distention of arteries or veins, as occurs with thrombotic or embolic occlusion, may be sources of pain; other mechanisms, particularly relevant to the genesis of headache, relate to traction on arteries or inflammation of the meningeal structures by which they are supported. Pain from intraneural lesions probably arises from the sheaths of the nerves. Nerve roots and sensory ganglia, when compressed (e.g., by a ruptured disc), give rise to pain. The subject of headache and its origins is taken up in detail in Chap. 9.

With damage to tissue, there is a release of proteolytic enzymes that act locally on tissue proteins to liberate substances that excite peripheral nociceptors. These pain-producing substances—which include histamine, prostaglandins, serotonin, and similar polypeptides, as well as potassium ions—elicit pain when they are injected intraarterially or intradermally. Other pain-producing substances such as kinins are released from sensory nerve endings or are carried there by the circulation. Local vascular permeability is also increased by these substances.

In addition, direct stimulation of nociceptors releases polypeptide mediators that enhance pain perception. The best studied of these is substance P, which is released from the nerve endings of C fibers in the skin during peripheral nerve stimulation. It causes erythema by dilating cutaneous vessels and edema by releasing histamine from mast cells; it also acts as a chemoattractant for leukocytes. This reaction, called *neurogenic inflammation*, is mediated by antidromic action potentials from the small nerve cells in the spinal ganglia and is the basis of the axon reflex of Lewis; the reflex is abolished in peripheral nerve diseases and can be studied electrophysiologically as an aid to clinical localization (White and Helme). The final pathway of activation of sensory nerves consists of opening the various channels that are expressed on the surface of sensory endings and axons, as detailed in an earlier section.

Perception of Pain

The threshold for perception of pain, that is, the lowest intensity of a stimulus recognized as pain, is approximately the same in all persons. Inflammation lowers the threshold for perception of pain by a process called *sensitization*. The pain threshold is, of course, raised by local anesthetics, centrally acting analgesic drugs, and by certain lesions of the nervous system. Mechanisms other than lowering or raising the pain threshold are important as well. Placebos reduce pain in about one-third of patients in which such effects have been studied (discussed in more detail further on). Distraction and suggestion, by turning attention away from the source of pain, reduce the awareness of and response to pain but not the threshold for its perception.

Strong emotion (fear or rage) suppresses pain, presumably by activation of the above-described descending noradrenergic system. The experience of pain appears to be lessened in manic states and enhanced in depression. Anxious patients in general have the same pain threshold as normal subjects but their reaction may be heightened. The pain thresholds of patients with severe frontal lobe disease (or, in previous times, following frontal lobotomy) are also unchanged but they show minimal or no reaction to painful stimuli.

The conscious awareness or perception of pain occurs only when pain impulses reach the thalamocortical level. The precise roles of the thalamus and cortical sensory areas in this mental process are not fully understood. It was believed that the recognition of a noxious stimulus as such is a function of the thalamus and that the parietal cortex is necessary for the appreciation of the intensity, localization, and other discriminatory aspects of sensation. This traditional separation of sensation (in this instance, awareness of pain) and perception (awareness of the nature of the painful stimulus) has evolved to the view that sensation, perception, and the various conscious and unconscious responses to a pain stimulus comprise an indivisible process. That the cerebral cortex governs the psychological reaction to pain cannot be doubted. It is also likely that the cortex can suppress or otherwise modify the perception of pain; for example, it has been shown that central transmission in the spinothalamic tract can be inhibited by stimulation of the sensorimotor areas of the cerebral cortex.

Functional imaging studies have given insights into the ensemble of brain regions that are activated by painful stimuli. In addition to the expected thalamic and parietal sensory regions, the hypothalamus, and both insular and cingulate cortices, are prominently involved, in proportion to the intensity of the stimulus (Wager). Physical pain in their experiments could be differentiated from social and emotional pain. Findings such as these suggest the possibility of objectively measuring the human pain response.

Endogenous Pain-Control Mechanisms

An important contribution to our understanding of pain has been the discovery of a neuronal analgesia system activated by naturally occurring brain substances that share the properties of opiates. This endogenous system was first demonstrated by Reynolds, who found that stimulation of the ventrolateral periaqueductal gray matter in the rat produced profound analgesia without altering behavior or motor activity. Subsequently, stimulation of other discrete sites in the medial and caudal regions of the diencephalon and rostral bulbar nuclei (notably the raphe magnus and paragigantocellularis) was shown to have the same effect. Under the influence of such electrical stimulation, the animal could be operated on without anesthesia and move around in an undisturbed manner despite the administration of noxious stimuli. Investigation disclosed that the effect of stimulation-produced analgesia (SPA) is inhibition of the neurons of Rexed laminae I, II, and V of the dorsal horn, which are the neurons activated by noxious stimuli. In human subjects, stimulation of the midbrain periaqueductal gray matter through stereotactically implanted electrodes can also produce a state of analgesia. Other sites in which electrical stimulation is effective in suppressing nociceptive responses are the rostroventral medulla (nucleus raphe magnus and adjacent reticular formation) and the dorsolateral pontine tegmentum. These effects are relayed to the dorsal horn gray matter via a pathway in the dorsolateral funiculus of the spinal cord. Ascending pathways from the dorsal horn, conveying noxious somatic impulses, are also important in activating the modulatory network.

Opiates act pre- and post-synaptically on the neurons of laminae I and V of the dorsal horn, suppressing afferent pain impulses from both the A-δ and C fibers as previously discussed. Furthermore, these effects can be reversed by the opioid antagonist naloxone. Interestingly, naloxone can reduce some forms of stimulation-produced analgesia. It has been demonstrated that not only does naloxone enhance clinical pain, but it also interferes with the pain relief produced by placebos (Levine and colleagues). These observations suggest that the beneficial effects of placebos may partly result from the activation of an endogenous system that mutes pain through the release of endogenous opioids, or *endorphins* (see below). Prolonged pain and fear are the most powerful activators of this endogenous opioid-mediated modulating system. The same system is probably operative under a variety of other stressful conditions; for example, some soldiers, wounded in battle, require little or no analgesic medication ("stress-induced analgesia"). The endorphins also act at several loci in the brainstem, at sites corresponding with those producing analgesia when stimulated electrically and generally conforming to areas in which neurons with endorphin receptors are localized.

The most widely studied endorphins are β-endorphin, a peptide sequence of the pituitary hormone β-lipotropin, and two other peptides, enkephalin and dynorphin (Snyder). They and their receptors are found in greatest concentration in the midbrain. At the level of the spinal cord, exclusively enkephalin receptors are found. Figure 7-4 illustrates a theoretical construct of the roles of enkephalin (and substance P) at the point of entry of pain fibers into the spinal cord. Different elements of the sensory system produce and release each of these peptides. A subgroup of dorsal horn interneurons that are in contact with spinothalamic tract neurons also contains enkephalin. It should be noted that in addition to opiate connections, the descending pain-control systems contain noradrenergic and serotonergic influences as well. A descending norepinephrine-containing pathway, as mentioned, has been traced from the locus ceruleus in the dorsolateral pons to the spinal cord, and its activation blocks spinal nociceptive neurons. The rostroventral medulla contains a large number of serotonergic neurons from which descending fibers inhibit dorsal horn cells concerned with pain transmission, perhaps providing a rationale for the use of certain antidepression serotonin agonist medications in patients with chronic pain.

Finally, there is remodeling of the types and densities of surface receptors in the posterior horns as a result of nerve injury. These changes alter the effects of the above-mentioned secondary modulating systems on pain

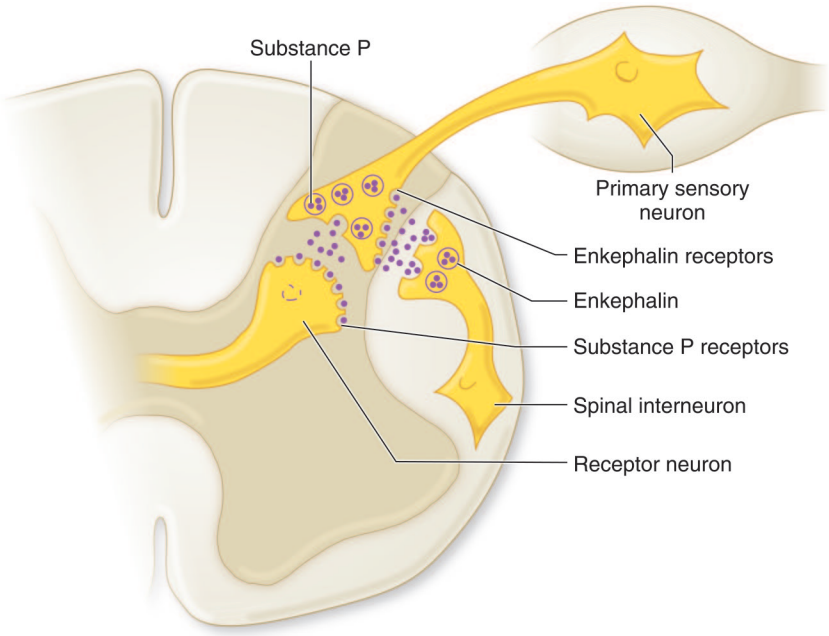

Figure 7-4. Mechanism of action of enkephalin (endorphin) and morphine in the transmission of pain impulses from the periphery to the CNS. Spinal interneurons containing enkephalin synapse with the terminals of pain fibers and inhibit the release of the presumptive transmitter, substance P. As a result, the receptor neuron in the dorsal horn receives less excitatory (pain) impulses and transmits fewer pain impulses to the brain. Morphine binds to unoccupied enkephalin receptors, mimicking the pain-suppressing effects of the endogenous opiate enkephalin.

pathways. This assumes importance in states of chronic pain after somatic and neural injury as discussed in the next sections.

CLINICAL AND PSYCHOLOGIC ASPECTS OF PAIN

Several terms specifically connote various aspects of altered sensory experiences and pain (Table 7-2). *Hyperesthesia* is a general term for heightened cutaneous sensitivity. The term *hyperalgesia* refers to an increased sensitivity and a lowered threshold to painful stimuli. Inflammation and burns of the skin are common causes of hyperalgesia. The term *hypalgesia*, or *hypoalgesia*, refers to the opposite state—that is, a decreased sensitivity and a raised threshold to painful stimuli. A demonstrable reduction in pain perception (i.e., an elevated threshold) associated with an increased reaction to the stimulus once it is perceived, is sometimes referred to as *hyperpathia* (subtly different from hyperalgesia). In this circumstance, there is an excessive reaction to all stimuli, even those (such as light touch) that normally do not evoke pain, a symptom termed *allodynia*. The elicited allodynic pain may have unusual features, outlasting the stimulus and being diffuse, modifiable by fatigue and emotion, and often being mixed with other sensations. The mechanism of these abnormalities is not clear but both hyperpathia and allodynia are common features of neuropathic or neurogenic pain, such as the pain generated by peripheral neuropathy. These features are also exemplified by causalgia, a type of burning pain that results from interruption of a peripheral nerve (see "Causalgia and Reflex Sympathetic Dystrophy").

Table 7-2

NOMENCLATURE IN THE DESCRIPTION OF PAIN AND ABNORMAL SENSATION (SEE ALSO TABLE 8-2)

Dysesthesia: Any abnormal sensation described as unpleasant by the patient
Hyperalgesia: Exaggerated pain response from a normally painful stimulus; usually includes aspects of summation with repeated stimulus of constant intensity and aftersensation
Hyperpathia: Abnormally painful reaction to a painful stimulus and elevated threshold for pain; related to hyperalgesia
Hyperesthesia (hypesthesia): Exaggerated perception of touch stimulus
Allodynia: Abnormal perception of pain from a normally nonpainful mechanical or thermal stimulus; usually has elements of delay in perception and of aftersensation
Hypoalgesia (hypalgesia): Decreased sensitivity and raised threshold to painful stimuli
Anesthesia: Reduced perception of all sensation, mainly touch
Pallanesthesia: Loss of perception of vibration
Analgesia: Loss of perception of pain stimulus
Paresthesia: Spontaneous positive, prickling sensation that is not unpleasant; usually described as "pins and needles"
Causalgia: Burning pain in the distribution of one or more peripheral nerves

Skin Pain and Deep Sensibility

As indicated earlier, the nerve endings in each tissue are activated by different mechanisms, and the pain that results is characterized by its quality, locale, and temporal attributes. Skin pain is of two types: a pricking pain, evoked immediately on penetration of the skin by a needle point; or a stinging or burning pain that follows in a second or two. Together they constitute the "double response" of Lewis. The first is transmitted by the larger (A-δ) fibers and the second pain, which is more diffuse and longer lasting, by the thinner, unmyelinated C fibers. Both types of dermal pain can be localized with precision. Compression of nerves by the application of a tourniquet to a limb abolishes pricking pain before burning pain because large fibers are more susceptible to pressure.

Deep pain from visceral and skeletomuscular structures is usually aching in quality; if intense, it may be sharp and penetrating (knife-like). Occasionally visceral derangements cause a burning type of pain, as in the "heartburn" of esophageal irritation and rarely in angina pectoris. The pain is felt as being deep to the body surface. It is diffuse and poorly localized, and the margins of the painful zone are not well delineated, presumably because of the relative paucity of nerve endings in viscera. Visceral pain produces two additional sensations. First, there is tenderness at remote superficial sites ("referred hyperalgesia") and, second, an enhanced pain sensitivity in the same and in nearby organs ("visceral hyperalgesia"). The concept of visceral hyperalgesia has received considerable attention with regard to the transition from acute to chronic pain, particularly in headache.

Referred Pain

By its very nature, the localization of deep pain of visceral origin is imprecise. Deep pain has indefinite boundaries and it is often perceived at a location that is distant from the visceral structure involved. This sensation, called *referred pain*, is perceived not in the skin overlying the viscera of origin but in other areas innervated by the same spinal segment (or segments). The ostensible explanation for the site of referral is that small-caliber pain afferents from deep structures project to lamina V neurons in the same dorsal horn as do cutaneous afferents. Referred pain occurs as a consequence of the convergence of deep and cutaneous afferent fibers on the same dorsal horn, coupled with the fact that the cutaneous afferents are far more numerous than visceral afferents and have direct connections with the thalamus.

Because the nociceptive receptors and nerves of any given visceral or skeletal structure may project on the dorsal horns of several adjacent spinal or brainstem segments, the pain from these structures may be fairly widely distributed. For example, afferent pain fibers from cardiac structures, distributed through segments T1 to T4, may be projected to the inner side of the arm and the ulnar border of the hand and arm (T1 and T2) as well as the precordium (T3 and T4). Once this pool of sensory neurons in the dorsal horns of the spinal cord is activated, additional noxious stimuli may heighten the activity in the whole sensory field ipsilaterally and, to a lesser extent, contralaterally.

The regions of projection of pain that originate in the bones and adjacent ligamentous structures have been called by Kellgren, "sclerotomes." His maps of pain referral patterns were established from studies of the injection of hypertonic saline into muscle and interspinous ligaments. Dermatomes and sclerotomes do not overlap precisely, as shown in Fig. 7-5 (Inman and Saunders). The concept of sclerotomes is useful to neurologists in analyzing the origins of unusual pains of the cranium, spine, and limbs (see Chaps. 9 and 10).

Another peculiarity of localization is *aberrant reference*, explained by an alteration of the physiologic status of the pools of neurons in adjacent segments of the spinal cord. For example, cervical arthritis or gallbladder disease, causing low-grade discomfort by constantly activating their particular segmental neurons, may induce a shift of cardiac pain cephalad or caudad from its usual locale. Once it becomes chronic, any pain may spread quite widely in a vertical direction on one side of the body. On the other hand, painful stimuli arising from a distant site can exert an inhibitory effect on segmental nociceptive flexion reflexes in the leg (DeBroucker).

Yet another clinical peculiarity of segmental pain is the reduction in power of muscle contraction that it may cause (known as *reflex paralysis*, or *algesic weakness*). The term *antalgia* is often used to describe this effort to avoid pain with movement, especially antalgic gait that arises from lumbar disc or other spinal or hip problems.

Chronic Pain

One of the most perplexing issues in the study of pain is the manner in which chronic pain syndromes arise. Several theories have been offered, none of which satisfactorily accounts for all the clinically observed phenomena. One hypothesis proposes that in an injured nerve, the unmyelinated sprouts of A-δ and C fibers become capable of spontaneous ectopic excitation and after discharge and are susceptible to ephaptic activation. A second proposal derives from the observation that these injured nerves are also sensitive to locally applied or intravenously administered catecholamines because of an overabundance of adrenergic receptors on the regenerating fibers. These mechanisms are thought to be the basis of causalgia (persistent burning and aching pain within and adjacent to the territory of a partially injured nerve) and its associated reflex sympathetic dystrophy; either would explain the relief afforded in these conditions by sympathetic block. This subject is discussed in greater detail in relation to peripheral nerve injuries (see "Peripheral Nerve Pain" and Chap. 43).

A third proposed mechanism is through central sensory structures, for example, sensory neurons in the dorsal horns of the spinal cord or thalamus, if chronically bombarded with pain impulses, may become autonomously overactive (being maintained in this state perhaps by excitatory amino acids) and may remain so even after the peripheral pathways have been interrupted. Peripheral nerve lesions have been shown to induce enduring derangements of pain signaling in the spinal cord (Fruhstorfer and Lindblom). For example, avulsion of nerves or nerve roots may cause chronic pain even in analgesic zones (anesthesia dolorosa or "deafferentation pain"). In experimentally deafferented animals, neurons of lamina V begin to discharge irregularly in the absence of stimulation. Later the abnormal discharge subsides in the spinal cord but can still be recorded in the thalamus. Consequently, painful states such as causalgia, spinal cord pain, and phantom pain are not abolished simply by cutting spinal nerves or spinal tracts.

It is likely that structural or physiologic changes in the spinal cord, of the type alluded to above, are able to produce persistent stimulation of pain pathways. Indo and colleagues review the molecular changes in the spinal cord that may give rise to persistence of pain after the cessation of an injurious episode. It is an open question

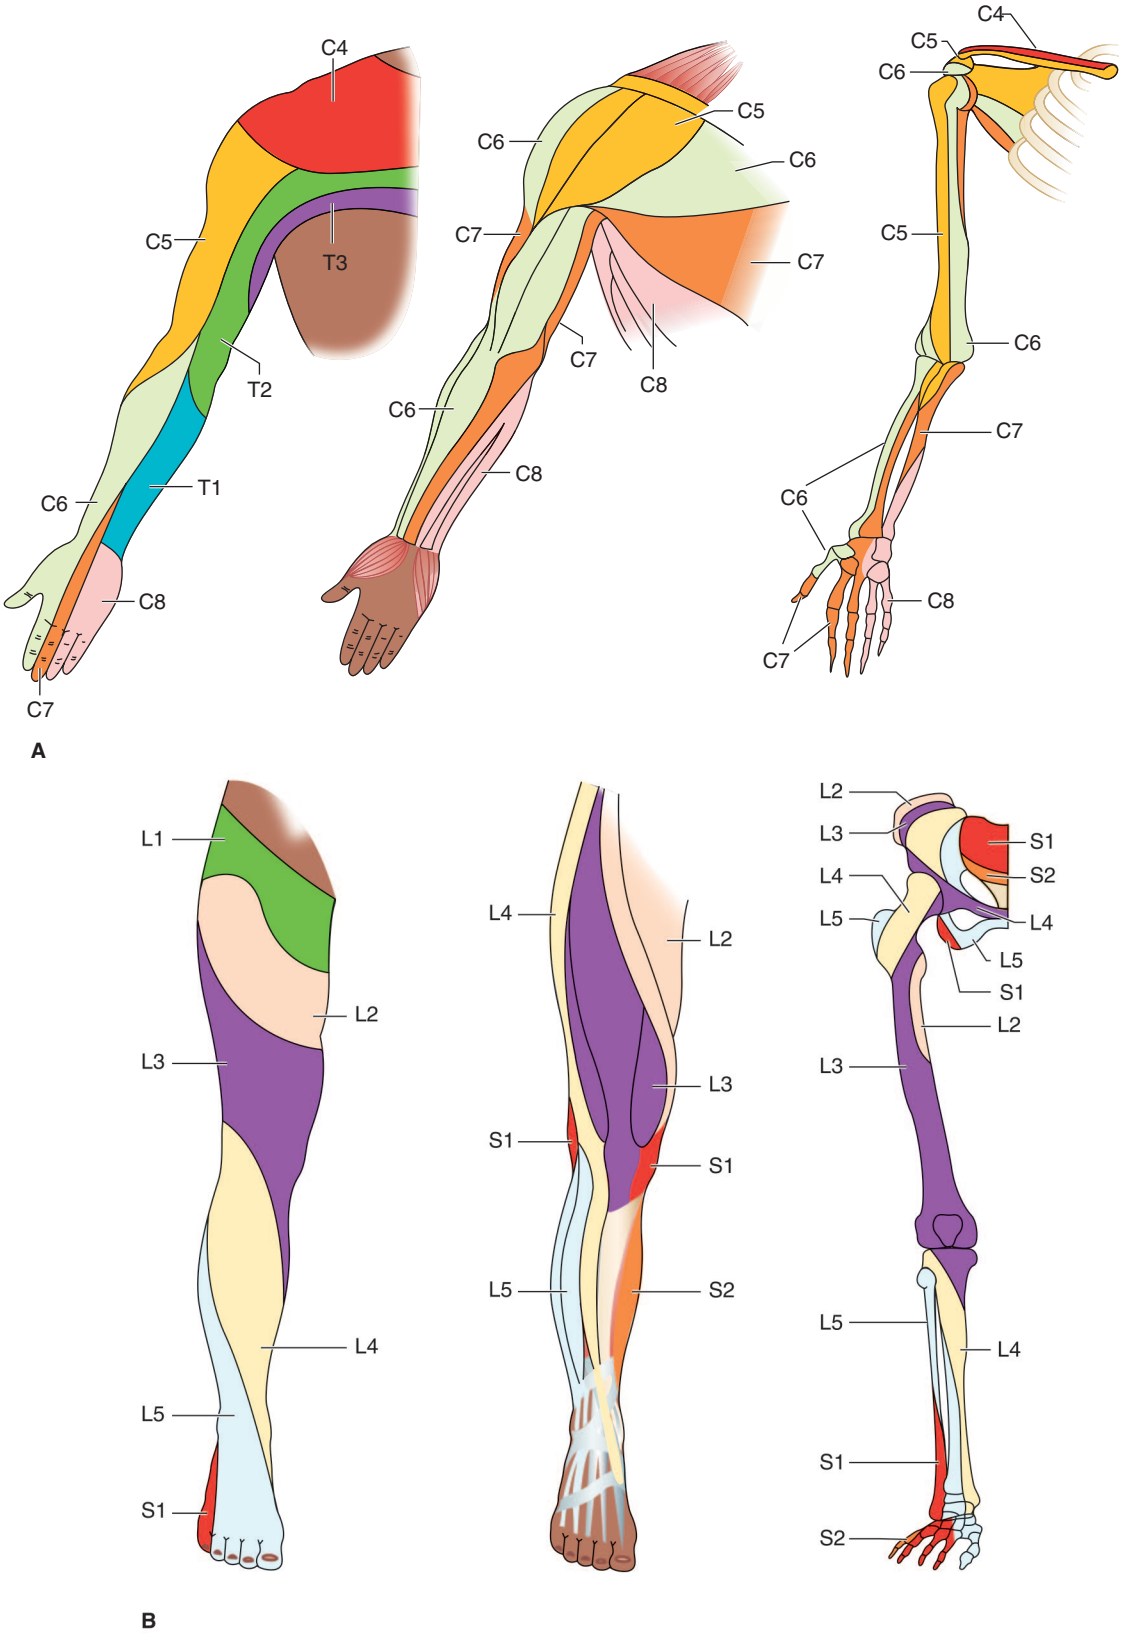

Figure 7-5. Sclerotome maps taken from Inman and Saunders with permission. The projections of pain from osteal and periosteal structures such as ligaments were established by the injection of hypertonic saline or formic acid into the upper extremity (*A*) and lower extremity (*B*) and can also be found in the articles of Kellgren. They may be compared to the dermatomal maps shown in Figs. 8-3 and 8-4. Reproduced with permission from Inman VT, Saunders JB. Referred pain from skeletal structures. *J Nerv Ment Dis* 99(5):660-667,1944.

whether the early treatment of pain may prevent the cascade of biochemical events that allows for both spread and persistence of pain in conditions such as causalgia, but it has been the experience of most clinical pain experts that preemptive treatment of certain painful conditions (e.g., herpes zoster) may reduce the risk of a chronic pain syndrome. None of these phenomena adequately explain the genesis of chronic pain in the absence of an ongoing painful stimulus.

Pain has several other singular attributes. It does not appear to be subject to negative adaptation—that is, pain may persist as long as the stimulus is operative—whereas other somatic stimuli, if applied continuously, soon cease to be perceived. Furthermore, prolonged stimulation of pain receptors sensitizes them, so that they become responsive to even low grades of stimulation, even to touch (allodynia).

The Emotional Reaction to Pain

Another remarkable characteristic of pain is the strong feeling or affect with which it is endowed, nearly always unpleasant. Since pain embodies this element, psychologic conditions assume great importance in all persistent painful states. It is of interest that despite this strong affective aspect of pain, it is difficult to recall precisely, or to reexperience from memory, a previously experienced acute pain. Also, the patient's tolerance of pain and capacity to experience it without verbalization are influenced by culture and personality. Some individuals—by virtue of training, habit, or phlegmatic temperament—remain stoic in the face of pain, and others react in an opposite fashion. In other words, there are inherent variations among individuals that determine the limbic system's response to pain and their expression of it. In this regard, it is important to emphasize that pain may be the presenting or predominant symptom in a depressive illness (see Chap. 48). Price reviews this subject of the affective dimension of pain in detail, but it must be acknowledged that the models offered are largely theoretical. It is noteworthy, however, that on functional imaging studies, regions of the cerebrum that are activated by experimentally induced physical pain overlap to a degree with those for the experience of emotional pain (Wager).

Finally, a comment should be made about the devastating behavioral effects of chronic pain. To quote from Ambroïse Paré, a sixteenth-century French surgeon, "There is nothing that abateth so much the strength as paine." Continuous pain increases irritability and fatigue, disturbs sleep, and impairs appetite. Patients in pain may seem irrational about their illness and may make unreasonable demands on family and physician. Characteristic is an unwillingness to engage in or continue any activity that might enhance their pain. They withdraw from the main current of daily affairs as their thoughts and speech come to be dominated by the pain. Once a person is subjected to the tyranny of chronic pain, depressive symptoms are practically always added. A person's entire identity may be dominated by the mixture of pain and depression (l'homme doloureux). Determining the cause and effect is usually a futile exercise.

APPROACH TO THE PATIENT WITH PAIN AS THE PREDOMINANT SYMPTOM

One learns quickly that not all pain is the consequence of serious disease. Every day, healthy persons of all ages have pains that must be taken as part of normal sensory experience. To mention a few, there are the "growing pains" of presumed bone and joint origin of children; the momentary shock-like pains over an eye or in the temporal or occipital regions ("ice-pick" pain), which strike with such suddenness as to raise the suspicion of a ruptured intracranial aneurysm; inexplicable split-second jabs of pain elsewhere; the more persistent ache in the shoulder, hip, or extremity that subsides spontaneously or in response to a change in position; the fluctuant precordial discomfort of gastrointestinal origin, which conjures up fear of cardiac disease; and the breathtaking "stitch in the side" caused by intercostal or diaphragmatic cramp during exercise. These "normal pains," as they may be called, tend to be brief and to depart as obscurely as they came. Such pains come to notice only when elicited by an inquiring physician or when experienced by a patient given to excessive worry and introspection. They must be distinguished from the pain of disease.

Whenever pain—by its intensity, duration, and the circumstances of its occurrence—appears to be abnormal or when it constitutes the chief complaint or one of the principal symptoms, the physician must attempt to reach a tentative decision as to its mechanism and cause. This is accomplished by a thorough interrogation of the patient, with the physician carefully seeking out the main characteristics of the pain in terms of the following:

- Location
- Mode and time of onset
- Associated features, for example, nausea, muscle spasm
- Quality and time-intensity attributes
- Duration
- Severity
- Provoking and relieving factors

Knowledge of these factors, together with the physical examination, including maneuvers designed to reproduce and relieve the pain and ancillary diagnostic procedures, enable the physician to identify the source of most pains and the diseases of which they are a part. Nevertheless, the severity of pain is often difficult to assess reliably. Extreme degrees of pain are betrayed by the patient's demeanor but lesser degrees can be roughly estimated by the extent to which the pain has interfered with the patient's sleep, work, and other activities, or by the patient's need for bed rest. Some physicians find it helpful, particularly in gauging the effects of analgesic agents, to use a "pain scale," that is, to have the patient rate the intensity of his pain on a scale of zero (no pain) to 10 (worst pain) or to mark it on a line (the Visual Analog Pain Scale). It has been our experience that this effort to quantify pain is often unhelpful to the neurologic analysis as patients rarely rate pain as trivial once they have decided to consult a physician about the problem. For most patients, pain that necessitates medical consultation is, by definition, considered to be serious.

In addition to the pains caused by the more common and readily recognized diseases of each organ system, there remain a significant number of chronic pains that fall into one of four categories: (1) pain from an as yet undiagnosed medical disease; (2) pain associated with disease of the central or peripheral nervous system (i.e., neurogenic, or neuropathic pain); (3) pain associated with psychiatric disease; and (4) pain of unknown cause.

Pain Caused by Undiagnosed Medical Disease

Here the source of the pain is usually in a bodily organ and is caused by a lesion that irritates and destroys nerve endings. Consequently, the term *nociceptive pain* is often used even though it is ambiguous. It usually means an involvement of structures bearing the origin of pain fibers. Cancer is the most frequent example. Osseous metastases, tumors of the kidney, pancreas, or liver, peritoneal tumor implants, invasion of retroperitoneal tissues or the hilum of the lung, and infiltration of nerves of the brachial or lumbosacral plexuses can be extremely painful, and the origin of the pain may remain obscure for a long time. Sometimes it is necessary to repeat all diagnostic procedures after an interval of a few months, even though at first they were negative. From experience one learns to be cautious about reaching a diagnosis from insufficient data. Treatment in the meantime is directed to the relief of pain, at the same time establishing a plan with the patient to proceed with a program of expectant observation.

Neurogenic and Neuropathic Pain

These terms are sometimes used interchangeably to designate pain that arises from direct stimulation of nervous tissue itself, central or peripheral, exclusive of pain caused by stimulation of C fibers by lesions of other bodily structures (i.e., the nociceptive pain described above). The term "neuropathic" has been attached more often to pain arising in the peripheral nervous system. This category comprises a variety of disorders involving single and multiple nerves, those caused by herpes zoster, diabetes, trauma, and trigeminal neuralgia; neuromas and neurofibromas, polyneuropathies of diverse type; root irritation from a prolapsed disc; and spinal arachnoiditis. Neurogenic pain of central origin includes the thalamic pain syndrome of Dejerine-Roussy and spinal cord injuries; and parietal lobe infarction (Schott; Schmahmann and Leifer). As a rule, lesions of the cerebral cortex and white matter are associated not with pain but with hypalgesia.

Particular diseases giving rise to neuropathic pain are considered in their appropriate chapters but the following remarks are applicable to the entire group. The sensations that characterize neuropathic pain vary and are often multiple—burning, gnawing, aching, and shooting or lancinating qualities are described. There is a frequent association with the symptoms of hyperesthesia, hyperalgesia, allodynia, or hyperpathia. The abnormal sensations coexist in many cases with a sensory deficit and local autonomic dysfunction. Chronic neuropathic pain generally responds less well to treatment in comparison to acute pain.

Peripheral Nerve Pain

Pain of peripheral nerve origin, for which the term *neuropathic* is more strictly applicable, is far more common than pain caused by spinal cord, brainstem, thalamic, and cerebral disease. Although the pain is localized to a sensory territory supplied by a nerve, plexus or nerve root, it often radiates to adjacent areas. Sometimes the onset of pain acuity follows an injury; more often it appears at some point during the evolution or recession of the disorder. The disease of the nerve may be obvious, expressed by the usual sensory, motor, reflex, and autonomic changes, or these changes may be undetectable by standard tests. In the latter case, the term *neuralgia* is used.

The postulated mechanisms of peripheral nerve pain are diverse and differ from those of central diseases. Some of the major ideas were mentioned in the earlier section on chronic pain. One mechanism is denervation hypersensitivity, first described by Walter Cannon. He noted that neurons that are deprived of their natural innervation become hyperactive. Others point to a reduced density of certain types of fibers as the basis of the burning pain, although the comparison of the density of nerves from painful and nonpainful neuropathies has not proved to be consistently different. For example, a study of painful versus nonpainful axonal neuropathies found no difference in terms of the type of fiber degeneration (Dyck). Also, the occurrence of ectopic impulse generation along the surface of injured axons and the possibility of ephaptic activation of unsheathed axons seem applicable particularly to some causalgic states. Stimulation of the nervi nervorum of larger nerves by an expanding intraneural lesion or a vascular change may be the mechanism of nerve trunk pain (Asbury and Fields). The sprouting of adrenergic sympathetic axons in response to nerve injury also contributed, and explains the abolition of some cases of causalgic pain by sympathetic blockade. This has given rise to the term *sympathetically sustained pain* for some cases of causalgia, as discussed below.

Regenerating axonal sprouts, as in a neuroma, are hypersensitive to mechanical stimuli. On a molecular level, it has been shown that voltage-gated sodium channels accumulate at the site of a neuroma and all along the axon after nerve injury, and that this gives rise to ectopic and spontaneous activity of the sensory nerve cell and its axon. Such firing has been demonstrated in humans after nerve injury. This mechanism is concordant with the relief of neurogenic pain by sodium channel-blocking antiepileptic drugs.

Spontaneous activity in nociceptive C fibers is thought to give rise to burning pain; firing of large myelinated A fibers is believed to produce dysesthetic pain induced by tactile stimuli. The abnormal response to stimulation is also influenced by sensitization of central pain pathways, probably in the dorsal horns of the spinal cord (Woolf and Mannion). Hyperalgesia and allodynia are thought to result from such a spinal cord mechanism.

Evidence that the sodium channel can generate neural pain is given by the extraordinary disease "paroxysmal extreme pain disorder" also known as "familial rectal pain syndrome." Here, a mutation of the sodium channel gene,

SCN9A, leads to the early onset of paroxysmal autonomic changes and attacks of excruciating deep or burning npatin either diffusely or localized to the specific regions such as the rectum, eye, or jaw. Similar but more diffuse painful states such as erythromelalgia and other pain disorders are being uncovered that are predicated on voltage-gated sodium channel mutations. The rare condition of congenital absence of the ability to experience pain arises from a loss of function mutation in a sodium channel gene and a mutation in the tyrosine kinase receptor gene. Fischer and Waxman provide a summary of the mutations in the sodium channel gene and their clinical presentations. Potassium channels have also been implicated in cases of severe pain, with IgG found against various components of voltage-gated potassium channels (VGKC) in a series of patients with idiopathic pain often accompanied by hyperhidrosis described by Klein and colleagues. They suggested that immune suppression and antiepileptic drugs were helpful but these proposals require corroboration.

Complex Regional Pain Syndrome (Causalgia and Reflex Sympathetic Dystrophy)

Causalgia is the name that Weir Mitchell applied to peripheral neuralgia consequent on trauma, most often following partial interruption of the median or ulnar nerve and, less often, the sciatic or peroneal nerve (see also "Chronic Pain" further on and discussion in Chap. 43, Diseases of the Peripheral Nerves). It is characterized by persistent, severe pain in the hand or foot, most pronounced in the digits, palm of the hand, or sole. The pain has a burning quality and frequently radiates beyond the territory of one peripheral nerve. The painful parts are exquisitely sensitive to contact, so the patient cannot bear the pressure of clothing or drafts of air; even ambient heat, cold, noise, or emotional stimuli intensify the causalgic symptoms. The affected extremity is kept protected and immobile, often wrapped in a cloth moistened with cool water. Sudomotor, vasomotor, and, later, trophic abnormalities are usual accompaniments of the pain.

The term *reflex sympathetic dystrophy* (RSD) has been used to encompass several additional aspects of sustained pain after limb injury in the absence of evident damage to adjacent nerves. The additional features, beyond the pain, are thinning of skin, warm surface temperature, poor nail growth, thinning of underlying bone and general disruption of thermal and vascular control. The skin of the affected part is moist and warm or cool and soon becomes shiny and smooth, at times scaly, devoid of hair, and discolored.

The current nomenclature for this syndrome is *complex regional pain syndrome type 1* (CRPS I) but a plethora of terms (e.g., Sudeck atrophy of bone, minor causalgia, shoulder–hand syndrome, algodystrophy, or algoneurodystrophy) have also been used. It may also follow nontraumatic lesions of the peripheral nerves or even lesions of the CNS ("mimocausalgia"). *Complex regional pain syndrome type 2* (CPRS 2), which is also referred to as *causalgia*, represents the same syndrome except that a history of direct injury to a peripheral nerve can be identified.

A number of theories have been proposed to explain these regional pain syndromes (Schott 2001; Schwartzman and McLellan). For many years they were attributed to a short-circuiting of impulses (ephaptic transmission), the result of an abnormal direct connection between efferent sympathetic and somatic afferent pain fibers at the point of the nerve injury. The demonstration that causalgic pain could be abolished by depletion of neurotransmitters at sympathetic adrenergic endings shifted the presumed site of sympathetic-afferent interaction to the nerve terminals and suggested that the abnormal cross-excitation is chemical rather than electrical in nature. Another possible explanation is that an abnormal adrenergic sensitivity develops in injured nociceptors and that circulating or locally secreted sympathetic neurotransmitters trigger the painful afferent activity. Yet another theory holds that a sustained period of bombardment by sensory pain impulses from one region results in the sensitization of central sensory structures. Molecular changes in sensory neurons and the spinal cord include alterations in *N*-methyl-d-aspartate (NMDA) receptors, induction of cyclooxygenase and prostaglandin synthesis, and changes in gabanergic inhibition in the dorsal horns have all been implicated (Woolf).

One peculiar presentation is a causalgia-dystonia syndrome (Bhatia et al) in which a fixed dystonic posture is engrafted on a site of causalgic pain. The clinical features of both the causalgic and dystonic elements of the syndrome have been somewhat unusual in the cases reported. The degree of injury was often trivial or nonexistent and no signs of a neuropathic lesion were evident. Remarkably, both the causalgia and dystonia spread from their initial sites to widely disparate parts of the limbs and body. The syndrome has not responded consistently to any form of treatment, although some patients recovered spontaneously. Another interesting type of causalgia and reflex sympathetic dystrophy follows deep venous thrombosis in a leg and had in the literature been recorded as "algodystrophy." It may be similar to the left shoulder and hand changes that come on months after a myocardial infarction ("shoulder–hand syndrome").

The treatment of reflex sympathetic dystrophy is largely unsatisfactory, although a certain degree of improvement can be expected if treatment is started early and the limb is mobilized. It can respond favorably, if only temporarily, to procaine block of the appropriate sympathetic ganglia and, for a longer time, to regional sympathectomy. Prolonged cooling and the intravenous injection of guanethidine, a sympathetic-blocking drug, into the affected limb (with the venous return blocked for several minutes) may alleviate the pain for days or longer. Epidural infusions, particularly of analgesics or ketamine, intravenous infusion of bisphosphonates, spinal cord stimulators, and instillation of intrathecal compounds are other forms of treatment, none entirely satisfactory (Kemler).

Central Neurogenic Pain

Various central lesions can damage the sensory system and produce severe pain (Scadding; Woolf and Mannion). With severe spinal cord injury, there may be intolerable pain in regions below the level of the lesion. It may be exacerbated

or provoked by movement, fatigue, or emotion and projected to areas disconnected from suprasegmental structures (akin to the phantom pain in the missing part of an amputated limb). Here, and in the rare cases of intractable pain with lateral medullary or pontine lesions, loss of the descending inhibitory systems seems a likely explanation. Altered sensitivity and hyperactivity of central neurons are alternative possibilities.

Pain in Association With Psychiatric Disease

It is not unusual for patients with depression to have pain as a dominant symptom. As emphasized previously, many patients with chronic pain of all types are depressed, as has been corroborated in a survey of a large number of patients (Wells). In such cases, one is faced with an extremely difficult clinical problem—that of determining whether a depressive state is primary or secondary. Complaints of weakness and fatigue, depression, anxiety, insomnia, nervousness, irritability, palpitations, etc., are woven into the clinical syndrome, attesting to the prominence of a psychiatric disorder. In some instances the diagnostic criteria for depression (cited in Chap. 48) provide some insight, but in others it is impossible to make this determination. Empiric treatment with antidepressant medication or, failing this, with electroconvulsive therapy may provide one way out of the dilemma.

Intractable pain may also be the leading symptom of both somatization and conversion reactions. Experienced physicians are familiar with the patient who has undergone multiple surgical procedures to address painful complaints, a situation referred to as Briquet disease. The recognition and management of this group of disorders are discussed in Chap. 47.

The desire for compensation (e.g., workman's compensation, disability status) can often provoke or perpetuate complaints of headaches, neck pain (i.e., "whiplash" injuries), low back pain, and other painful conditions. The question of ruptured disc is often raised, and laminectomy and spinal fusion may be performed (sometimes more than once) based on dubious radiologic findings. A long delay in the settlement of litigation, allegedly to determine the seriousness of the injury, only enhances the symptoms and prolongs the disability. The medical and legal professions have no certain approach to such problems and often work at cross-purposes. We have found that a frank, objective appraisal of the injury, an assessment of any psychiatric problem, and encouragement to settle the legal claims as quickly as possible work in the best interests of all concerned. Although hypersuggestibility and relief of pain by placebos may reinforce the physician's belief that there is a prominent factor of hysteria or malingering (see Chap. 47), such data are difficult to interpret.

The possibility of drug addiction as a motivation for visiting the physician and reporting severe pain should be addressed. It is can be very challenging to assess pain in individuals with addiction, for their complaints are embedded into a need for medication. Temperament and mood should be evaluated carefully; the physician must remember that the depressed patient often denies feeling dysphoric and may even occasionally smile. The use of alcohol to self-medicate for pain usually indicates a depressive illness or lifelong alcohol dependence.

Chronic Pain of Indeterminate Cause

Pain in the thorax, abdomen, flank, back, face, head, or other part that cannot be traced to any visceral abnormality can create challenging clinical problems. In most cases, obscure neurologic sources, such as a spinal cord tumor and neuroma, have been excluded by repeated examinations and imaging procedures. A psychiatric disorder to which the patient's symptoms and behavior might be attributed cannot be discerned. Yet the patient complains continuously of pain, is disabled, and spends a great deal of effort and resources seeking medical aid.

In such a circumstance, some physicians and surgeons, rather than concede their helplessness, may resort to extreme measures, such as exploratory thoracotomy, laparotomy, or laminectomy. Or they may injudiciously attempt to alleviate the pain and avoid drug addiction by severing roots and spinal tracts, often with the result that the pain moves to an adjacent segment or to the other side of the body.

This type of patient benefits from being seen frequently by the same physician. All the medical facts should be reviewed and the clinical and laboratory examinations repeated if some time has elapsed since they were last done. Tumors in the hilum of the lung or mediastinum; in the retropharyngeal, retroperitoneal, and paravertebral spaces; or in the uterus, testicle, kidney, or prostate pose a special difficulty in diagnosis and are often undetected for many months. More than once, we have seen a patient for months before a kidney or pancreatic tumor became apparent. Neurofibroma causing pain in an unusual site, such as one side of the rectum or vagina, is another type of tumor that may defy diagnosis for a long time.

Truly neurogenic pain is almost invariably accompanied by alterations in cutaneous sensation and other neurologic signs, the finding of which facilitates diagnosis; however, the appearance of the neurologic signs may be delayed—for example, in brachial neuritis. Whether investigation for earlier mentioned abnormalities of the sodium and potassium channels in cases of idiopathic severe unexplained pain is advisable has not been established. The frequent attribution of such pains to an unspecified small fiber neuropathy may be valid but also requires further study.

Because of the complexity and difficulty in diagnosis and treatment of chronic pain, it is common for medical centers to establish a comprehensive interdisciplinary pain clinic. Here a staff of physiatrists, internists, anesthesiologists, neurologists, neurosurgeons, and psychiatrists can review each patient in terms of drug dependence, neurologic disease, and psychiatric problems. Success is achieved by treating each aspect of chronic pain, addressing the individual's problems rather than treating the pain generically, with emphasis on increasing the patient's tolerance of pain by means of biofeedback, meditation, and related techniques; by using special analgesic procedures (discussed later in the chapter); by establishing a regimen of pain medication that does not lead to a rebound

exaggeration of pain between doses; and by controlling depressive illness.

Rare and Unusual Disturbances of Pain Perception

A rare condition known as *congenital insensitivity to pain*, in which anhidrosis is also present, has been attributed to a mutation in the neural tyrosine kinase receptor, a nerve growth factor receptor (Indo). Related versions of this syndrome can be caused by a mutation in the sodium channels expressed in high concentration in nociceptive neurons of the dorsal root ganglia and other genetic causes. A similar loss of pain sensibility is encountered in the Riley Day syndrome (congenital dysautonomia, see Chap. 25).

Neuroma Formation After Nerve Injury

Persistent and often incapacitating pain and dysesthesias may follow any type of injury that leads to partial or complete interruption of a nerve, with subsequent *neuroma formation* or *intraneural scarring*—fracture, contusion of the limbs, compression from lying on the arm while intoxicated, severing of sensory nerves in the course of surgical operations or biopsy of nerve, or incomplete regeneration after nerve suture. It is stated that the nerves in these cases contain a preponderance of unmyelinated C fibers and a reduced number of A-δ fibers; this imbalance is presumably related to the genesis of painful dysesthesias. These cases are best managed by complete excision of the neuromas with end-to-end suture of healthy nerve, but not all cases lend themselves to this procedure.

Another special type of neuroma is the one that forms at the end of a nerve severed at amputation (stump neuroma). Pain from this source is occasionally abolished by relatively simple procedures such as injection of lidocaine, resection of the distal neuroma, proximal neurotomy, or resection of the regional sympathetic ganglia. More common in clinical practice is the mundane, but painful, *Morton neuroma*, usually found on the plantar nerve between the third and fourth metatarsal bones. Pain on compression of the forefoot is the characteristic Mulder sign.

Erythromelalgia

This rare disorder of the microvasculature produces a burning pain and bright red color change, usually in the toes and forefoot and sometimes in the hands, precipitated by changes in ambient temperature. Since its first description by Weir Mitchell in 1878, many articles have been written about it, and recently the cause of a primary familial form was traced to a mutation in a sodium channel protein. Each patient has a temperature threshold above which symptoms appear and the feet become bright red, warm, and painful. The afflicted patient rarely wears stockings or regular shoes because these tend to bring out the symptoms. The pain is relieved by walking on a cold surface or soaking the feet in ice water and by rest and elevation of the legs. The peripheral pulses are intact, and there are no motor, sensory, or reflex changes (Mann, King, and Murphy).

Most cases are idiopathic, some familial and inherited as a dominant trait. There are secondary forms of the disease, the most important one being that associated with essential thrombocythemia (up to 25 percent of patients may have erythromelalgia as the first symptom) but also with other myeloproliferative disorders such as polycythemia vera and with collagen vascular diseases, including thrombotic thrombocytopenic purpura (TTP), during the use of calcium channel blockers and certain dopaminergic agonists such as pergolide and bromocriptine, and with occlusive vascular diseases. Some instances arise as a result of a painful polyneuropathy that predominantly affects the small sensory fibers; more often in these latter conditions, the redness and warmth are constant and the result of damage to sympathetic nerve fibers; see Chap. 43. These symptomatic forms have led some experts to question whether erythromelalgia is a type of neuropathy (Davis et al).

The familial form of erythromelalgia has been traced to a mutation in a sodium channel (NaV 1.7) that is selectively expressed in dorsal root ganglia nociceptive neurons. In addition to its inherent value in explaining the manifestations of this disease, the discovery of this channelopathy has evinced interest in novel ways to treat pain by manipulating sodium channels.

Treatment Aspirin may be useful in the treatment of paroxysms of secondary erythromelalgia and of some primary cases as well (Abbott and Mitts); some clinicians had recommended methysergide, which has fallen out of use because of retroperitoneal and cardiac valvular fibrosis. Even small doses of aspirin may provide relief within an hour, lasting for several days, a feature that is diagnostic. Cyclosporine was reportedly of benefit in a case of familial erythromelalgia but this requires corroboration (Sano et al) and confusingly, the same medication can produce erythromelalgia.

A similar condition, restricted in topography to the region of an acquired single nerve or skin injury, has been described by Ochoa under the term *ABC syndrome* (angry, backfiring C-nociceptors). Episodes of pain and cutaneous vasodilatation were induced by mechanical or thermal stimulation and relieved by cooling. There may be persistent hyperalgesia over the affected area. A similar mechanism may operate in the "red ear syndrome" as a result of irritation of the third cervical root (Lance).

Myofascial Pain Syndrome and Fibromyalgia

A confusing problem in the differential diagnosis of neck and limb pain is posed by the patient with pains that are clearly musculoskeletal in origin but are not attributable to a disease of the spine, articular structures, or nerves. The pain is localized to certain vague points in skeletal muscles, particularly the large muscles of the neck and shoulder girdle, arms, and thighs. We have been unable to corroborate the ill-defined tender nodules or cords (trigger points) that have been reported as an essential element of this illness. Excision of such nodules has not revealed any sign of inflammation or other disease process. The currently fashionable terms *myofascial pain syndrome*, *fibromyalgia*, and *fibrositis* have been attached to the syndrome. Many of the patients are middle-aged women, who also have the equally vague *chronic fatigue syndrome*

(myalgic encephalopathy). Some relief is afforded by interventions such as local anesthetic injection, administration of local coolants, stretching of underlying muscles ("spray and stretch"), and massage, but the results in any given individual are unpredictable and the status of the disorder is not settled.

Lesions of the parietooccipital regions of one cerebral hemisphere sometimes have peculiar effects on the patient's capacity to feel and react to pain. Hecaen and Ajuriaguerra used the term *pain hemiagnosia* to describe patients with right parietal lesion causing left-sided paralysis who became distressed when pinched on the affected side, but made no effort to fend off the painful stimulus with the other hand or to withdraw from it. In contrast, if the good side was pinched, the patient reacted normally and moved the normal hand to the site of the stimulus to remove it.

The phenomenon of *asymbolia for pain* is another rare and unusual condition wherein the patient, although capable of distinguishing different types of pain stimuli from one another and from touch, is said to make none of the usual emotional, motor, or verbal responses to pain. The patient seems totally unaware of the painful or hurtful nature of stimuli delivered to any part of the body, whether on one side or the other. The current interpretation of asymbolia for pain is that it represents a particular type of agnosia called *analgognosia* (see Chap. 21), in which the person loses his ability to adapt his emotional, motor, and verbal actions to the consciousness of a nociceptive impression. Prefrontal lobe lesions from stroke, trauma, tumor, or in former times, frontal lobotomy, can produce a version of this syndrome.

TREATMENT OF PAIN

Once the nature of the patient's pain and underlying disease has been determined, therapy must include some type of pain control. Initially, of course, attention is directed to the underlying disease with the idea of eliminating the source of the pain by appropriate medical, surgical, or radiotherapeutic measures. When the primary disease is not treatable, the physician should, if time and circumstances permit, attempt to use the milder measures for pain relief first—for example, nonnarcotic analgesics and antidepressants or antiepileptic drugs, before resorting to narcotics, local nerve blocks or surgical approaches for pain relief. Not all situations allow this graduated approach, and narcotics may be required early in the course of some illnesses—for example, to treat the pain of visceral and bone cancer. The same measured strategy is appropriate in the treatment of neuropathic pain and of pain of unclear origin, except that one generally stops short of ablative procedures that irrevocably damage nerves or parts of the central nervous system.

In addition to analgesic procedures that block nerves, alter neural conduction, or administer conventional medications in new ways, a number of procedures such as intrathecal pumps and spinal cord stimulators and medications can also play a role in providing effective pain relief in specific situations. For example, trigeminal neuralgia may be relieved by microvascular decompression of a branch of the basilar artery or by controlled damage of the gasserian ganglion; painful dystonic disorders may be relieved by the intramuscular injection of botulinum toxin. The following discussion provides some guidance for the physician. Recently, selective blockers of the Na_v 1.8 sodium channel have been tested for the treatment of acute pain (Alsaloum et al).

Narcotics (Opioids and Opiates)

The main medications used in the treatment of pain are summarized in Table 7-3. If oral medication fails to control the pain, the parenteral administration of opioids may become necessary. One must be aware of the ratios of oral to parenteral dosages required to produce equivalent analgesia.

Should continued use of opiates become necessary, the optimal dose for the relief of pain should be established and the drug then ideally given at regular intervals, rather than "as needed" to avoid breakthrough pain that requires higher cumulative doses of drugs. The administration of morphine (and other narcotics) in this way represents a shift in attitude among physicians because for many years it was widely believed that the drug should be given in the smallest possible doses, spaced as far apart as possible, and repeated only when severe pain reasserted itself. It has become clear that this approach results in unnecessary discomfort and, in the end, the need to use larger doses. Most physicians now realize that the fear of creating narcotic dependence and the expected phenomenon of increasing tolerance must be balanced against the overriding need to relieve pain.

Antidepressant and Anticonvulsant Medications for the Treatment of Pain

Tricyclic antidepressants, especially the methylated forms (imipramine, amitriptyline, and doxepin), enhance the action of serotonin at synapses by blocking its reuptake and putatively facilitate the action of the intrinsic opiate analgesic system. As a general rule, relief is afforded with tricyclic antidepressants in the equivalent dose range of 75 to 125 mg daily of amitriptyline, but little benefit accrues with higher amounts. The specific serotonin reuptake inhibitors (SSRI) antidepressants seem not to be as effective for the treatment of chronic neuropathic pain (McQuay).

Certain antiepileptic drugs (AEDs) have a beneficial effect on many central and peripheral neuropathic pain syndromes but are generally less effective for causalgic pain caused by partial injury of a peripheral nerve. Phenytoin, carbamazepine, gabapentin, levetiracetam, and other AEDs serve an important role in suppressing the lancinating pains of tic douloureux and certain polyneuropathies, as well as pain after spinal cord injury and myelitis. Their action has been attributed to the blocking of sodium channels on axons, thereby reducing the evoked and spontaneous activity in nerve fibers. The full explanation is certainly more complex and related to separate central

Table 7-3

DRUGS FOR THE MANAGEMENT OF CHRONIC PAIN

GENERIC NAME	ORAL DOSE, mg[a]	INTERVAL	COMMENTS
Nonopioid analgesics			
Aspirin	650	q6h	Enteric-coated preparations available
Acetaminophen	650	q4h	Side effects uncommon
Ibuprofen	400	q4–6h	
Naproxen	250–500	q12h	Delayed effects may be due to long half-life
Ketorolac	10–20	q4–6h	Useful postoperatively and for weaning from narcotics. Can be used intramuscularly
Trisalicylate	1,000–1,500	q12h	Fewer gastrointestinal or platelet effects than aspirin
Indomethacin	25–50	q8h	Gastrointestinal side effects common
Tramadol	50	q6h	Potent nonnarcotic with similar side effects but less respiratory depression
Narcotic analgesics			
Codeine	30–60	q4h	Nausea common
Oxycodone	5–10	q4–6h	Usually available combined with acetaminophen or aspirin
Morphine	1-2	q4h	
Morphine, sustained release	90	q12h	Oral slow-release preparation
Hydromorphone	1–2	q4h	Shorter acting than morphine sulfate
Levorphanol	2	q6–8h	Longer acting than morphine sulfate; absorbed well orally
Methadone	10	q6–24h	Delayed sedation because of long half-life
Meperidine	75–100	q4h	Poorly absorbed orally; normeperidine is a toxic metabolite
Fentanyl	25–100 μg	apply q72h	Parenteral and transcutaneous ("patch") use
Antiepileptic and related drugs			
Phenytoin	100	q6–8h	Side effects of drowsiness, ataxia, nystagmus
Carbamazepine	200–300	q8h	
Gabapentin	300–900	q8h	
Pregabalin	25–75	q12h	
Special agents			
Mexiletine	150–200	q4–6h	Heart block, torsade de pointes
Ketamine	10–25 μg/kg/h IV	Bolus or continuous IV infusion	Dysphoria, confusion

[a]mg, unless otherwise noted.

and peripheral sites (Jensen). Often, large doses must be utilized—for example, more than 2,400 mg per day for gabapentin for full effect—but the soporific and ataxic effects of these medications may be poorly tolerated.

Most often a combination of medications is used for the treatment of intractable chronic pain. A common combination is the addition of gabapentin to an opioid such as morphine; perhaps not surprisingly, this was superior to either drug alone in a crossover trial in patients with postherpetic neuralgia and diabetic neuropathy (Gilron).

Treatment of Neuropathic Pain

The treatment of pain induced by nerve root or intrinsic peripheral nerve disease is a challenge for the neurologist and includes several techniques that are generally administered by an anesthesiologist. A typical approach is to begin with one of the medications discussed earlier and listed in Table 7-3. The next simplest treatments are topical; if the pain is regional and has a predominantly burning quality, capsaicin cream can be applied locally, care being taken to avoid contact with the eyes and mouth. The irritative effect of this chemical, which releases substance P, seems in some cases to mute the pain. There has also been limited success with several "eutectic" mixtures of local anesthetic (EMLA) creams or the simpler lidocaine gel with ketorolac, gabapentin, and other medications; these are applied directly to the affected area, usually the feet, in the morning and evening. These preparations may provide some relief in postherpetic neuralgia and painful peripheral neuropathies.

Several types of spinal injections, including epidural, root, and facet blocks, have long been used for the treatment of spinal pain. Injections of epidural corticosteroids or mixtures of analgesics and steroids have been helpful in selected cases of lumbar or thoracic nerve root pain, and occasionally in painful peripheral neuropathy, but precise criteria for the use of this measure are not established. Several randomized trials have failed to support a long-term beneficial effect of these treatments but a number of our patients have been helped for short durations (see Chap. 10 for a more complete discussion of these approaches). Nerve root blocks with lidocaine or with longer-acting local anesthetics are sometimes helpful in establishing the precise source of radicular pain. Their main therapeutic use in our experience has been for thoracic radiculitis from shingles, chest wall pain after thoracotomy, and diabetic radiculopathy. Similar local injections are used in the treatment of occipital neuralgia. Injection of analgesic compounds into and around facet joints and the extension of this procedure, radiofrequency ablation of the small nerves that innervate the joint, are as controversial as epidural injections, with most studies failing to find a consistent benefit. Despite these drawbacks, we have found both of these approaches

useful when pain can be traced specifically to a derangement of these spinal joints, as discussed in Chap. 10.

The intravenous infusion of lidocaine may have a brief beneficial effect on many types of pain, including neuropathic varieties, localized headaches, trigeminal neuralgia, and other facial pains; it is said to be useful in predicting the response to longer-acting agents such as mexiletine, its oral analogue, although this relationship has been erratic in our experience. Mexiletine was used cautiously in patients with heart block but has fallen very much out of favor due to cardiac conduction abnormalities and rare instances of torsade de pointe arrhythmia during and after administration.

Reducing sympathetic activity within somatic nerves by direct injection of the sympathetic ganglia in affected regions of the body (stellate ganglion for arm pain and lumbar ganglia for leg pain) has met with mixed success in neuropathic pain, including that of causalgia and reflex sympathetic dystrophy. A variant of this technique uses regional intravenous infusion of a sympathetic-blocking drug (bretylium, guanethidine, reserpine) into a limb that is isolated from the systemic circulation by the use of a tourniquet. This is known as a "Bier block," after the developer of regional anesthesia for single-limb surgery. These techniques, as well as the administration of clonidine by several routes and the intravenous infusion of the adrenergic blocker phentolamine, is predicated on the concept of "sympathetically sustained pain," meaning pain that is mediated by the interaction of sympathetic and pain nerve fibers or by the sprouting of adrenergic axons in partially damaged nerves. These forms of treatment have been under study for many decades and have given variable results but the most consistent responses to regional sympathetic blockade are obtained in cases of causalgia resulting from partial injury of a single nerve (CRPS I).

A number of other treatments have proven successful in some patients with reflex sympathetic dystrophy and other neuropathic pains but the clinician should be cautious about their chances of success over the long run. One of these has been bisphosphonates (pamidronate, alendronate), which have been beneficial in painful disorders of bone, such as Paget disease and metastatic bone lesions. It is theorized that this class of drug reverses the bone loss consequent to reflex sympathetic dystrophy but how this relates to pain control is unclear (Schott, 1997). Electrical stimulation of the posterior columns of the spinal cord by an implanted device, as discussed below, has become popular. Another treatment of last resort is the intravenous or epidural infusion of drugs such as ketamine; sometimes this has a lasting effect on causalgic pain.

The approaches enumerated here are usually undertaken in sequence; a combination of drugs—such as antiepileptics, narcotics, and clonidine—in addition to anesthetic techniques—is usually required (Katz). The ongoing attention and support of the neurologist are often a cornerstone of a successful treatment plan.

Ablative Surgery in the Control of Pain

Only when a variety of analgesic medications (including opioids) and other practical measures, such as regional analgesia or anesthesia, have completely failed, should one turn to neurosurgical procedures. The least-destructive procedure consists of surgical exploration for a neuroma if a prior injury or operation may have partially sectioned a peripheral nerve. Magnetic resonance imaging of the region should be performed first and will demonstrate most such lesions, but small neuromas may be difficult to visualize, and it is this ambiguity that justifies exploration. Another nondestructive procedure is implantation of a spinal electrical stimulator, usually adjacent to the posterior columns. A sustained reduction in pain intensity and an improved quality of life in patients has been shown in patients with intractable reflex sympathetic dystrophy, even after 2 years (Kemler). Others have found it less durable. It is clear that careful selection of patients, including a test trial of an externalized device, is partial assurance of a good outcome.

Nerve section and dorsal rhizotomy as definitive measures for the relief of regional pain were discussed above under "Treatment of Pain." However, with regard to ablative procedures, the risks are great and the results can be unpredictable. Neurosurgeons, therefore, have largely abandoned these operations. They are, however, sometimes performed for intractable pain produced by cancer.

Spinothalamic tractotomy, in which the anterior half of the spinal cord on one side is sectioned at an upper thoracic level, effectively relieves pain in the opposite leg and lower trunk but is now infrequently performed. This may be done as an open operation or as a transcutaneous procedure in which a radiofrequency lesion is produced by an electrode. The analgesia and thermoanesthesia may last a year or longer, after which the level of analgesia tends to descend and the pain tends to return. Bilateral tractotomy is also feasible but with greater risk of loss of sphincteric control and, at higher levels, of respiratory paralysis. Motor power is nearly always spared because of the position of the corticospinal tract in the posterior part of the lateral funiculus.

Pain in the arm, shoulder, and neck is more difficult to relieve surgically. High cervical transcutaneous cordotomy had been used successfully, with the achievement of analgesia up to the chin. Commissural myelotomy by longitudinal incision of the anterior or posterior commissure of the spinal cord over many segments has also been performed, with variable success. Dorsal root entry zone (DREZ) lesions may temporarily relieve pain in the distribution of one or two nerve roots. Lateral medullary tractotomy is another possibility but must be carried almost to the midline to relieve cervical pain.

Stereotactic surgery on the thalamus for one-sided chronic pain is still used in a few centers and the results have been instructive. Lesions placed in the ventroposterior nucleus are said to diminish pain and thermal sensation over the contralateral side of the body while leaving the patient with all the affective experience of pain; lesions in the intralaminar or parafascicular-centromedian nuclei relieve the painful state without altering sensation (Mark). As mentioned, because these procedures have not yielded predictable benefits to the patient, they are now seldom used. The same unpredictability pertains to cortical ablations. Some patients in whom severe depression of mood is

associated with a chronic pain syndrome have been treated with bilateral stereotactic cingulotomy or subcaudate tractotomy; a degree of success had been claimed for these operations but the results are difficult to evaluate. Orbitofrontal leukotomy has been discarded because of the personality change that it produces. Stimulation of the dorsal cingulate is an emerging treatment for chronic pain, as are other forms of electrical and magnetic stimulation of various brain structures, but none are entirely validated and commonly used as yet.

Nonmedical Methods for the Treatment of Pain

Included under this heading are certain techniques such as biofeedback, meditation, imagery, acupuncture, spinal manipulation, as well as transcutaneous electrical stimulation. Among the most intriguing treatments for patients with complex regional pain syndrome or phantom limb pain has been mirror therapy, in which the patient is instructed to perform movements in the painful arm while observing the unaffected arm in a mirror (Cacchio et al).

Each of the aforementioned methods may be of value in the context of a comprehensive pain management program, usually conducted in a pain clinic as a means of providing relief from pain and suffering, reducing anxiety, and diverting the patient's attention, even if only temporarily, from the painful body part. Although attempts to quantify the benefits of these techniques—judged usually by a reduction of drug dosage—have given mixed or negative results, these approaches play an important role in a comprehensive treatment plan for some patients. Conventional psychotherapy in combination with the use of medication and, at times, electroconvulsive therapy can be of benefit in the treatment of associated depressive symptoms, as discussed above (under "Pain in Association with Psychiatric Diseases") but it should not otherwise be expected to change the experience of pain.

Similarly, the role of placebo in all branches of medicine is being explored, nowhere more saliently than for pain. While the placebo effect rests on the qualities of the therapeutic encounter, it appears to work through conventional neurobiologic mechanisms including endogenous opioids (Kaptchuk and Miller; Fields and Levine).

Whatever treatment is undertaken, medical, procedural or surgical, the objective should be to allow and encourage increased use and mobilization of the affected limb or part, as success at this is most closely associated with relief of pain and reduced suffering.

Disorders of Non-Painful Somatic Sensation

The preceding chapter dealt with pain and its pathways and mechanisms. There are, of course, several other somatosensory experiences that also utilize specialized end organs, pathways, and neurophysiologic mechanisms; these include touch, vibration, and joint position senses, appreciation of deep pressure, as well as integrated sensory experiences that depend on cortical functions and are the subject of the current chapter. The separation between these two broad somatosensory systems (nociceptive, meaning potentially tissue damaging, and non-nociceptive) is logical in so far as each depends on distinctive tracts in the peripheral nerves, spinal cord, and brain. In clinical practice, they are tested to contribute information regarding the localization and nature of a lesion. Because the peripheral nervous system is organized in a segmental pattern, the superficial representation of somatic sensation, nociceptive, and non-nociceptive, follows the dermatomal and peripheral nerve map shown in Fig. 8-1. The special sensory functions of smell, taste, vision, hearing, and vestibular proprioception are covered in the chapter dedicated to those sensory functions.

The sphere of tactile sensory experiences is every bit as rich as that originating in vision and audition. The receptors that translate mechanical forces on the skin are varied and well adapted to allow the brain to distinguish among subtle experiences, from the texture of water to the coarseness of sand between the fingers. Furthermore, sensory and motor functions are interdependent, as was dramatically illustrated by the early animal experiments of Claude Bernard and Charles Sherrington, in which practically all effective movement of a limb was abolished by eliminating only its sensory innervation (sectioning of posterior roots). Interruption of other sensory pathways and destruction of the parietal cortex also has profound effects on motility. To a large extent, human motor activity depends on a constant influx of sensory impulses (most of them not consciously perceived). Sensory-motor integration is therefore necessary for normal nervous system function, but disease may affect motor or sensory functions independently. There also may be loss or impairment of sensory function, and this can represent the principal manifestation of neurologic disease.

ANATOMIC AND PHYSIOLOGIC CONSIDERATIONS

All sensation depends on impulses that are excited by stimulation of receptors and conveyed to the central nervous system by afferent (sensory) fibers. Sensory receptors are of two general types: those in the skin, mediating superficial sensation (*exteroceptors*), and those in the deeper somatic structures (*proprioceptors*). Skin receptors are particularly numerous and transduce four types of sensory experience: warmth, cold, touch, and pain. Proprioceptors provide information on the position of the body or parts of the body; of the force, direction, and range of movement of the joints (kinesthetic sense); and a sense of pressure, both painful and painless. Histologically, a wide variety of sensory receptors have been described, from simple, free terminals to highly branched and encapsulated structures, the latter bearing the names of the anatomists who first described them (see below). In some texts, these nerve endings are called "dendrites" because they are the distal processes of the sensory ganglion cell and the direction of flow of physiologic activity and of sensory information from these structures in the periphery is toward the cell body.

Mechanisms of Cutaneous Sensation

As indicated in the preceding chapter, it had been thought that each of the primary modalities of cutaneous sensation is subserved by a morphologically distinct end organ, each with its separate peripheral nerve fibers. These can be broadly categorized as cutaneous and subcutaneous mechanoreceptors, muscle and joint mechanoreceptors, thermal receptors, and pain receptors (nociceptors). According to this formulation, postulated by von Frey and still largely correct but modified as noted further on, there is a degree of specificity for each receptor and nerve fiber type, each type of end organ responding preferentially to a modality of sensory stimulus.

There are several *cutaneous mechanoreceptors*: Meissner corpuscles (named after Georg Meissner), touch; Merkel discs (named after Friedrich Sigmund Merkel), pressure; Ruffini plumes (named after Angelo Ruffini), skin stretch;

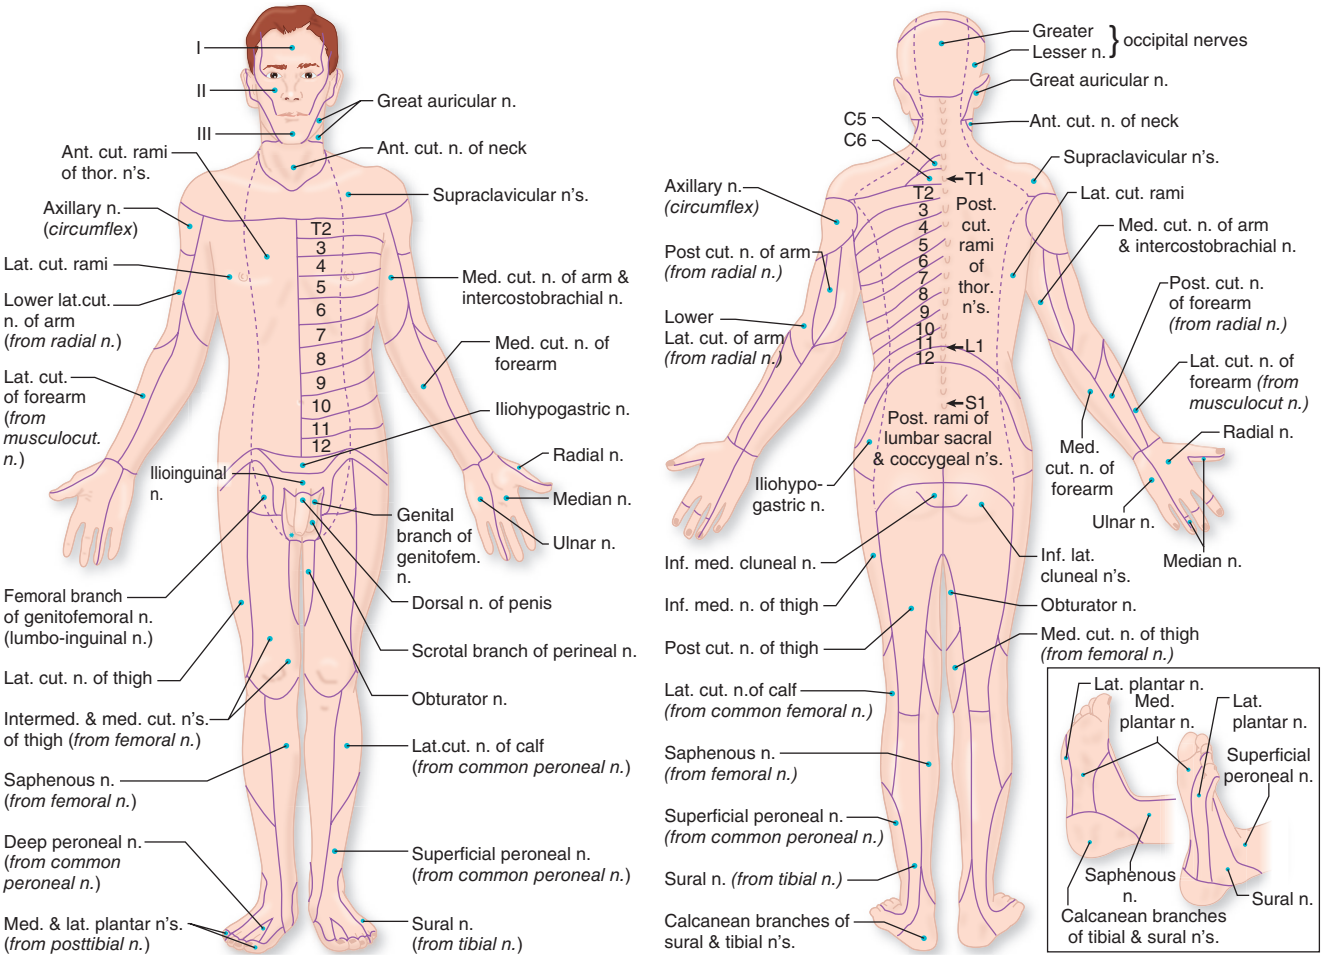

Figure 8-1. The cutaneous fields of peripheral nerves. (Reproduced with permission from Haymaker W, Woodhall B: Peripheral Nerve Injuries, 2nd ed. Philadelphia, Saunders, 1953.)

and Pacini (Pacinian) corpuscles (named after Filippo Pacini), vibration, and several others that are more specialized. Likewise, several receptors detect *muscle force, length, and joint angle*: the intrafusal muscle spindle, stretch, and speed of contraction; Golgi tendon organ, muscle length; joint capsule receptors; joint angle; stretch sensitive-free endings, which is sensitive to force. There are also, as mentioned in the previous chapter, specialized nerve endings for *temperature* (cool and warm), for extremes of temperature (cold and hot) such as Krause end bulbs (named after Wilhelm Krause and also called bulboid receptors) for cold; and for *pain*, nerve endings that are not associated with a transducer ("free nerve endings"). The last of these are also termed "naked" because they are surrounded by Schwann cells but are not myelinated (Table 8-1 and Fig. 8-2).

The *specificity theory*, expressed in the preceding paragraph, has been modified in respect to some somatosensory modalities. For example, Merkel discs and Meissner corpuscles and free nerve endings can all be activated by moving or stationary tactile stimuli. The concept of specificity

Table 8-1

SENSORY RECEPTORS RESPONSIBLE FOR DETECTION OF TOUCH (SEE ALSO TABLE 7-1)

RECEPTOR TYPE	MAIN FUNCTION	MOST SENSITIVE STIMULUS	LOCATION	PHYSIOLOGIC CHARACTERISTICS
Merkel	Sustained pressure, form, and roughness	Edges, points	Tip of epidermal sweat glands	Small receptive field and slowly adapting
Pacinian	Skin deformation	Detects objects down to 200 microns, high frequency vibration (optimal at 250 Hz)	Deep dermis	Large receptive field and rapidly adapting
Meissner	Light touch, low frequency vibration	Moving superficial stimulus	Dermal papillae close to surface	Small receptive field, rapidly adapting
Ruffini ending	Lateral deformation	Skin stretch	Mid-dermis and throughout skin	Sustained response and slowly adapting

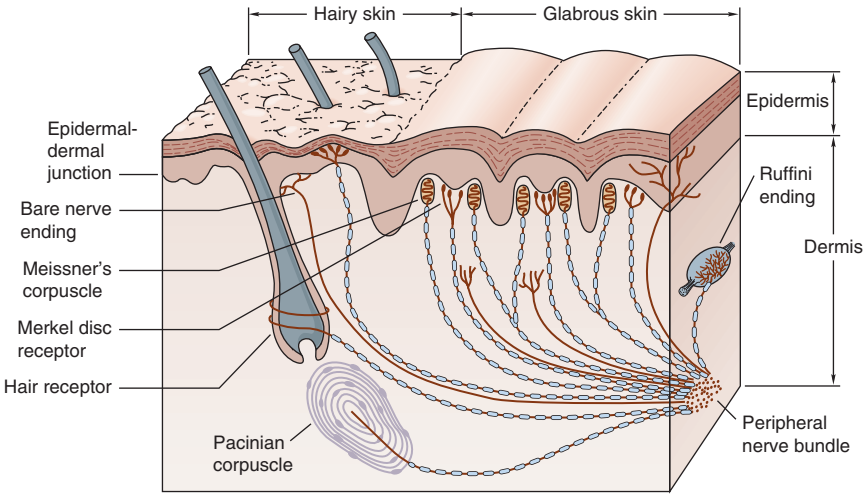

Figure 8-2. Mechanoreceptors in hairy and hairless (glabrous) skin of the hand. Receptors are located in the superficial skin, at the junction of the dermis and epidermis, and more deeply in the dermis and subcutaneous tissue. The receptors of the glabrous skin are Meissner's corpuscles, in the dermal papillae; Merkel disc receptors, between the dermal papillae; and bare nerve endings. The receptors of the hairy skin are hair receptors, Merkel's receptors, and bare nerve endings. Subcutaneous receptors, include Pacinian corpuscles and Ruffini endings. Nerve fibers that terminate in the superficial layers of the skin are branched at their distal terminals, innervating several nearby receptor organs; nerve fibers in the subcutaneous layer innervate only a single receptor organ. The structure of the receptor determines its physiological function. (Reproduced with permission from Kandel ER, Schwartz JH, Jessell TM: *Principles of Neural Science,* 4th ed. New York, McGraw-Hill, 2000.)

has held up best in relation to peripheral mechanisms for pain insofar as certain primary afferent fibers, namely the C and A-δ fibers and their free nerve endings, respond maximally to noxious stimuli. Even these freely branching receptor endings and their pain fibers convey considerable non-noxious information; that is, their specificity as pain fibers is not absolute (see Chap. 7). With appropriate stimulation of the cornea, each of the four primary modalities of somatic sensibility (touch, warmth, cold, and pain) can be recognized, even though the cornea contains only free nerve endings (Lele and Weddell). In the outer ear, which is also sensitive to these four modalities, only two types of receptors—freely ending and perifollicular—are present. The lack of organized receptors in the cornea and ear makes it evident that these types of receptors are not essential for the recognition of cold and warmth as von Frey and other anatomists had postulated.

Instructive refinements of the specificity theory have emerged based on observations to the responses of warm and cold spots to different stimuli (Kibler and Nathan). Warm and cold spots are those small areas of skin that respond most consistently to thermal stimuli with a sensation of warmth or cold. They found that a cold stimulus applied to a warm spot gave rise to a sensation of cold and that a noxious stimulus applied to a warm or cold spot gave rise only to a painful sensation; they also noted that mechanical stimulation of these spots gave rise to a sensation of touch or pressure. These experiments indicate that cutaneous receptors, some not distinguishable from each other on morphologic grounds, are probably endowed with only relative degrees of specificity in the sense that each responds preferentially (i.e., has a lower threshold) to one form of stimulation.

Physiologic studies have shown that rather than the type of receptor, the quality of sensation depends on the type of *nerve fiber* that is activated. Microstimulation of single sensory fibers in a peripheral nerve arouses different sensations, depending on which fibers are stimulated. The intensity of sensation, on the other hand, is governed by the frequency of stimulation and the number of sensory units that are stimulated. Stated somewhat differently, the magnitude or intensity of sensation is encoded by afferent impulse frequency (*temporal summation*). In addition, as the intensity of stimulation increases, more sensory units are activated (*spatial summation*).

Localization of a stimulus was formerly thought to depend on the simultaneous activation of overlapping sensory units. Tower defined a peripheral sensory unit as a dorsal root ganglion cell, its central and distal processes, and all the sensory endings in the territory supplied by those distal processes (the receptive field of the sensory cell). In the very sensitive pulp of the finger, where the error of localization is less than 1 mm, there are 240 overlapping, low-threshold mechanoreceptors per square centimeter. Specialized physiologic techniques have demonstrated that activation of even a single sensory unit is sufficient to localize the point stimulated and that the body map in the parietal lobe is capable, by its modular columnar organization, of encoding such refined topographic information. Also, each point in the skin that is stimulated may involve more than one type of receptor. To gain access to its receptor, a stimulus must pass through the skin and possess enough energy to transduce, that is, depolarize, the nerve ending.

Another feature of the sensory endings is their variable *adaptation* to continued tactile forces. The impulse that is generated by a sensory ending is a graded one, not an all-or-none phenomenon like an action potential in nerve. This poorly understood peripheral generator determines the frequency of impulses in the nerve and to what degree the nerve response is sustained or fatigues. While anatomists have separated sensory receptors by morphology and physiologists classify them by the associated nerve fiber type as discussed below, there has been a trend to further separate receptors into low or high-threshold types and to classify them by the rapidity of adaptation. Low-threshold receptors respond to weak and innocuous forces, and high-threshold nerve endings are mainly nociceptive. The low-threshold ones show different patterns of adaptation depending on whether there is sustained firing during deformation (slowly adapting, mainly Merkel discs and Ruffini endings) or respond maximally to objects moving across the skin (rapidly adapting and firing at the onset and offset of stimuli, mainly Meissner and

Pacinian corpuscles). The high-threshold receptors can be separated by neuropeptide and other expression markers (Abraira and Ginty).

Sensory Pathways

Sensory Nerves

As just noted, each sensory end organ is most fully characterized by morphology and sensitivity to a stimulus, its physiologic characteristics of threshold and adaptation, and singularly, by the nerve fiber type to which it is connected. Fibers that mediate superficial sensation are in cutaneous sensory or mixed sensorimotor nerves. In cutaneous nerves, unmyelinated pain and autonomic fibers exceed myelinated fibers by a ratio of 3 or 4:1. The myelinated fibers are of two types: small, lightly myelinated, A-δ fibers for pain and cold, as discussed in Chap. 7 (see Table 7-1), and larger, faster-conducting A-α fibers for touch and pressure. Nonmyelinated autonomic fibers are efferent (postganglionic) and innervate piloerector muscles, sweat glands, and blood vessels. The differing conduction velocities of these fibers are discussed in Chap. 2.

Each cutaneous afferent fiber connects to several receptors of the same type (touch, pain, or temperature), which are irregularly distributed in the skin and account for what had been termed "sensory spots" as alluded to above and in the preceding chapter. Proprioceptive fibers carry pressure sense and, with endings in articular structures, the sense of position and movement; they enable one to discriminate the form, size, texture, and weight of objects. However, sensations of tickle, itch, and wetness are believed to arise from combinations of several types of receptors. *Itch*, for example, is a distinctive sensation that can be separated on clinical and neurophysiologic grounds from touch and from pain. It is transmitted by specific C fibers, not by touch mechanisms; regions of analgesia no longer can be stimulated to itch, but areas of anesthesia retain this sensation.

Spinal Roots

The sensory nerves are incorporated into plexi (lumbosacral, brachial plexus) and then divided into the dorsal roots. All the sensory neurons have their cell bodies in the dorsal root ganglia. The peripheral extensions of these cells are the sensory nerves; the central projections of these same cells form the posterior (dorsal) roots and enter the spinal cord. Each dorsal root contains all the fibers from skin, muscles, connective tissue, ligaments, tendons, joints, bones, and viscera that lie within the distribution of a single body segment (somite). This segmental innervation has been amply demonstrated in humans and animals by observing the effects of lesions that involve one or two spinal nerves, such as (1) herpes zoster, which also causes visible vesicles in the corresponding area of skin; (2) the effects of a prolapsed intervertebral disc, which causes hypalgesia in a single root zone; and (3) surgical section of several roots on each side of an intact root. Maps of the dermatomes derived from these several types of data are shown in Figs. 8-1, 8-3, and 8-4. It should be noted that there is considerable overlap between adjacent dermatomal segments, more so for touch than for pain. By contrast, there is less overlap between adjacent peripheral nerves and almost none between the divisions of the trigeminal nerve. Also, the maps differ somewhat according to the methods used in constructing them. In contrast to most dermatomal charts, those of Keegan and Garrett (based on the injection of local anesthetic into single dorsal root ganglia) show bands of hypalgesia to be continuous longitudinally from the periphery to the spine (Fig. 8-4). The distribution of pain fibers from deep structures, although not exactly corresponding to that of pain fibers from the skin, also follows a segmental pattern. In Chap. 7, it was commented that the areas of projection of referred pain from the visceral organs and musculoskeletal structures roughly correspond to the overlying dermatomes, but they have distinctive patterns, termed sclerotomes (see Fig. 7-5).

Posterior Root Entry Zone, Dorsal Horns, and Posterior Columns

In the dorsal roots, the sensory fibers are first rearranged according to function. Large and heavily myelinated fibers enter the cord just medial to the dorsal horn and divide into ascending and descending branches. These descending fibers and some of the ascending ones enter the gray matter of the dorsal horn within a few segments of their entrance and synapse with nerve cells in the posterior horns as well as with large ventral horn cells that are the origin of the efferent limb of the segmental reflexes. Some of the ascending fibers run uninterruptedly in the *dorsal columns* of the *same side of the spinal cord*, terminating in the gracile and cuneate nuclei in the upper cervical spinal cord and medulla (Fig. 8-5). The central axons of the primary sensory neurons are joined in the posterior columns by other secondary neurons whose cell bodies lie in the posterior horns of the spinal cord. The fibers in the posterior columns assume a medial position as new fibers from each successively higher root are added laterally, thereby creating somatotopic laminations (see Fig. 7-3).

Of the long ascending posterior column fibers, which are activated by mechanical stimuli of skin and subcutaneous tissues and by the movement of joints, only about 25 percent (from the lumbar region) reach the gracile nuclei at the upper cervical cord. The remaining fibers send collaterals to, or terminate in, the dorsal horns of the spinal cord, at least in the cat (Davidoff). An estimated 20 percent of ascending posterior column fibers originate from cells in Rexed layers IV and V of the posterior horns (see Fig. 7-1) and convey impulses from low-threshold mechanoreceptors that are sensitive to hair movement, skin pressure, or noxious stimuli. There are also descending fibers in the posterior columns, including fibers from cells in the dorsal column nuclei.

The posterior columns contain a portion of the fibers for the sense of touch as well as the fibers mediating the senses of pressure, vibration, direction of movement, and position of joints, which are also necessary for the integrative sensory experience of stereoesthesia—recognition of surface texture, shape, numbers, and figures written on the skin and two-point discrimination. The nerve cells of the nuclei gracilis and cuneatus and accessory cuneate nuclei give rise to a secondary afferent path, which crosses the

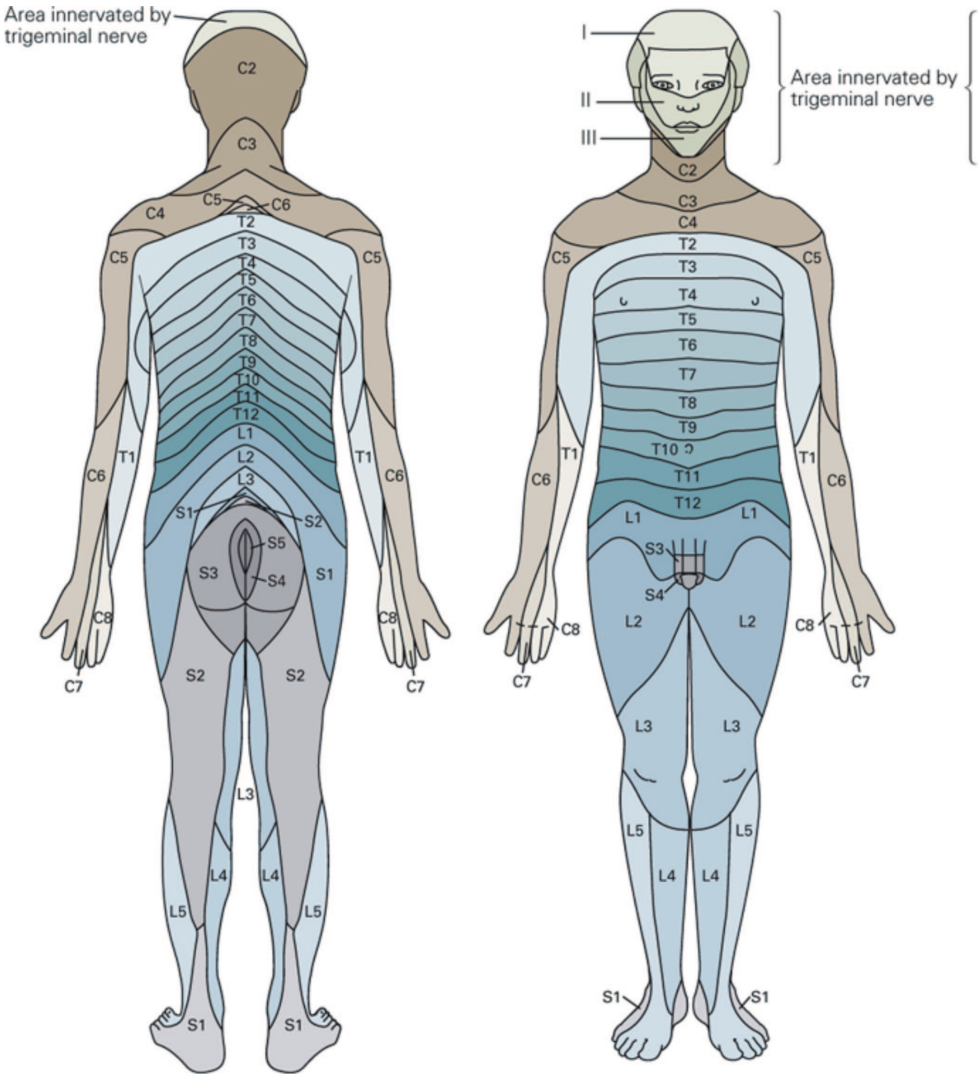

Figure 8-3. Distribution of the sensory spinal roots on the surface of the body (dermatomes). (Reproduced with permission from Receptors of the Somatosensory System. In: Kandel ER, Koester JD, Mack SH, Siegelbaum SA. *Principles of Neural Science*, 6e. New York: McGraw Hill; 2021.)

midline in the medulla and ascends as the medial lemniscus to the posterior thalamus (Fig. 8-5). However, the fiber pathways in the posterior columns are not the sole mediators of proprioception in the spinal cord (see "Posterior [Dorsal] Column Syndrome" further on).

In addition to the well-defined posterior column pathways, there are cells in the more loosely structured "reticular" part of the dorsal column that receive secondary ascending fibers from the dorsal horns of the spinal cord and from ascending fibers in the posterolateral columns. These dorsal column fibers project to brainstem nuclei, cerebellum, and thalamic nuclei. Many other cells of the dorsal horn nuclei are interneurons, with both excitatory and inhibitory effects on local reflexes or on the primary ascending sensory neurons. The functions of many of the extrathalamic projections of dorsal column cells are unknown (Davidoff).

As described in the previous chapter, thinly myelinated or unmyelinated fibers, subserving mainly pain sensibility but some sensitive to touch and pressure, enter the cord on the lateral aspect of the dorsal horn and synapse with dorsal horn cells, mainly within a segment or two of their point of entry into the cord. The dorsal horn cells, in turn, give rise to secondary sensory fibers, some of which may ascend ipsilaterally but most of which decussate and ascend in the spinothalamic tracts (see Figs. 7-1 and 7-2). Observations based on surgical interruption of the anterolateral funiculus indicate that fibers mediating touch and deep pressure occupy the ventromedial part (anterior spinothalamic tract). Also as remarked in Chap. 7, an ascending tract of secondary sensory axons lies in or medial to the descending corticospinal system.

After the posterior columns terminate in the gracile and cuneate nuclei of the rostral cervical cord and medulla, synapses are made with fibers that cross the midline and ascend to form the medial lemniscal tracts in the brainstem. The lemniscal system is situated in a paramedian position, changing orientation slightly at different levels of the brainstem and joining the spinothalamic system in the rostral midbrain to terminate in the posterior thalamic nuclei (Fig. 8-5 and also Fig. 7-2).

Trigeminal Connections

Similar to the peripheral nerves, the sensory cell bodies for touch, pressure, and pain from these regions lie in the gasserian ganglion. The pathways mediating cutaneous

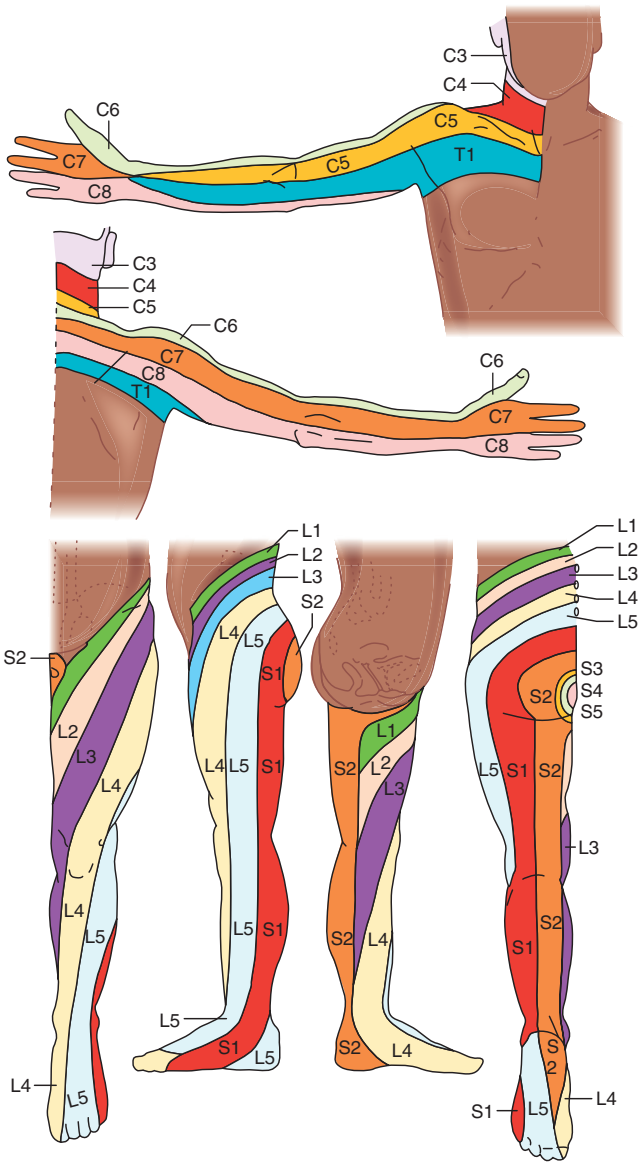

Figure 8-4. Dermatomes of the upper and lower extremities, outlined by the pattern of sensory loss following lesions of single nerve roots. (Reproduced with permission from Keegan JJ, Garrett FD. The segmental distribution of the cutaneous nerves in the limbs of man. *Anat Rec*. 1948;102(4):409-437.)

sensation from these areas—especially touch, pain, and temperature—are conveyed to the brainstem by the trigeminal nerve. After entering the pons, the fibers for touch synapse in the principal trigeminal sensory nucleus and the secondary neurons cross and join the medial lemniscus on its transit to the thalamus. A specialized system for proprioception of mandibular (masseter) movement originates in muscle spindles and has cell bodies in the mesencephalic nucleus of the fifth nerve.

As discussed in the preceding chapter, the pain and temperature fibers of the trigeminal nerve turn caudally and run through the ipsilateral medulla as the descending spinal trigeminal tract, synapsing with the long, vertically oriented spinal trigeminal nucleus that lies beside the tract. Axons from the neurons of this nucleus cross the midline and ascend as the trigeminal quintothalamic tract (also termed, somewhat imprecisely, trigeminal lemniscus) along the medial side of the spinothalamic tract (see Figs. 7-2 and 8-5), of which it is the equivalent. There is a somatotopic organization of fibers for pain and temperature, but not touch, in the trigeminal nucleus, so that the central part of the face is represented most rostrally, and the peripheral portion, most caudally, giving rise to an "onion skin" pattern of sensory loss (see also Chap. 44).

Thalamocortical Connections

The ventral posterior thalamic nucleus receives fibers from the medial lemniscal, spinothalamic, and trigeminal (fibers from the principal sensory and spinal trigeminal nuclei) tracts, and projects mainly to two somatosensory cortical areas. The first area (S1) corresponds to the postcentral cortex or Brodmann areas 3, 1, and 2 (see Fig. 3-3). S1 afferents are derived primarily from the ventral posterolateral nucleus (VPL, the terminus of medial lemniscal and spinothalamic fibers) and the ventral posteromedial nucleus (VPM, the terminus of trigeminal fibers) and are distributed somatotopically, with the leg represented superomedially and the face inferolaterally (face and hand are juxtaposed). Figure 8-6 ("sensory homunculus") shows the cortical representation of sensory information in the postcentral gyrus. As in the case of the motor representation (see also Fig. 3-4), a disproportionate area is devoted to localization in the fingers, lips, and face.

Electrical stimulation of this area yields sensations of tingling, numbness, and warmth in specific regions on the opposite side of the body. The information transmitted to S1 is tactile and proprioceptive, derived mainly from the dorsal column–medial lemniscus system and concerned mainly with sensory discrimination. The second somatosensory area (S2) lies on the upper bank of the Sylvian fissure, adjacent to the insula. Localization of function is less discrete in S2 than in S1, but S2 is also organized somatotopically, with the face rostrally and the leg caudally. The sensations evoked by electrical stimulation of S2 are much the same as those of S1 but, in distinction to the latter, may be felt bilaterally.

Undoubtedly, the perception of sensory stimuli involves more of the cerebral cortex than the two discrete areas described above. Some sensory fibers probably project to the precentral gyrus and others to the superior parietal lobule. Moreover, S1 and S2 are not purely sensory in function; motor effects can be obtained by stimulating them electrically. It has been shown that sensory neurons in VPL, cuneate and gracile nuclei, and sensory neurons in the dorsal horns of the spinal cord all receive descending as well as ascending cortical projections. This reciprocal arrangement probably influences movement and the transmission and interpretation of some sensations, as discussed in Chap. 7.

Because they are situated as way stations in a serial system, if the thalamus and subcortical projections are severely damaged, sensations such as pain, touch, pressure, and extremes of temperature do not reach consciousness. Damage to the sensory cortex allows some appreciation of contralateral sensory experience but degrades accurate localization, as well as the patient's ability to make other fine sensory discriminations. This clinical application of

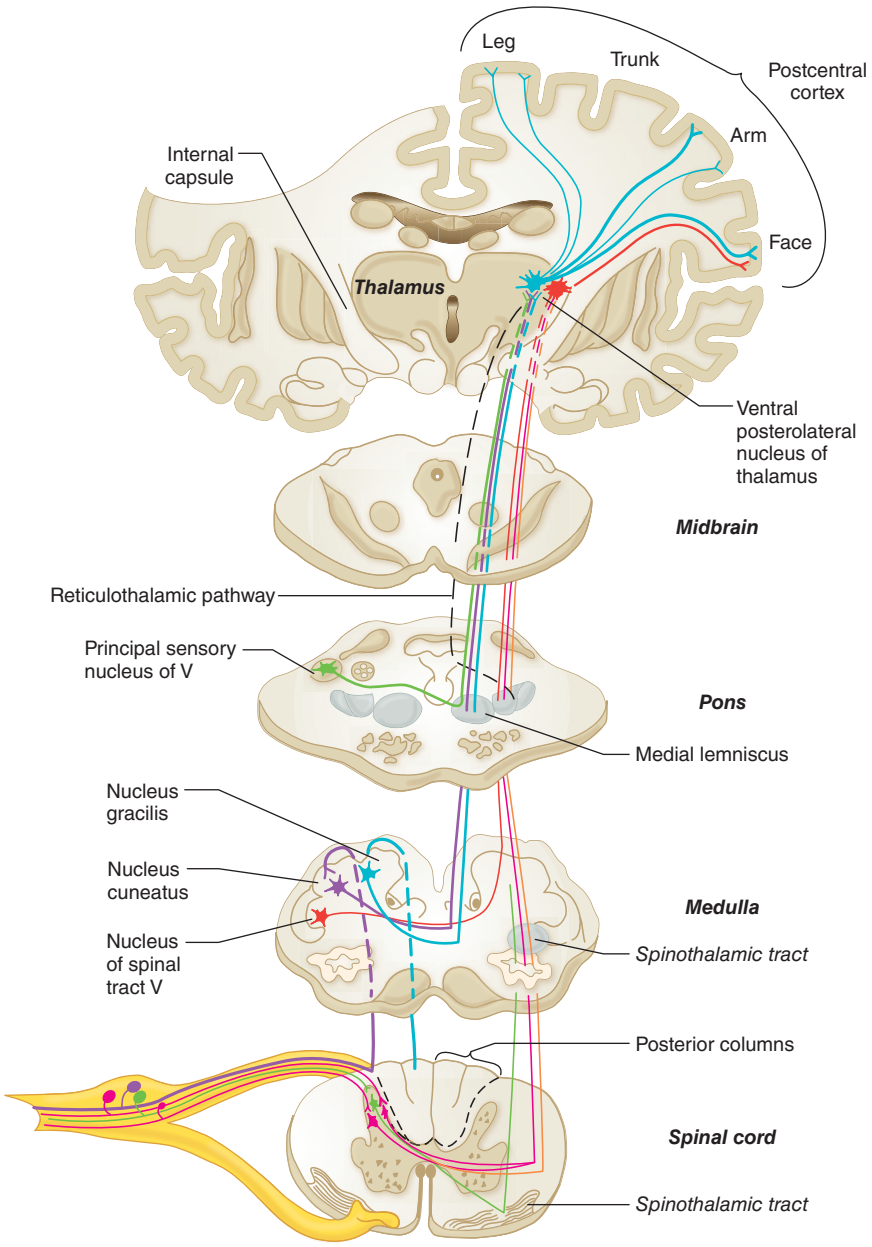

Figure 8-5. The main somatosensory pathways emphasizing the posterior column–lemniscal system (*purple and blue lines*). See Fig. 7-2 for comparison with the spinothalamic system (*red lines*).

these features is elaborated in the discussion of the sensory syndromes further on.

From this brief account of the various channels of sensory information, one must conclude that at every level there is the possibility of feedback control from higher levels. Most external and some internal stimuli are highly complex and induce activity in more than one sensory system. In every system, there is enough redundancy to allow lesser-used systems to compensate partially for the deficits incurred by disease.

Terminology of Sensory Signs and Symptoms (Table 7-2)

A few terms introduced in the last chapter require definition, as they are commonly encountered in discussions of sensation. Some of these, relating to pain, were mentioned in Chap. 7. Experimental data support the view that partially damaged touch, pressure, thermal, and pain fibers become hyperexcitable and generate ectopic impulses along their course, either spontaneously or in response to stimuli (Ochoa and Torebjork). These abnormal sensations are experienced as *paresthesias* or *dysesthesias* if they are severe and distressing, as noted in Table 8-2. Another positive sensory symptom is *allodynia*, referring to a phenomenon in which a non-painful stimulus such as touch evokes pain.

Anesthesia refers to a complete loss, and *hypesthesia* to a partial loss of all forms of sensation. Loss or impairment of specific cutaneous sensations may be indicated by an appropriate prefix or suffix, for example, *thermoanesthesia* or *thermohypesthesia* (loss and reduction in temperature sense), *analgesia* (loss of pain sense), *hypalgesia* (reduction in pain sensibility), *tactile anesthesia*, and *pallanesthesia*, or *apallesthesia* (loss of vibratory sense). The term *hyperesthesia*, as explained in Chap. 7, refers to an increased sensitivity to various stimuli and is usually used with

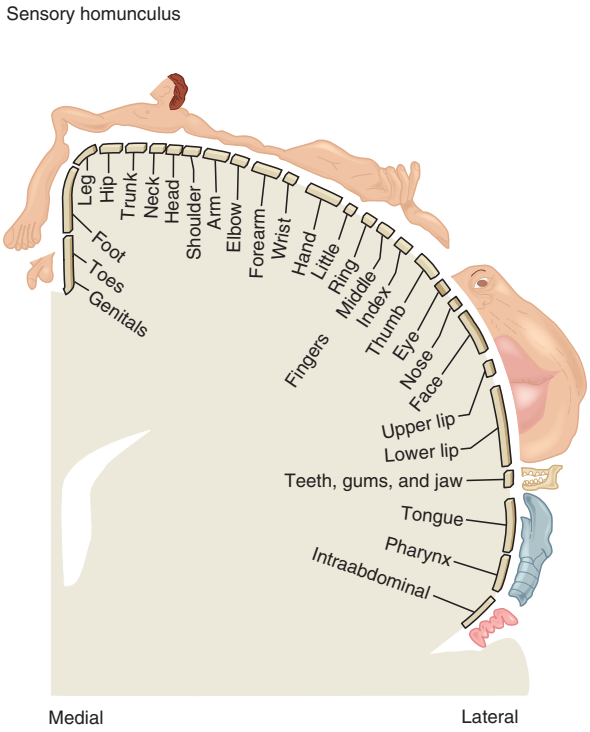

Figure 8-6. The "sensory homunculus," or cortical representation of sensation in the postcentral gyrus; compare this to the distribution of body areas in the motor cortex as shown in Fig. 3-4. (Reproduced with permission from Kandel ER, Schwartz JH, Jessel TM. *Principle of Neural Science*, 4th ed. New York: McGraw-Hill; 2000.)

respect to cutaneous sensation. It implies a heightened activity of the sensory apparatus. Under certain conditions (e.g., sunburn), there does appear to be an enhanced sensitivity of cutaneous receptors, but usually, the presence of hyperesthesia betrays an underlying sensory defect. Careful testing will demonstrate an elevated threshold to tactile, painful, or thermal stimuli; but once the stimulus is perceived, it may have a severely painful or unpleasant quality (*hyperpathia*). Some clinicians use this last term to denote an exaggerated response to a painful stimulus (hyperalgesia which is subtly different from hyperpathia, denotes an abnormally painful reaction to a painful stimulus; see Table 8-2). In *alloesthesia* or *allesthesia*, a tactile or painful stimulus delivered on the side of hemisensory loss is experienced in a corresponding area of the opposite side or at a distant site on the same side. This phenomenon is observed most frequently with right-sided putaminal lesions (usually hemorrhage) and with anterolateral lesions of the cervical spinal cord; it presumably depends on the existence of an uncrossed ipsilateral spinothalamic pathway (see the original studies of Ray and Wolff).

Table 8-2

ORIGIN OF ABERRANT SENSATIONS

SYMPTOMS	STRUCTURES AFFECTED
Paresthesia, tingling, buzzing	Large fibers (in nerve or posterior columns)
Burning, heat, cold	Small fibers
Prickling pain	Combined small- and large-fiber
Pseudocramp	A type of paresthesia, probably related to large-fiber dysfunction
Band tightness	Lemniscal system of cord
Lancinating pain	Small-fiber neuropathy and radiculopathy
Hyperalgesia	Partial peripheral nerve damage

EXAMINATION OF SENSATION

Most neurologists would agree that sensory testing is the most challenging part of the neurologic examination. For one thing, test procedures are relatively crude and are unlike the natural modes of stimulation with which the patient is familiar. It is also fair to say that few diagnoses are made solely based on the sensory examination; more often, the exercise serves to complement the remainder of the examination. There is often difficulty in evaluating the response to sensory stimuli, as it depends on the patient's interpretation of sensory experiences. This, in turn, will depend on the patient's general awareness and responsiveness and ability to cooperate, as well as degree of suggestibility. Children, by virtue of their simple and direct responses, are often better witnesses than more sophisticated individuals who are likely to analyze their experiences minutely and report small and insignificant differences in stimulus intensity.

Quite often, no objective sensory loss can be demonstrated despite symptoms that suggest the presence of such an abnormality. Only rarely does the opposite occur, in which one discovers a sensory deficit when there has been no complaint of sensory symptoms. Sensory symptoms such as paresthesias or dysesthesias may be generated from nerves not sufficiently diseased to reduce sensory function. Furthermore, loss of sensory function may be so mild and gradual as to pass unnoticed.

General Principles of the Sensory Examination

Before proceeding to sensory testing, the physician should question patients about changes in sensation; this poses problems. Patients may be confronted with derangements of sensation that are unlike anything they have previously experienced, and they have limited terms to describe what they feel. They may say that a limb feels "numb" and "dead" when in fact they mean that it is weak. Occasionally a loss of sensation is discovered almost accidentally, for example, by a lack of pain on touching an object hot enough to blister the skin or unawareness of articles of clothing and other objects in contact with the skin. Often, disease induces new and unnatural sensory experiences such as a band of tightness, a feeling of the feet being encased in cement, lancinating pains, an unnatural feeling when stroking the skin, a sensation as if walking on pebbles, and so on. Even adventitious muscle movements may be reported as a sensory experience akin to paresthesias or other sensations.

If nerves, sensory roots, or spinal tracts are damaged or partially interrupted, the patient may complain of tingling or prickling feelings ("like Novocain" or like the feelings in a limb that has "fallen asleep," the colloquialism for nerve compression), cramp-like sensations, or burning or

cutting pain occurring either spontaneously or in response to stimulation.

The clinical description of a sensation may divulge the particular sensory fibers involved (Table 7-1). It is known that stimulation of touch fibers gives rise to a sensation of tingling and buzzing; of muscle proprioceptors, to pseudocramp (the sensation of cramping without actual muscle contraction); of thermal fibers, to heat (including burning) and coldness; and of A-δ fibers, to prickling and pain. Paresthesia arising from ectopic discharges in large sensory fibers can be induced by nerve compression, hypocalcemia, hypomagnesemia, certain medications (niacin being an example), and diverse diseases of nerves. Band-like sensations on a limb or the trunk are the result of dysfunction in large sensory fibers, either in the periphery or their continuation in the posterior columns. Certain sensory symptoms suggest an anatomic location of nerve disease; for example, lancinating pains that radiate to the back or neck implicate root or, less often, sensory ganglion disease.

Persistent paresthesias incriminate a lesion involving sensory pathways in nerves, spinal cord, or higher structures. Most often, the large diameter, heavily myelinated fibers in the peripheral nerves or posterior columns are involved. Evanescent paresthesia, of course, is usually of no significance. Every person has had the experience of resting a limb on the ulnar, sciatic, or peroneal nerve and having the extremity "fall asleep." This is because of compressive interruption of axonal transport and not of ischemia of the nerves or other structures of the limb as is commonly assumed. The hyperventilation of anxiety may cause paresthesia of the lips and hands (sometimes unilateral) from diminution of CO_2 and thereby of ionized calcium; tetany may also occur, with carpopedal spasms. However, these sensory experiences are transient and should not be confused with the persistent, albeit sometimes fluctuating, paresthesias of structural disease of the nervous system. Severe acral and peripheral paresthesias with perversion of hot and cold sensations are characteristic of certain neurotoxic shellfish poisonings (*ciguatera*) and other toxins, such as mercury. Vibratory paresthesias are rarely encountered. One articulate physician patient described the sensation as a high amplitude, low-frequency "buzz" that was distinctly different from the more common prickling paresthesia, burning, and numbness. These sensations are almost always a manifestation of central sensory diseases, such as posterior columns or cerebral disease.

Effect of Age on Sensory Function (See also Chap. 28)

A challenging feature in the testing of sensation is the progressive impairment of sensory perception that occurs with advancing age. This requires that sensory thresholds, particularly in the feet and legs, be assessed in relation to age standards. The effect of aging is most evident in relation to vibratory sense, but proprioception, the perception of touch, and fast pain are also diminished with age. Sweating and vasomotor reflexes are reduced as well. These aging changes, which are discussed further in Chap. 28, are probably caused by neuronal loss in dorsal root ganglia and are reflected in a progressive depletion of fibers in the posterior columns. Receptors in the skin and special sense organs (taste, smell) also atrophy with age. On the other hand, it is too facile to attribute sensory loss to aging alone because it risks overlooking important disorders, some treatable.

Testing of Sensory Function

The detail with which sensation is tested is determined by the clinical situation. If the patient has no sensory complaints, it is enough to test vibration and position sense in the fingers and toes and the perception of pinprick over the extremities and to determine whether the findings are the same in symmetrical parts of the body. A rough survey of this sort occasionally detects sensory defects of which the patient was unaware. More thorough testing is in order if the patient has complaints referable to the sensory system or if one finds localized atrophy or weakness, ataxia, trophic changes of joints, or painless ulcers.

A few other general rules are useful. It is easier for a patient to perceive the boundary of an abnormal area of sensation if the examiner proceeds from an area of reduced sensation toward the normal area. One should not press the sensory examination in the presence of fatigue, for an inattentive patient is a poor witness. Also, the examiner must avoid suggesting symptoms to the patient. After explaining in the simplest terms what is required, the examiner interposes as few questions and remarks as possible. Patients should generally not be asked, "Do you feel that?" each time they are touched; they are simply told to say "yes" or "sharp" every time they are touched or feel pain. Repetitive pinpricks within a small area of skin should be avoided, as this will make inapparent a subtle hypalgesia because of the phenomenon of temporal summation, as discussed earlier. In patients who may be overinterpreting slight changes in pinprick, differentiating between warm and cold is often more informative than differentiating between "sharp" and "dull." The patient should not directly observe the part under examination. A cooperative patient may if asked to use a pin or his fingertips, outline an analgesic or anesthetic area or determine whether there is a graduated loss of sensation in the distal parts of a leg or arm. Finally, the findings of the sensory examination should be accurately recorded in narrative or in the record by shading affected regions on a preprinted figure of the body or a sketch of a hand, foot, face, or limb.

Described below are the usual bedside methods of testing sensory function. These tests are enough for most clinical purposes. For clinical investigation and research into the physiology of pain, which require the detection of threshold values and quantification of sensory impairment, a wide range of instruments are available.

Testing of Tactile Sensation

This is usually done with a wisp of cotton, a tissue, or light touch of a finger. The patient is first acquainted with the stimulus by applying it to a normal part of the body. Then, with eyes closed, he is asked to indicate if the sensation feels "natural" or to say "yes" each time various other parts

are touched. A patient with factitious sensory loss may say "no" in response to a tactile stimulus. Cornified areas of skin, such as the soles and palms, will require a heavier stimulus than other areas and the hair-clad parts a lighter one because of the numerous nerve endings around the follicles. Patients will be more sensitive to a moving stimulus of any kind than to a stationary one. The deft application of the examiner's or the patient's roving fingertips is a useful refinement and aids in demarcating an area of tactile loss, as Trotter and Davies originally showed.

More precise testing is possible by using a von Frey hair. By this method, a stimulus of constant strength can be applied and the threshold for tactile sensation determined by measuring the force required to bend a hair of known length. Spurious areas of hypesthesia or hyperesthesia may arise when a series of contactual stimuli lead to a decrement of sensation, either through adaptation of the end organ or because the initial sensation outlasts the stimulus and seems to spread.

Testing of Pain Perception

This is most efficiently assessed by pinprick, although it may be evoked by a variety of noxious stimuli. Patients must understand that they are to report the feeling of sharpness, not simply the feeling of contact or pressure of the pinpoint. If pinpricks are applied rapidly in one area, their effect may be summated and a heightened perception of pain may result; therefore, they should be delivered about one per second and not over the same spot. Small differences in intensity can be discounted. An effective approach is to ask the patient to compare the pin sensation in two areas on a scale of 1 to 10; a report of "8 or 9" as compared to "10" is usually insignificant.

It is almost impossible, using an ordinary pin, to apply each stimulus with equal intensity. A pinwheel (Wartenberg wheel) was sometimes more effective because it allows the application of more constant pressure, but the risk of transmission of blood-borne infection from patient to patient has made this method outdated. For research purposes, this difficulty can be overcome by the use of an algesimeter, which delivers stimuli of constant intensity or with devices using lasers to produce graduated spots of heat intensity on the skin. Quantification of small-fiber sensation can be better assessed in the clinical laboratory using thermal stimuli delivered by a computerized device, as described below.

If an area of diminished or absent touch or pain sensation is encountered, its boundaries should be demarcated to determine whether it has a segmental or peripheral nerve distribution or is lost below a certain level on the trunk. As mentioned, such areas are best delineated by proceeding from the region of impaired sensation toward the normal. The changes may be confirmed by dragging a pin lightly over the parts in question. Areas of reduced pinprick sensation can be corroborated by the thermal sense examination, as below.

Testing of Thermal Sense

A quick but rough way to assess thermal loss (or to corroborate a previously found zone of hypalgesia) is to warm one side of a tuning fork by rubbing it briskly against the palm and apply its alternate sides to the patient's skin, and asking the patient which side is colder (or warmer). One advantage of this mode of testing is that it offers the patient a binary choice of "warm" or "cold" response. This suffices for most bedside examinations.

If more careful examination is required, the skin should first be exposed to room air for a brief time. The test objects should be large, ideally, two stoppered test tubes containing hot (45°C/113°F) and cold (20°C/68°F) tap water. The use of warm and cool water from a tap is adequate and more practical for this purpose. The side of each tube is applied successively to the skin for a few seconds and the patient is asked to report whether the flask feels "less hot" or "less cold" in comparison to a normal part. It is of interest that normal people are able to recognize a difference of 1°C (1.8°F) or even less in the range of 28°C (82.4°F) to 32°C (89.6°F); in the warm range, differences between 35°C (95°F) and 40°C (104°F) can be recognized, and in the cold range, between 10°C (50°F) and 20°C (68°F). If the temperature of the test object is below 10°C (50°F) or above 50°C (122°F), sensations of cold or heat become confused with pain. This technique has been largely supplanted by commercial devices that can present a series of slightly differing thermal stimuli in sequence to a probe placed on the finger or toe. Special algorithms are used to vary the order and magnitude of temperature change and to determine whether the patient's reports are consistent and valid. The results are reported in the form of a "just noticeable difference" (JND) between temperatures and intensities of pain.

Testing of Deep-Pressure Pain

One can estimate the perception of this modality simply by pressing deeply on the tendons, muscles, or bony prominences. Pain can be elicited by heavy pressure even when superficial sensation is diminished; conversely, in some diseases, such as tabetic neurosyphilis, loss of deep pressure pain may be more striking than loss of superficial pain. This uncomfortable examination should be omitted in routine neurological cases. Deep pain, strictly speaking, is a proprioceptive sense because it is below the skin surface, but the sensory pathways are spinothalamic and therefore more allied with pain.

Testing of Proprioceptive Sense

Awareness of the position and movements of our limbs, fingers, and toes is derived from receptors in the muscles, tendons (Golgi tendon organs, according to Roland and Ladegaard-Pederson), and joints and is probably facilitated by the activation of skin receptors (Moberg). The two modalities comprising proprioception, that is, sense of movement and of position, are usually impaired in parallel, although clinical situations do arise in which perception of the position of a limb or digits is lost while that of passive and active movement (kinesthesia) of these parts is retained. The opposite occurs but is infrequent. Moreover, it is our impression that within the limits of what is done in bedside examination, patients more easily perceive joint movement (arthresthesia) than static joint position or posture (statognosis).

Perception of passive movement is first tested in the fingers and toes as the defect, when present, is reflected maximally in these parts. It is important to grasp the digit at the sides, perpendicular to the plane of movement; otherwise, the pressure applied by the examiner may allow the patient to identify the direction of movement. This applies as well to testing of the more proximal segments of the limb. The patient may be instructed to first report the perception of joint movement and then to indicate each movement as being "up" or "down." It is useful to demonstrate the test with a large and easily identified movement, but once the idea is clear to the patient, the smallest detectable changes should be determined. The part being tested should be moved rapidly. Normally, a very slight degree of movement is appreciated in the digits (as little as 1 or 2 degrees of an arc). The test should be repeated enough times to account for the possibility of chance guessing.

Defective perception of passive movement is judged by comparison with a normal limb or, if perception is bilaterally defective, based on what the examiner has learned through experience to be normal. Slight impairment may be disclosed by a slowness of response or, if the digit is displaced very slowly, by an unawareness or uncertainty that movement has occurred; or, after the digit has been displaced in the same direction several times, the patient may misjudge the first movement in the opposite direction; or, after the examiner has moved the digit, the patient may make a number of small voluntary movements of the toe in an apparent attempt to determine its position or the direction of the movement. Inattentiveness will also cause some of these errors. If joint position sense is impaired at a distal site, the next proximal joint may be tested. The lack of position sense in the legs can also be demonstrated by displacing the limb from its original position and having the patient, with eyes closed, place the other leg in the same position or point to the great toe. The same is true for the arm and hand.

If proprioception is abnormal in axial structures, the patient will be unable to maintain his balance with feet together and eyes closed (*Romberg sign*). This test is often interpreted imprecisely. In the Romberg position, even a normal person whose eyes are closed will sway slightly, and the patient who lacks balance because of cerebellar ataxia or some other motor disorder will sway considerably more if his visual cues are removed. Only a marked discrepancy in balance with eyes open and with eyes closed qualifies as a Romberg sign. The most certain indication of abnormality is the need to step to the side or backward to avoid falling. Mild degrees of unsteadiness in an anxious or suggestible patient may be overcome by diverting his attention, for example, by having him touch the index finger of each hand alternately to his nose while standing with eyes closed or by following the examiner's finger with his eyes. Patients with authentic proprioceptive problems will sway when their gaze is diverted from the ground and then become more unsteady when the eyes are closed. Patients with factitious unsteadiness usually will remain stable when they follow the examiner's fingers or look alternately at the ceiling and then at a distant object but then appear to be very unsteady when the eyes are closed. It is important to remember that any defect in proprioception (e.g., peripheral neuropathy, myelopathy, or vestibulopathy) will lead to a Romberg sign even though the sign, described by Moritz Romberg, was meant to diagnose tabes dorsalis.

Abnormalities of position sense may also be disclosed when the patient has his arms outstretched and eyes closed. The affected arm will wander from its original position; if the patient's fingers are spread apart, they may undergo a series of changing postures ("piano-playing" movements, or pseudoathetosis); in attempting to touch the tip of his nose with the index finger, the patient may miss the target repeatedly, but the performance is corrected when the eyes are open.

Testing of Vibratory Sense

This is a composite sensation comprising touch and rapid alterations of deep-pressure sense, but for clinical work, it may be considered a useful single modality. The cutaneous structure capable of registering stimuli of frequencies that are used for clinical testing is probably the Pacinian corpuscle. The conduction of vibratory sense depends on large sensory fibers that ascend mainly in the dorsal columns of the cord. Consequently, it is rarely affected by lesions of single nerves but will be disturbed in patients with disease of multiple peripheral nerves, dorsal columns, medial lemniscus, and thalamus. Vibration and position sense are usually impaired in similar conditions, although one of them (most often vibration sense) may be affected disproportionately. With advancing age, vibration is the sensation most commonly diminished, especially at the toes and ankles (see further on).

Vibration sense is tested by placing a tuning fork with a low frequency and long duration of vibration (generally 128 Hz) over the bony prominences, making sure that the patient responds to the vibration, not simply to the pressure of the fork, and that he is not trying to listen to the generated sound. Quantitative tuning forks with a 0 to 8 scale are available, but it is sufficient for clinical purposes to compare the point tested with a normal part of the patient or the examiner. The examiner may detect the vibration after it ceases for the patient by holding a finger under the distal interphalangeal joint, the handle of the tuning fork being placed on the dorsal aspect of the joint. Or the tuning fork is allowed to run down until the moment that vibration is no longer perceived, at which point the fork is transferred quickly to the corresponding part of the examiner and the time to extinction is noted. There is a small degree of accommodation to the vibration stimulus so that slight asymmetries detected by rapid shifting from a body part on one side to the other or to the examiner should be interpreted accordingly. The perception of vibration at the patella after it has disappeared at the ankle or at the anterior iliac spine after it has disappeared at the knee is indicative of a length-dependent peripheral neuropathy. The approximate level of pinprick loss from a spinal cord lesion can be corroborated by testing vibratory sensation over the iliac crests and successive dorsal vertebral spines. As with thermal and pain testing, there are mechanical devices that can quantitate vibration sense.

Testing of Discriminative (Parietal Lobe Cortical) Sensation

Damage to the parietal lobe sensory cortex or to the thalamocortical projections results in a disturbance—namely, an inability to make sensory discriminations and to integrate spatial and temporal sensory information (see further under "Sensory Loss Caused by Lesions of the Parietal Lobe" and Chap. 21). Lesions in these structures usually disturb complex sensory perception but leave the primary modalities (touch, pain, temperature, and vibration sense) relatively less affected. The integrity of discriminative sensory functions can be assessed only if it is first established that the primary sensory modalities on which they depend (mainly touch) are largely normal. If a cerebral lesion is suspected, discriminative function can be tested further in the following ways.

Two-Point Discrimination

The ability to distinguish two points from one is tested by using a compass or similar device, the points of which should be blunt and applied simultaneously and painlessly. The distance at which such stimuli can be recognized as a distinct pair varies but is roughly 1 mm at the tip of the tongue, 2 to 3 mm on the lips, 3 to 5 mm at the fingertips, 8 to 15 mm on the palm, 20 to 30 mm on the dorsal hands and feet, and 4 to 7 cm on the trunk. It is characteristic of the patient with a lesion of the sensory cortex to mistake two points for one, although occasionally the opposite occurs.

Cutaneous Localization and Figure Writing (Graphesthesia)

Localization of cutaneous tactile or painful stimuli is tested by touching various points on the body and asking the patient to place the tip of his index finger on the point stimulated or on the corresponding point of the examiner's limb. Recognition of numbers or letters traced on the skin (these should be larger than 4 cm on the palm) with a pencil or similar object or the direction of a line drawn across the skin also depends on localization of tactile stimuli, but the two may be dissociated. Normally, traced numbers as small as 1 cm can be detected on the pulp of the finger if drawn with a pencil. These are also useful tests of posterior column function.

Appreciation of Texture, Size, Weight, and Shape

Appreciation of texture depends mainly on cutaneous impressions, but recognition of the shapes and sizes of objects is based on sensory experience from deeper receptors as well. Inability to recognize shape and form is frequently a manifestation of cortical disease, but a similar clinical defect will occur if tracts that transmit proprioceptive and tactile sensation are interrupted by lesions of the spinal cord and brainstem (and, of course, of the peripheral nerves). This type of sensory defect is called *stereoanesthesia* (see further on, under "Posterior [Dorsal] Column Syndrome") and is distinguished from *astereognosis*, which connotes an inability to identify an object by palpation, even though the primary sense data (touch, pain, temperature, and vibration) are intact. In practice, pure astereognosis is rarely encountered, and the term is employed when the impairment of superficial and vibratory sensation in the hands seems to be of insufficient severity to account for the defect in tactile object identification. Defined in this way, astereognosis is either right or left-sided and, with the qualifications mentioned below, is the product of a lesion in the opposite hemisphere involving the sensory cortex, particularly S2 or the thalamoparietal projections.

The traditional doctrine that somatic sensation is represented only in the contralateral parietal lobe is not absolute. Beginning with the report by Oppenheim in 1906, there have been patients who showed bilateral astereognosis or loss of tactile sensation as a result of an apparently unilateral cerebral lesion. These observations were corroborated by Semmes and colleagues, who tested a large series of patients with traumatic lesions involving either the right or left cerebral hemisphere. They found that the impairment of sensation (particularly discriminative sensation) following right-and left-sided lesions was not strictly comparable; the left hand as well as the right tended to be impaired by injury to the left sensorimotor region, whereas only the left hand tended to be affected by injury to the right sensorimotor region. These observations, with minor qualifications, have been confirmed (Carmon and by Corkin and associates 1965), by investigations of the sensory effects of cortical excisions in patients with focal epilepsy. Thus it appears that certain somatosensory functions in some patients are mediated not only by the contralateral hemisphere but also by the ipsilateral one, although the contribution of the former is undoubtedly the more significant.

This concept of left hemispheric dominance in respect to tactile perception has also been questioned (Carmon and Benton), by the finding that the right hemisphere is particularly important in perceiving the direction of tactile stimuli. Also, patients with lesions of the right hemisphere show a consistently greater failure of tactile-maze learning than those with left-sided lesions, pointing to a relative dominance of the right hemisphere in the mediation of tactile performance involving a spatial component (Corkin and associates). Certainly, the related phenomenon of sensory inattention or extinction is more prominent with lesions of the right as opposed to the left parietal lobe and is most informative if the primary and secondary sensory cortical areas are spared. These matters are considered further on in this chapter and in Chap. 21.

Finally, there is a distinction between astereognosis and tactile agnosia. Some authors (e.g., Caselli) have defined tactile agnosia as a strictly unilateral disorder, right or left, in which the impairment of tactile object recognition is unencumbered by a disturbance of the primary sensory modalities. Such a disorder would be designated by others as a form of astereognosis (see above). In our view, *tactile agnosia* is a disturbance in which a one-sided lesion lying posterior to the postcentral gyrus of the *dominant* parietal lobe results in an inability to recognize an object by touch in *both* hands. According to this view, tactile agnosia is a disorder of apperception of stimuli and of translating them into symbols, akin to the defect in naming parts of the body, visualizing a plan or a route, or understanding the meaning of the printed or spoken word (visual or auditory verbal agnosia). These and other agnosias are discussed in Chap. 21.

SENSORY SYNDROMES (SEE TABLE 8-3)

Interruption of a Single Peripheral Nerve

The region of sensory loss after complete transection of a sensory or mixed nerve corresponds to the distribution of the cutaneous fibers that derive from the nerve. This is the basis of the sensory map shown in Fig. 8-1. This can be contrasted with the patterns of sensory loss due to section of nerve roots, depicted by the dermatomal map (see Fig. 8-3), which is highly predictable but has less distinctive boundaries. Of course, section of a mixed nerve weakens the muscles that it innervates and the full syndrome can be identified by the combination of these features.

If a large area of skin is involved, the sensory defect characteristically consists of a central portion in which all forms of cutaneous sensation are lost, surrounded by a zone of partial loss, which becomes less marked as one proceeds from the center to the periphery. Following the experimental cutting of a nerve, the area of cutaneous sensory loss is less than its anatomic distribution because of overlap from adjacent nerves. After a period of time, the area of tactile loss is greater than that for analgesia because collateral growth from adjacent fibers is more rapid for small free nerve ending carrying pain than it is for fibers for touch. Moreover, there is a greater overlap of adjacent pain sensory fields. Along the margin of the hypesthetic zone, the skin becomes excessively sensitive (hyperesthetic); light contact may be felt as smarting and mildly painful. According to Weddell, dysesthesias are attributable to the greater sensitivity of collateral regenerating fibers that have made their way from surrounding healthy pain fibers into the denervated region. With a section of purely cutaneous nerves, perceptions of deep pressure and passive movement remain intact because these modalities are mediated by nerve fibers from subcutaneous structures and joints.

Table 8-3

EXAMINATION FEATURES OF THE PERIPHERAL AND SPINAL CORD SENSORY SYNDROMES

Polyneuropathy
Symmetrical distal sensory loss
Sensory loss may affect one modality preferentially
Areflexia or hyporeflexia
Weakness, if present, relatively symmetrical
Polyradiculopathy
Asymmetrical sensory and motor loss
Proximal and distal parts of limb differentially affected
Reflex loss limited to region of affected root(s)
Ganglionopathy
Implicates all sensory modalities
Proximal body parts affected
Ataxia (sensory type) often prominent
Tabetic Syndrome
Prominent loss of vibratory and position sense in feet with sensory ataxia
Romberg sign
Secondary (Charcot) joint deformities
Areflexia in root disease; preserved reflexes if posterior column disease
Myelopathy
Complete transverse lesion: loss of all sensory modalities below level of lesion
Syringomyelia: loss of pain and thermal sense with preservation of touch and joint position/vibration over restricted region of neck, cape, arms, hands
Anterior spinal artery syndrome: loss of pain sense with preservation of vibration and joint position below level of lesion
Posterior column: same as tabetic but reflexes preserved
Hemicord (Brown-Séquard): loss of pain sense opposite to the lesion and beginning several levels below it; loss of vibration and joint position sense on the side of the lesion and below it

(See Fig. 8-7 and also Chap. 43.)

Various types of lesions have differing effects on sensory nerve fibers. *Compression* of a nerve ablates mainly the function of large touch and pressure fibers and leaves the function of small pain, thermal, and autonomic fibers intact; lidocaine has the opposite effect. The effects of sustained pressure on a nerve for as long as 30 min produces paresthesiae within a few minutes, followed by sensory loss—first of touch and vibration, then of cold, fast pain, heat, and slow pain, in that order and spreading centripetally. Physiologic studies have confirmed the theory of Lewis and colleagues that compression blocks the function of nerve fibers in order of their size. Release of the pressure results in postcompression paresthesia, which has been shown to arise from spontaneous activity that is generated along the myelinated nerve fibers from ectopic sites at a distance from the compression. Within seconds of releasing the pressure, there is an array of tingling, stinging, cramp-like sensations that reach maximum intensity in 90 to 120 s and slowly fade (Lewis et al). Sensory function is recovered in an order inverse to that in which it was lost. Similar spontaneous and ectopic discharges probably explain the paresthetic symptoms early in the acute demyelinating neuropathies, even before the appearance of sensory loss or numbness. These features of compression are not because of nerve ischemia, as commonly believed; instead, they result from reversible physiologic changes in the myelin and underlying axon.

Certain maneuvers for the provocation of positive sensory phenomena—e.g., the *Tinel sign* of tingling upon percussion of a regenerating peripheral nerve and the *Phalen sign* of paresthesia in the territory of the median nerve on wrist flexion—typify the susceptibility of a damaged nerve to pressure. In the case of a severed nerve, regeneration from the proximal end begins within days. The thin, regenerating sprouts are unusually sensitive to mechanical stimulation, which produces tingling or the Tinel sign.

Diffuse Involvement of Nerves (Polyneuropathy) (See Table 8-3)

As most polyneuropathies affect mixed nerves, the sensory changes are accompanied by varying degrees of motor and reflex loss. Usually, the sensory impairment is roughly symmetrical and the predominant symptoms are numbness and paresthesias. Because in most types of polyneuropathy, the longest and largest axons are the most affected ("length dependent," axonal neuropathy), sensory loss begins in and is most severe over the feet and legs and, if the upper limbs are affected, over the hands. As polyneuropathy progresses, the margin of sensory loss "ascends," meaning it moves proximally on the limbs.

The term *glove-and-stocking*, employed to describe the distribution of sensory loss of polyneuropathy, draws attention to the predominantly distal pattern of involvement but does not convey that the change from normal to impaired sensation is characteristically gradual. (In psychogenic sensory loss, by contrast, the border between normal and absent sensation is usually sharply defined.) The abdomen, thorax, and face are spared in polyneuropathy except in the most severe cases, in which sensory changes may be found over the anterior thoracoabdominal escutcheon and around the mouth and the crown of the scalp.

In processes that affect axons, numbness and loss of pain, and thermal sensations are the main features. When the neuropathy is primarily demyelinating rather than axonal, paresthesia may be the earliest feature. The sensory loss of polyneuropathy usually involves all modalities of sensation, and—although it is difficult to compare the degrees of impairment of pain, touch, temperature, vibration, and position senses—one modality may be impaired disproportionately to the others. This clinical feature is explained by the fact that some diseases of the peripheral nerves selectively damage sensory fibers of different sizes. For example, degeneration or demyelination of the large fibers that subserve kinesthetic sense causes a loss of vibratory and position sense and relative sparing of pain, temperature, and, to some degree, tactile perception. When extreme, such a polyneuropathy results in pseudoathetoid movements of the outstretched fingers or toes, manifestations of searching movements of the limbs; it may also result in a sensory ataxia because of dysfunction of the large diameter nerves destined for the spinocerebellar tracts.

By contrast, involvement of the small-caliber, thinly myelinated, and unmyelinated axons affects pain, temperature, and autonomic function, with preservation of proprioceptive, vibration, and tactile sense—producing a syndrome of "pseudosyringomyelia," simulating the dissociated pain from tactile sensory loss that is seen in this disease of the spinal cord (see further on, under "Sensory Spinal Cord Syndromes"). Prolonged analgesia may lead to trophic ulcers and Charcot joints. These patterns of sensory loss, as well as those produced by the plexopathies and mononeuritis multiplex, are discussed further in Chap. 43.

Involvement of Nerve Roots (Radiculopathy and Polyradiculopathy) (Figs. 8-1, 8-3, and Table 8-3)

The surface innervation of the sensory nerve roots serves as one of the most useful and dependable guides to localization in neurology and the main dermatomes are known to all physicians. As already noted, there is considerable overlap from adjacent roots so that division of a single sensory root does not produce a complete loss of sensation in any area of skin. However, compression of a single sensory cervical or lumbar root (e.g., by a herniated intervertebral disc) can cause a segmental impairment of cutaneous sensation. When two or more contiguous roots have been completely divided, there may be a zone of sensory loss, which is surrounded by a narrow zone in which there is a raised threshold accompanied by excessive sensitivity (hyperpathia). For reasons not altogether clear, partial sensory loss from root lesions is easier to demonstrate using a painful stimulus than by a tactile or pressure stimulus.

Disease of the nerve roots frequently gives rise to "shooting" (lancinating) pains and burning sensations that project down the course of their derivative sensory nerves. The common examples are sciatica from lower lumbar or upper sacral root compression and sharp pain radiating from the shoulder and down the upper arm from cervical root compression.

When multiple roots are affected (*polyradiculopathy*) by an infiltrative, inflammatory, or compressive process, the syndrome is more complex and must be differentiated from polyneuropathy. The distinguishing features of a polyradiculopathy, typically aside from pain, are asymmetrical muscle weakness that involves proximal and distal parts differentially in each limb and a pattern of sensory loss that is consistent with the distribution of several roots, not necessarily contiguous ones. Viewed differently, the distribution of sensory and motor deficits defies the pattern expected of multiple single peripheral nerves and fails to display the length-dependent pattern of a generalized polyneuropathy. Further details can be found in Chap. 43.

Involvement of Dorsal Root Ganglia (Sensory Neuronopathy, Ganglionopathy) (See Table 8-3)

Widespread disease of the sensory (dorsal root) ganglia produces many of the same sensory defects as disease of the posterior nerve roots (see below under "Tabetic Syndrome"), but it has greater hypesthesia and hypalgesia of proximal areas of the body such as the face, oral mucosa, scalp, trunk, and genitalia. Proprioception is diminished or lost in distal and, to a variable extent, proximal body parts and occurs in parallel with ataxic movements, often quite severe, and with pseudoathetosis. These latter features, perhaps more than any others, are characteristic of ganglionopathy and may render the patient incapable of using the limbs, despite preserved strength. Tendon reflexes are lost. Sometimes there are additional features of dysautonomia, but strength is entirely spared. Recognition of this unusual pattern of pansensory loss is of considerable diagnostic importance because it raises for consideration several underlying diseases that might otherwise be overlooked; these diseases are discussed in Chap. 43. The main causes of this syndrome are paraneoplastic, connective tissue disease, particularly Sjögren syndrome, toxic exposure, and idiopathic inflammation.

Tabetic Syndrome (See Table 8-3 and Fig. 8-7)

The tabetic syndrome, characterized by tabes dorsalis, consists of sensory ataxia and severe imbalance with a positive Romberg test as a result of proprioceptive loss. In its most extreme form, the feet slap and stomp as they meet the ground. It can be considered a subtype of polyradiculopathy or ganglionopathy but it also classified with diseases of the spinal cord because the same disorder derives from diseases that affect the posterior columns. Furthermore, the processes that affect that root or ganglion lead to Wallerian degeneration of posterior columns. Although

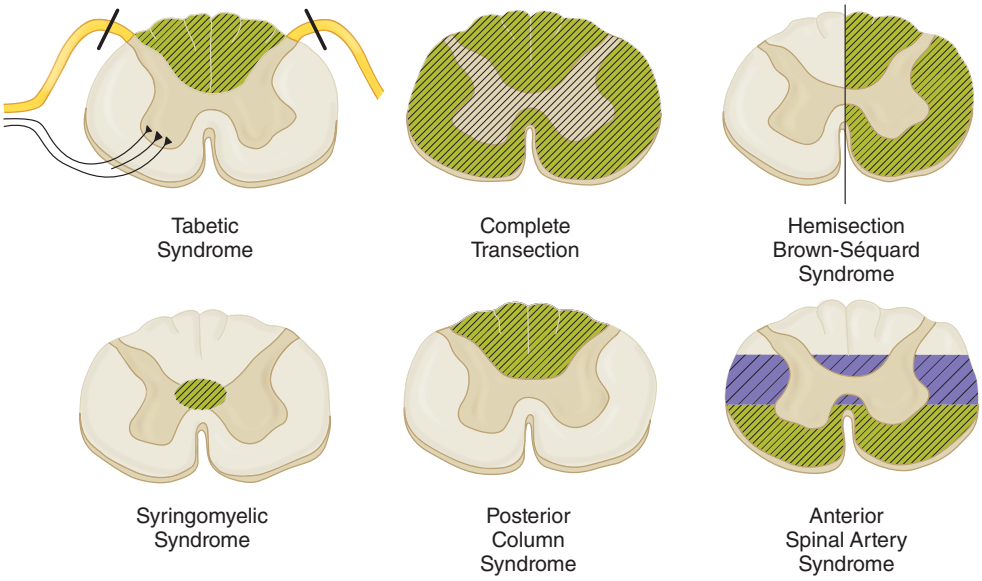

Figure 8-7. Sites of lesions of the characteristic spinal cord sensory syndromes (shaded areas indicate regions of damage). The lower right figure shows a variable extent of damage to the mid-axial cord but always sparing the posterior columns.

inextricably allied in the past with neurosyphilis, it occurs in diabetes mellitus and other diseases that involve the posterior roots or dorsal root ganglia, such as paraneoplastic ganglionopathies.

In addition to the sensory ataxia, numbness or paresthesia and "lightning" or lancinating pains are frequent complaints; areflexia and hypotonia without significant muscle weakness is found. The sensory loss may involve only vibration and position senses in the lower extremities, but loss or impairment of superficial or deep pain sense or of touch may appear in severe cases. Loss of deep tendon reflexes distinguishes the sensory root syndrome from a lesion in the posterior columns. The feet and legs are most affected in tabes, much less often the arms and trunk. The Romberg sign is prominent, as noted earlier. In extreme cases, atonicity of the bladder with retention of urine and trophic joint changes (Charcot joints) and crises of abdominal ("gastric") pains are associated.

Cases of congenital absence of all cutaneous sensation resulting from the lack of development of small sensory ganglion cells may produce the tabetic syndrome; this is discussed in Chap. 7. A similar but partial defect may be found in the Riley-Day syndrome (see Chap. 25). There are also forms of hereditary polyneuropathy that cause universal insensitivity.

Sensory Spinal Cord Syndromes (See Also Chap. 42)

Complete Spinal Sensory Syndrome (Fig. 8-7)

With a complete transverse disruption of the spinal cord, the most striking features are paralysis and loss of all forms of sensation below a level that corresponds to the lesion. There may be a narrow zone of hyperesthesia at the upper margin of the anesthetic zone. Loss of pain, temperature, and touch sensation may begin one or two segments below the level of the lesion; vibratory and position senses have less-discrete levels, but they can be detected by careful examination. The sensory (and motor) loss in spinal cord lesions that involve both gray and white matter is expressed in patterns corresponding to bodily segments or dermatomes. These are shown in Figs. 8-3 and 8-4 and are most obvious on the trunk, where each intercostal nerve has a transverse distribution.

Also, during the subacute evolution of a transverse spinal cord lesion, there may be a discrepancy between the level of the lesion and that of the sensory loss, the latter ascending as the lesion progresses. This can be understood if one conceives of a lesion as evolving from the periphery to the center of the cord, affecting first the outermost fibers carrying pain and temperature sensation from the legs. Conversely, a lesion advancing from the center of the cord will affect these modalities in the reverse order, in a pattern of *sacral sparing*, meaning that sensation is preserved over the buttocks and anal region but is absent over the trunk and legs.

Hemisection of the Spinal Cord (Brown-Séquard Syndrome)

Disease may be confined to or predominate on one side of the spinal cord; pain and thermal sensation are affected on the opposite side of the body, and proprioceptive sensation is affected on the same side as the lesion. This pattern is the result of loss of pain and thermal senses corresponding to the opposite spinothalamic tract and loss of touch and proprioceptive sense corresponding to the ipsilateral posterior column. Although rarely present in its entirety, a partial Brown-Séquard syndrome is common in practice. The loss of pain and temperature sensation begins one or two segments below the lesion. An associated spastic motor paralysis on the side of the lesion completes the syndrome (see Fig. 8-7). Touch sensation is less affected as the fibers from one side of the body are distributed in tracts (posterior columns, anterior and lateral spinothalamic) on both sides of the cord.

Syringomyelic Syndrome (Lesion of the Central Gray Matter)

Because spinothalamic fibers conducting pain and temperature sensation cross the cord in the anterior commissure, a lesion of considerable vertical extent in this location characteristically abolishes these modalities on both sides over several segments (dermatomes) but spares tactile sensation because the posterior columns are unaffected (see Fig. 8-7). This is termed *dissociated sensory loss*. Because the lesion frequently involves other parts of the gray matter, varying degrees of segmental amyotrophy and reflex loss are usually present as well. If the lesion has extended to the white matter, corticospinal, spinothalamic, and posterior column signs will be conjoined. The most common cause of such a lesion in the cervical region is the centrally situated developmental syringomyelia; less common are intramedullary tumor, trauma, and hemorrhage. A *pseudosyringomyelic* syndrome was mentioned earlier in relation to small-fiber neuropathies that simulate syringomyelia.

Posterior (Dorsal) Column Syndrome

Paresthesias in the form of tingling and pins-and-needles sensations or girdle- and band-like sensations are common complaints with posterior column disease. In some cases, there may be the additional feature of a diffuse, burning, unpleasant sensation in response to pinprick. Loss of vibratory and position sense occurs below the level of the lesion, but the perception of pain and temperature is affected relatively little or not at all. Because posterior column lesions are caused by the interruption of central projections of the dorsal root ganglia cells, they may be difficult to distinguish from a process that affects large fibers in sensory roots (tabetic syndrome discussed above); however, the tendon reflexes are spared in the former and eliminated in tabes. In some diseases that involve the dorsal columns, vibratory sensation may be involved predominantly, whereas in others, position sense is more affected.

With posterior column lesions, only a few of which have been verified by postmortem examinations, touch sensation is not lost, or it recovers after an acute lesion, but the patient is deprived of knowledge of movement and position of parts of the body below the lesion. Nathan and colleagues confirmed that lesions of the posterior columns cause only slight defects in touch and pressure sensation. However, a combined lesion in both posterior columns and spinothalamic tracts causes a total loss of tactile and pressure sensibility below the lesion. If the posterior column lesion is in the cervical region, there is clumsiness in the palpation of objects and an inability to recognize the qualities of objects by touch (agraphesthesia), even though touch-pressure sensation is relatively intact. There may be unusual disturbances of touch and pressure, manifesting as lability of threshold, persistence of sensation after removal of the stimulus, and sometimes tactile and postural hallucinations.

The loss of sensory functions that follows a posterior column lesion—such as impaired two-point discrimination; figure writing; detection of size, shape, weight, and texture of objects; and ability to detect the direction and speed of a moving stimulus on the skin—may simulate a parietal "cortical" lesion (see below under "Sensory Loss Caused by Lesions of the Parietal Lobe"), but differs in that vibratory sense is also lost in lesions limited to the posterior columns.

It should be realized therefore, that not all proprioceptive fibers ascend to the gracile and cuneate nuclei; some proprioceptive fibers leave the posterior columns in the lumbar region and synapse with secondary neurons in the spinal gray matter and ascend in the ipsilateral posterolateral funiculus. Only cutaneous fibers continue to the gracile and cuneate nuclei.

The usual causes of the posterior column syndrome are multiple sclerosis, vitamin B_{12} deficiency, copper deficiency, tabes dorsalis, and HIV and human T-lymphotropic virus (HTLV) type 1 infection.

Anterior Myelopathy (Anterior Spinal Artery Syndrome)

With infarction of the spinal cord in the territory of supply of the anterior spinal artery or with other lesions that affect the ventral portion of the cord predominantly, as in some cases of myelitis, one finds a loss of pain and temperature sensation below the level of the lesion but with relative or absolute sparing of proprioceptive sensation. Because the corticospinal tracts and the ventral gray matter also lie within the area of distribution of the anterior spinal artery, paralysis is a prominent feature (Fig. 8-7).

Disturbances of Sensation from Lesions of the Brainstem

A characteristic feature of medullary lesions is the occurrence, in many instances, of a crossed sensory disturbance, that is, a loss of pain and temperature sensation on one side of the face and on the opposite side of the body. This is accounted for by involvement of the descending spinal trigeminal tract or its nucleus and the crossed lateral spinothalamic tract on one side of the brainstem and is nearly always caused by a lateral medullary infarction (Wallenberg syndrome). In the upper medulla, pons, and midbrain, the crossed trigeminothalamic and lateral spinothalamic tracts run together; a lesion at these levels causes loss of pain and temperature sense on the opposite half of the face and body. Spontaneous and induced thermal or painful dysesthesias are often reported ("feeling as if sunburned"). In the upper brainstem, the spinothalamic tract and the medial lemniscus become confluent, so that an appropriately placed lesion causes a contralateral loss of all superficial and deep sensation. Cranial nerve palsies, cerebellar ataxia, and motor paralysis are almost invariably associated, as indicated in the discussion of strokes in this region (see Chap. 33). In other words, a lesion in the brainstem at any level is unlikely to cause an isolated sensory disturbance.

Hemisensory Loss Caused by a Lesion of the Thalamus

Involvement of the VPL and VPM nuclei of the thalamus, usually because of a vascular lesion, causes loss or diminution of all forms of sensation on the opposite side of the

body. Position sense is affected more frequently than any other sensory function and is usually, but not always, more profoundly reduced than loss of touch and pinprick. With partial recovery of sensation or with an acute but incomplete lesion, spontaneous pain, or discomfort (*Dejerine-Roussy syndrome; thalamic pain syndrome*), sometimes of the most distressing type, may appear on the affected side of the body. A stimulus may then have a diffuse, unpleasant, lingering quality. Thermal—especially cold—stimuli, emotional disturbance, loud sounds, and even certain types of music may aggravate the painful state. In spite of this overresponse to stimuli, the patient usually shows an elevated pain threshold, that is, a stronger stimulus than normal is necessary to produce a sensation of pain (hypalgesia with hyperpathia). The same type of pain syndrome may occasionally accompany lesions of the white matter of the parietal lobe, the medial lemniscus, or even the posterior columns of the spinal cord.

A symptomatic hemisensory syndrome, usually with few objective changes, occurs frequently without manifest evidence of thalamic or spinal cord damage. This unexplained syndrome has been reported in young women, (Toth). Some of these patients with this apparently benign condition have had migraine and rarely had antiphospholipid syndrome, but the connections between all these entities are tenuous, and some cases are considered to be functional.

Sensory Loss Caused by Lesions of the Parietal Lobe

In the anterior parietal lobe syndrome (Verger-Dejerine syndrome), there are disturbances mainly of discriminative sensory functions of the opposite arm, leg, and side of the face without impairment of the primary modalities of sensation (unless the lesion is extensive and deep). Loss of position sense and sense of movement, impaired ability to localize touch and pain stimuli (topagnosia), widening of two-point threshold, and astereognosis are the most prominent findings, as described earlier in this chapter and in Chap. 21, "Clinical Effects of Parietal Lobe Lesions."

Another characteristic manifestation of parietal lobe lesions is *sensory inattention*, *extinction*, or *neglect*. In response to bilateral simultaneous testing of symmetrical parts, using either tactile or painful stimuli, the patient may acknowledge only the stimulus on the sound side; or, if the face and hand or foot on the affected side is touched or pricked, only the stimulus to the face may be noticed. Apparently, cranial structures command more attention than other less richly innervated parts. Yet each stimulus, when applied separately to each side or to each part of the affected side, is properly perceived and localized. In the case of sensory neglect, the patient ignores one side of the body and extrapersonal space contralateral to the parietal lesion, which is usually in the nondominant hemisphere. Left parietal lesions may also cause right sensory neglect, but less frequently and less profoundly. Sensory neglect or extinction, which may also occur occasionally with posterior column and medial lemniscus lesions, may be detected in persons who disclaim any sensory symptoms. These phenomena and other features of parietal lobe lesions are, as mentioned, considered further in Chap. 21.

Yet another parietal lobe syndrome, Dejerine-Mouzon, is featured by a severe impairment of the primary modalities of sensation (pain, thermal, tactile sense, but usually with relative sparing of vibratory sense) over the contralateral half of the body. Motor paralysis is variable; with partial recovery, there may be a clumsiness that resembles cerebellar ataxia. Because the sensory disorder simulates that caused by a thalamic lesion, it was called *pseudothalamic* by Foix and coworkers. Hyperpathia, much like that of the Dejerine-Roussy syndrome (see above), has also been observed in patients with cortical–subcortical parietal lesions. The pseudothalamic syndrome was related by Foix and colleagues to a Sylvian infarct; Bogousslavsky and associates traced it to a parietal infarct caused by occlusion of the ascending parietal branch of the middle cerebral artery. In each of the aforementioned parietal lobe syndromes, if the dominant hemisphere is involved, there may be aphasia, bimanual tactile agnosia, or a Gerstmann syndrome; with nondominant lesions, there may be anosognosia (see Chap. 21).

Often with parietal lesions, the patient's responses to sensory stimuli are variable. A common mistake, as emphasized by Critchley, is to attribute this abnormality to a functional disorder (see also below under "Sensory loss due to Suggestibility"). A lesion confined to only a part of the parietal cortex (the best examples have been caused by glancing bullet or shrapnel wounds of the skull) may result in a circumscribed loss of superficial sensation in an opposite limb, mimicking a root, or peripheral nerve lesion.

Sensory Loss due to Suggestibility (See Also Chap. 47)

The possibility of suggesting sensory loss to a patient is a very real one, as has already been indicated. Suggestible patients may complain of a complete hemianesthesia—sometimes with the anatomically implausible findings of reduced hearing, sight, smell, and taste on the same side—as well as impaired vibration sense over only half the skull and sternum, most of these being anatomic impossibilities. A frequently used test to disclose this feature is performed by placing a vibrating tuning fork on each side adjacent to the middle of the forehead. The transmission of vibration through the bone ensures that loss of sensation on one side of the midline is not possible. Anesthesia of an entire limb or a sharply defined sensory loss over part of a limb, not conforming to the distribution of a root or cutaneous nerve, may also be observed. The diagnosis of functional hemianesthesia is best made by eliciting the other relevant symptoms of a functional disorder or, if this is not possible, by noting the discrepancies between the sensory loss displayed by the patient and that which occurs as part of the known, anatomically verified sensory syndromes.

Sometimes, in a patient with no other neurologic abnormality or in one with a definite neurologic syndrome, one is dismayed by sensory findings that are completely inexplicable and discordant. In such cases, one must try to reason through to the diagnosis by disregarding the

sensory findings or approach the finding as revealing a second disorder such as a neurofibroma of a nerve root.

Laboratory Diagnosis of Somatosensory Syndromes

Affirmation of a clinical sensory syndrome is often possible by the application of electrophysiologic testing. Slowing and reduced amplitude of sensory nerve conduction is found with lesions of nerve, but only if the lesion lies distal to (or within) the sensory ganglion. Severe sensory loss in a neuropathic pattern with preserved sensory nerve action potentials therefore indicates radiculopathy. Loss or slowing of the H reflex and F responses corroborates the presence of lesions in proximal parts of nerves, plexuses, and roots. Using somatosensory evoked potentials, it is possible to demonstrate slowing of conduction in the peripheral nerves or roots, in the pathways from spinal cord to a point in the lower medulla, in the medial lemniscus to the thalamus, and in the pathway from the thalamus to the cerebral cortex. In the context of regional sensory loss, evoked potentials find their greatest utility in demonstrating root disease when sensory nerve conduction studies are normal; otherwise, they are used most frequently to support the diagnosis of multiple sclerosis, in which case there may or may not be corresponding sensory features. (See Chap. 2 for discussion of evoked potential testing.)

In practice, it is seldom necessary to examine all modalities of sensation and perception. With single peripheral nerve lesions, touch and pinprick testing are the most informative. With spinal cord disease, pinprick and thermal stimuli are most revealing of lateral column lesions; testing the senses of vibration, position, and movement, and particularly the sense of direction of a dermal stimulus, reliably indicates posterior column lesions. Touch is the least useful. In diseases of the sensory ganglia, all modes of sensation, including touch, may be affected throughout the body, and this applies in general to thalamic lesions, but of course, only on the side opposite the lesion. Thus, one is guided in the selection of tests by the suspected locale of the disease.

Headache and Other Craniofacial Pains

Of all the painful states that afflict humans, headache is undoubtedly the most frequent and rivals backache as one of the most common reasons for seeking medical help. In fact, there are so many cases of headache that headache clinics have been established in many medical centers. In addition to its frequency in general practice, many headaches are caused by medical rather than neurologic diseases and the subject is the legitimate concern of the general physician.

Why so many pains are centered in the head is a question of some interest. Several explanations come to mind. For one thing, the face and scalp are more richly supplied with pain receptors than many other parts of the body, perhaps to protect the contents of the skull. Also, the nasal and oral passages, the eye, and the ear—all delicate and highly sensitive structures—reside here and must be protected; when affected by disease, each is capable of inducing pain in its own way. Finally, there is great concern among patients about what happens to the head perhaps more than other parts of the body because headache raises the specter of brain tumor or other cerebral disease.

Semantically, the term *headache* encompasses all aches and pains located in the head, but in practice, its application is restricted to discomfort in the region of the cranial vault. Facial, lingual, and pharyngeal pains are discussed in the latter part of this chapter and separately in Chap. 44, because they pertain to the cranial nerves.

GENERAL CONSIDERATIONS

In the introductory chapter on pain, reference was made to the necessity of determining the quality, severity, location, duration, and time course of any pain as well as the conditions that produce or relieve it. In the case of headache, a detailed history following these lines will determine the diagnosis more often than will the physical examination or imaging. Nevertheless, a few aspects of the examination are worth emphasizing. For example, auscultation of the skull may rarely disclose a bruit (with large arteriovenous malformations); palpation may disclose the tender, hardened or elevated arteries of temporal arteritis; sensitive areas overlying a cranial metastasis or an inflamed paranasal sinus may be apparent; or there may be a tender occipital nerve. Examination of neck flexion may reveal meningitis; however, apart from these special instances, examination of the head itself, although necessary, seldom discloses the diagnosis.

The *quality* of cephalic pain is essential to diagnosis but the sensation may be difficult for the patient to describe. When asked to compare the pain to some other sensory experience, the patient may allude to tightness, aching, pressure, burning, bursting, sharpness, or stabbing. Among the most important aspects is whether the headache is pulsatile, usually implying migraine, but one must keep in mind that patients sometimes use the word *throbbing* to refer to a waxing and waning of the headache without any relation to the pulse, or use the term to transmit the severity of pain.

Similarly, statements about the *intensity* of the pain reflect to some extent the patient's temperament, attitudes, and customary ways of experiencing and reacting to pain. One useful index of severity is the degree to which the pain has incapacitated the patient. A severe migraine attack seldom allows the migraineur to perform the day's work. Other rough indices of the severity of headache are its propensity to awaken the patient from sleep or to prevent sleep, and autonomic reactions to the pain such as sweating and tachycardia. The most intense cranial pains are those associated with meningitis and subarachnoid hemorrhage, which can have grave consequences, but also migraine, cluster headache, or tic douloureux that do not have the same implications.

Information regarding the *location* of a headache is informative. Migraine headache is unilateral in two-thirds of attacks and is commonly associated with nausea, vomiting, and sensitivity to light, sound, and smells. Inflammation of an extracranial artery from temporal arteritis causes pain localized to the site of the vessel. Lesions of the paranasal sinuses, teeth, eyes, and upper cervical vertebrae induce a less sharply localized pain but still one that is referred to a certain region, usually the forehead or maxilla or around the eyes. Intracranial lesions in the posterior fossa generally cause pain in the occipitonuchal region and usually are ipsilateral if the lesion is one-sided. Supratentorial lesions induce frontotemporal pain that approximates the site of an intracranial lesion. Localization, however, may also be deceiving. Pain in the frontal regions may be caused by such diverse disorders as glaucoma, sinusitis, thrombosis of the vertebral or basilar artery, pressure on the tentorium, and increased intracranial pressure. Similarly, ear pain may signify disease of the ear itself, but as

often, it is referred from other regions, such as the throat, cervical muscles, spine, or structures in the posterior fossa. Periorbital and supraorbital pain, while usually indicative of local ocular disease, may reflect dissection of the cervical portion of the internal carotid artery. Headaches localized to the vertex or biparietal regions are infrequent and should raise the suspicion of sphenoid or ethmoid sinus disease or thrombosis of the superior sagittal venous sinus.

The *mode of onset,* the *variation* of the pain over time, and the *duration* of the headache, with respect both to a single attack and to the profile of a series of headaches over a period of months or years, are also useful data. At one extreme, the headache of subarachnoid hemorrhage (caused by a ruptured aneurysm) occurs as an abrupt attack that attains its maximal severity in a matter of seconds or, in the case of meningitis, it may come on more gradually, over several hours or days. Simulating the rapid onset, severe headaches of subarachnoid hemorrhage are a group of "thunderclap headaches" of diverse causes but principally cerebral venous thrombosis and vasospasm syndromes. Brief sharp pain, lasting a few seconds, in the eyeball (ophthalmodynia) or cranium ("ice-pick" pain) and "ice-cream headache" caused by pharyngeal cooling are more common in migraineurs and are significant only by reason of their benignity.

With regard to characteristic temporal patterns, migraine of the typical type usually has its onset in the early morning hours or in the daytime, reaches its peak of severity over several to 30 min, and lasts, unless treated, for 4 to 24 h, occasionally longer. Often, it is terminated by sleep. A migrainous patient having several attacks per week usually proves to have a chronic form of migraine or a combination of migraine and analgesic "overuse headache," meaning that the headache returns when the effect of the drug has worn off or rarely, this pattern is associated with some unexpected intracranial lesion. By contrast, cluster headache is characterized by the occurrence of unbearably severe unilateral orbitotemporal pain coming on within 1 or 2 h after falling asleep or at predictable times during the day and recurring nightly or daily for a period of several weeks to months; usually an individual attack of "cluster" dissipates in 30 to 45 min but may occasionally last several hours. The headache of intracranial tumor may appear at any time of the day or night; it may interrupt sleep, vary in intensity, and last a few minutes to hours as the tumor raises intracranial pressure. With posterior fossa masses, the headache tends to be worse in the morning, on awakening. Tension headaches (a vague category now called "tension-type headache") can persist with varying intensity for weeks to months or even longer; when such headaches are protracted, there is often an associated depressive illness. In general, headaches that have recurred regularly for many years prove to be migraine or tension in type.

The relationship of headache to certain biologic events and to *precipitating, aggravating, or relieving* factors can be of significance in diagnosis. Headaches that occur regularly in the premenstrual period are usually generalized and mild in degree, but attacks of migraine may also occur at this time (catamenial migraine). Headaches that have their origin in cervical spine disease are most typically intense after a period of inactivity, such as a night's sleep, and the first movements of the neck are stiff and painful. Headache, or more often face ache, from infection of the nasal sinuses may appear on awakening or in midmorning and is characteristically worsened by stooping and changes in atmospheric pressure; there is associated midfrontal or maxillary tenderness. Eyestrain after long-sustained periods of reading, or exposure to the glare of video displays, may be associated with head pain but it is transient and not an important cause of headache. In certain individuals alcohol, intense exercise (such as weight lifting), stooping, straining, coughing, and sexual intercourse are known to initiate a bursting (thunderclap) headache, lasting a few seconds to minutes. If a headache is made worse by sudden movement or by coughing or straining, an intracranial source is tentatively suggested. Migraine often occurs several hours or a day following a period of intense activity and stress ("weekend," or "letdown" migraine). Some patients have discovered that their migraine is relieved momentarily by gentle compression of the carotid or superficial temporal artery on the painful side, and others report that the carotid near the angle of the jaw is tender during the headache. Pain that is noticed when the scalp is stroked in combing or fixing the hair (allodynia) is common in migraine but could be a symptom of inflammation of the temporal arteries (temporal arteritis). Certain medications, most vasodilators such as nitroglycerin and dipyridamole but also monosodium glutamate, are apt to cause headaches. The headaches that follow a period or excessive alcohol (hangover) or a concussion are well known. In many of these instances, a propensity for migraine may create a susceptibility to headache that is induced by these precipitants.

Pain-Sensitive Cranial Structures

Our understanding of headache has been augmented by observations made during operations on the brain (Ray and Wolff). These observations inform us that only certain cranial structures are sensitive to noxious stimuli: (1) skin, subcutaneous tissue, muscles, extracranial arteries, and external periosteum of the skull; (2) the delicate structures of the eye, ear, nasal cavities, and paranasal sinuses; (3) intracranial venous sinuses and their large tributaries because they are intradural; (4) parts of the dura at the base of the brain and the arteries within the dura, particularly the proximal parts of the anterior and middle cerebral arteries and the intracranial segment of the internal carotid artery; (5) the middle meningeal and superficial temporal arteries; and (6) the first three cervical nerves and cranial nerves as they pass through the dura. Interestingly, pain is practically the only sensation produced by the stimulation of these structures. Much of the pia-arachnoid, the parenchyma of the brain, and the ependyma and choroid plexuses lack sensitivity.

The sites of referred pain from the aforementioned structures are important in understanding the genesis of cranial pain. Pain that arises from distention of the middle meningeal artery is projected to the back of the eye and temporal area. Pain from the intracranial segment of the internal carotid artery and proximal parts of the middle and anterior cerebral arteries is felt in the eye and orbitotemporal regions. The pathways whereby cephalic sensory stimuli are transmitted to the central nervous system

(CNS) are the trigeminal nerves, particularly their first and, to some extent, second divisions, which convey impulses from the forehead, orbit, anterior and middle fossae of the skull, and the upper surface of the tentorium. The sphenopalatine branches of the facial nerve convey impulses from the nasoorbital region. The ninth and tenth cranial nerves and the first three cervical nerves transmit impulses from the inferior surface of the tentorium and all of the posterior fossa. The tentorium roughly demarcates the trigeminal from the cervical–vagal–glossopharyngeal innervation zones. The central sensory connections, which ascend through the brainstem or the cervical spinal cord and brainstem to the thalamus, are described in Chaps. 7 and 8. Sympathetic fibers from the three cervical ganglia and parasympathetic fibers from the sphenopalatine and otic ganglia are mixed with the trigeminal and other sensory fibers. These assume importance in certain headache syndromes considered further on.

There may be local tenderness of the scalp at the site of the referred cranial pain. Dental or temporomandibular joint pain impulses are carried by the second and third divisions of the trigeminal nerve. With the exception of the cervical portion of the internal carotid artery, from which pain is referred to the eyebrow and supraorbital region, and the upper cervical spine, from which pain may be referred to the occiput, pain from disease in extracranial parts of the body is not referred to the head. There are, however, rare instances of angina pectoris that may produce discomfort at the cranial vertex or adjacent sites and, of course, in the jaw.

Mechanisms of Cranial Pain

The studies demonstrated that relatively few mechanisms are operative in the genesis of cranial pain (Ray and Wolff). More specifically, *intracranial mass lesions* cause headache if they deform, displace, or exert traction on vessels and dural structures, and this may happen long before intracranial pressure rises. In fact, artificially raising the intraspinal and intracranial pressure by the subarachnoid or intraventricular injection of sterile saline solution does not consistently result in headache. This has been interpreted to mean that raised intracranial pressure does not cause headache—a questionable conclusion when one considers the relief of headache in some patients that follows lumbar puncture (LP) and lowering of the cerebrospinal fluid (CSF) pressure, particularly after subarachnoid hemorrhage and in pseudotumor cerebri, and similar relief of headache when brain edema surrounding an intracranial mass is treated with glucocorticoids. Actually, most patients with high intracranial pressure complain of bioccipital and bifrontal headaches that fluctuate in severity and are worse when supine.

Dilatation of intracranial or extracranial arteries (and possibly sensitization of these vessels), of whatever cause, is likely to produce headache. The headaches that follow seizures and ingestion of alcohol are probably caused by cerebral vasodilatation. Nitroglycerin, nitrites in cured meats ("hot-dog headache"), and monosodium glutamate in some foods may cause headache by the same mechanism. It is possible that the throbbing or steady headache that accompanies febrile illnesses has a vascular origin as well; it is likely that the increased pulsation of meningeal vessels activates pain-sensitive structures within their walls or around the base of the brain. Febrile headache may be generalized or predominate in the frontal or occipital regions and is relieved on one side by carotid or superficial temporal artery compression and on both sides by jugular vein compression. Like migraine, it is also increased by shaking the head. Certain systemic infectious agents, enumerated further on, have a tendency to cause severe headache, even without meningitis.

A similar mechanism may be operative in the severe, bilateral, throbbing headaches associated with extremely rapid rises in blood pressure, as occurs with pheochromocytoma, malignant hypertension, sexual activity, and in patients being treated with monoamine oxidase inhibitors. Mild to moderate degrees of chronic hypertension, however, do not cause headaches despite a popular notion to the contrary. So-called cough and exertional headaches may also have their basis in the distention of intracranial vessels.

For many years, following the investigations of Harold Wolff, the headache of migraine was attributed to dilatation of the extracranial arteries. Now, it appears that this is not a constant relationship and that the headache is of complex intracranial as much as extracranial origin, perhaps related to the sensitization of blood vessels and their surrounding structures. Activation of the trigeminovascular system (the trigeminal nerves and the blood vessels they supply), leading to an inflammatory response that is generated by local neural mechanisms, "neurogenic inflammation," has also been assigned a role in migraine headache. These and other theories of causation are summarized by Cutrer and discussed further on in this chapter in the section on migraine.

With regard to *cerebrovascular diseases* causing head pain, the extracranial temporal and occipital arteries, when involved in giant cell arteritis (cranial or "temporal" arteritis), give rise to severe, persistent headache, at first localized on the scalp and then more diffuse. Most strokes caused by vascular occlusion do not cause head pain. However, with occlusion or dissection of the vertebral artery, there may be pain in the upper neck or postauricular area; basilar artery thrombosis causes pain to be projected to the occiput and sometimes to the forehead; and the ipsilateral eye and brow, and the forehead above it are the most common sites of projected pain from dissection of the carotid artery and occlusion of the stem of the middle cerebral arteries. Expanding intracranial aneurysms of the posterior communicating or distal internal carotid arteries very often cause pain projected to the eye. The distinctive headache caused by aneurysmal rupture is mentioned below and in a separate section later in the chapter.

Infection or blockage of paranasal sinuses is accompanied by pain over the affected maxillary or frontal sinuses. Usually, it is associated with tenderness of the skin and cranium in the same distribution. Pain from the ethmoid and sphenoid sinuses is localized deep in the midline behind the root of the nose or occasionally at the vertex (especially with disease of the sphenoid sinus). The mechanism in these cases involves changes in pressure and irritation of pain-sensitive sinus walls.

With frontal and ethmoidal sinusitis, the pain tends to be worse on awakening and gradually subsides when the patient

is upright; the opposite pertains with maxillary and sphenoidal sinusitis. These relationships are believed to disclose their mechanism; pain is ascribed to filling of the sinuses and its relief to their emptying, induced by the dependent position of the ostia. Bending over intensifies the pain by causing changes in pressure, as does blowing the nose and air travel, especially on descent, when the relative pressure in the blocked sinus rises. Sympathomimetic drugs, such as phenylephrine hydrochloride, which reduce swelling and congestion of sinus membranes, tend to relieve the pain. However, the pain may persist after all purulent secretions have disappeared, probably because of persistent inflammation of the membranes, or blockage of the orifices and dissipation of air from the blocked sinus, so-called *vacuum sinus headaches.*

Headache of ocular origin, located as a rule in the orbit, forehead, or temple, is of the steady, aching type and tends to follow prolonged use of the eyes in close work. However, cranial pain is too frequently attributed to ocular causes, particularly if the external appearance of the sclera and conjunctiva are normal. The main faults are hypermetropia and astigmatism (rarely myopia), which result in sustained contraction of extraocular as well as frontal, temporal, and even occipital muscles. In the uncommon and overemphasized circumstance of a refractive error causing headache, correction rapidly ameliorates the headache. Traction on the extraocular muscles or the iris during eye surgery evokes pain. Patients who develop diplopia from neurologic causes or are forced to use one eye because the other has been occluded by a patch often complain of frontal headache. Another mechanism is involved in *iridocyclitis* and in *acute angle closure glaucoma*, in which raised intraocular pressure causes steady, aching pain in the region of the eye, radiating to the forehead. When acute angle closure glaucoma causes headache, the sclera is invariably red. Dilating the pupil risks precipitating angle closure glaucoma, a situation that can be reversed by the administration of pilocarpine 1 percent drops.

Headaches that accompany disease of ligaments, muscles, and apophyseal joints in the *upper part of the cervical spine* are referred to the occiput and nape of the neck on the same side and sometimes to the temple and forehead. These headaches have been reproduced by the injection of hypertonic saline solution into the ligaments, muscles, and facet joints and are comparable to the regions of sclerotogenous referred pain that is discussed in Chap. 7. Such pains are especially frequent in late life because of the prevalence of degenerative changes in the cervical spine and tend also to occur after whiplash injuries or other forms of sudden flexion, extension, or torsion of the head on the neck. If the pain referred pain of cervical spine disease is arthritic in origin, the first movements after the individual has been still for some hours are stiff and painful. The pain of fibromyalgia is characterized by tender areas near the cranial insertion of cervical and other muscles. There are no pathologic data as to the nature of these vaguely palpable and tender regions, and it is uncertain whether the pain actually arises in them. They may represent only the deep tenderness felt in the region of referred pain or the involuntary secondary protective spasm of muscles. Unilateral occipital headache is often misinterpreted as occipital neuralgia (see further on).

The headache of meningeal irritation (usually due to infection or hemorrhage) is typically acute in onset, usually severe, generalized, deep-seated, constant, and associated with stiffness of the neck, particularly on forward bending of the neck. It has been ascribed to increased intracranial pressure; indeed, the withdrawal of CSF may afford some relief. However, dilatation and inflammation of meningeal vessels and the chemical irritation of pain receptors in the large vessels and meninges by endogenous chemical agents are probably more important in the production of pain and spasm of the neck extensors. In the chemically induced meningitis from rupture of an epidermoid cyst, for example, the spinal fluid pressure is usually normal, but the headache is severe. Meningeal irritation or inflammation may also be chronic and have as its main feature a concurrently ongoing headache.

Lumbar puncture (LP) and *spontaneous low CSF pressure headache,* as discussed in Chap. 2, is characterized by a steady occipitonuchal and frontal pain coming on within a few minutes after arising from a recumbent position (orthostatic headache) and is relieved within a minute or two by lying down. Its cause is a persistent leakage of CSF into the lumbar tissues through the needle track, or a tear of the meninges that may be spontaneous or induced by spinal trauma. It is a subset of "Spontaneous Intracranial Hypotension," which is covered in Chap. 29.

Headaches that are aggravated by lying down or lying on one side occur with acute and chronic subdural hematoma and with some brain masses, particularly those in the posterior fossa. The headache of subdural hematoma, when it occurs, is dull and unilateral, perceived over most of the affected side of the head. The global and nuchal headaches of idiopathic intracranial hypertension (pseudotumor cerebri) are also generally worse in the supine position (see Chap. 29). In all these states of raised intracranial pressure, headaches are typically worse in the early morning hours after a long period of recumbency. *Exertional headaches*, for example those that are associated with sexual activity or weight lifting, are usually benign but they are sometimes related to pheochromocytoma, arteriovenous malformation (AVM), or other intracranial lesions, in addition to the subarachnoid hemorrhage from ruptured aneurysm and cervical arterial dissection. The same usually benign nature applies to headaches induced by stooping and at worst, are accounted for by sinus infection but there are exceptions and subdural hematoma is a known cause (see further on).

PRINCIPAL VARIETIES OF IDIOPATHIC HEADACHE

The clinician's first goal when confronted with a patient with cranial pain is to determine if the headache is primary, in which head pain is the only identifiable disease, or if it is a secondary cranial pain. The main primary headache syndromes are migraine, tension-type headache, and cluster headache.

In the following broad categories of primary headaches, migraine being the most important and frequent, should be considered (Table 9-1). In general, the classification of

Table 9-1

COMMON TYPES OF HEADACHE

TYPE	SITE	AGE AND SEX	CLINICAL CHARACTERISTICS	DIURNAL PATTERN	LIFE PROFILE	PROVOKING FACTORS	ASSOCIATED FEATURES	TREATMENT
Migraine without aura (common migraine)	Frontotemporal	Adolescents, young to middle-aged adults, sometimes children, more common in women	Throbbing (pulsatile); worse behind one eye or ear	Upon awakening or later in day	Irregular intervals, weeks to months	Bright light, noise, tension, alcohol	Nausea and vomiting in some cases	Triptans, ergotamine, nonsteroidal anti-inflammatory agents
	Uni- or bilateral		Becomes dull ache and generalized	Duration: 4–24 h in most cases, sometimes longer	Tends to decrease in middle age and during pregnancy	Relieved by darkness and sleep		Propranolol or amitriptyline for prevention
			Scalp sensitive					
Migraine with aura (neurologic migraine)	Same as above	Same as above	Same as above	Same as above	Same as above	Same as above	Scintillating lights, visual loss, and scotomas	Same as above
			Family history frequent				Unilateral paresthesias, weakness, dysphasia, vertigo, rarely confusion	
Cluster (histamine headache, migrainous neuralgia)	Orbitotemporal	Adolescent and adult males (90%)	Intense, nonthrobbing	Usually nocturnal, 1–2 h after falling asleep	Nightly or daily for several weeks to months	Alcohol in some	Lacrimation	O_2, sumatriptan, ergotamine before anticipated attack
	Unilateral			Occasionally diurnal	Recurrence after many months or years		Stuffed nostril	Corticosteroids, verapamil, valproate, and lithium in recalcitrant cases
							Rhinorrhea Injected conjunctivum Ptosis	
Tension headaches	Generalized	Mainly adults, both sexes, more common in women	Pressure (nonthrobbing), tightness, aching	Continuous, variable intensity, for days, weeks, or months	One or more periods of months to years	Fatigue and nervous strain	Depression, worry, anxiety	Antianxiety and antidepressant drug
Meningeal irritation (meningitis, subarachnoid hemorrhage)	Generalized, or bioccipital, or bifrontal	Any age, both sexes	Intense, steady deep pain, may be worse in neck	Rapid evolution—minutes to hours	Single episode	None	Neck stiff on forward bending	For meningitis or bleeding (see text)
							Kernig and Brudzinski signs	

(*Continued*)

Table 9-1

COMMON TYPES OF HEADACHE (*CONTINUED*)

TYPE	SITE	AGE AND SEX	CLINICAL CHARACTERISTICS	DIURNAL PATTERN	LIFE PROFILE	PROVOKING FACTORS	ASSOCIATED FEATURES	TREATMENT
Brain tumor	Unilateral or generalized	Any age, both sexes	Variable intensity	Lasts minutes to hours; worse in early A.M., increasing severity	Once in a life time: weeks to months	None	Papilledema	Corticosteroids
			May awaken patient			Sometimes position	Vomiting	Mannitol
			Steady pain				Impaired mentation Seizures Focal signs	Treatment of tumor
Temporal arteritis	Unilateral or bilateral, usually temporal	Older than 50 years, either sex	Throbbing, then persistent aching and burning, arteries thickened and tender	Intermittent, then continuous	Persists for weeks to months	None	Loss of vision	Corticosteroids
							Polymyalgia rheumatica Fever, weight loss, increased sedimentation rate, jaw claudication	

these headaches and other types of craniofacial pain follow the plan outlined by the International Headache Society (see http://www.ihs-classification.org/en).

Migraine

Migraine is a prevalent and largely familial disorder characterized by periodic, commonly unilateral, usually pulsatile headaches that often begin in childhood, adolescence, or early adult life and recurs with diminishing frequency during advancing years.

Two clinical syndromes have been identified, *migraine with aura* and *migraine without aura* (terminology of the International Headache Society). For many years, the first syndrome was referred to as *classic* or *neurologic* migraine and the second as *common* migraine. Individuals may experience both types over their lives. The ratio of classic to common migraine is approximately 1:5. Migraine with aura is ushered in by a disturbance of nervous function, most often a very characteristic visual change described further on, followed in a few minutes to hours by hemicranial (or, in about one-third of cases, bilateral) headache, nausea, and sometimes vomiting, all of which last for hours or as long as a day or more; or there may be a typical visual aura without subsequent headache. Migraine without aura is characterized by an unheralded onset over minutes or longer of increasing hemicranial headache or, less often, by generalized headache with or without nausea and vomiting, which then follows the same temporal pattern as the migraine with aura. Sensitivity to light, noise, and often smells (photophobia, phono- or sonophobia, and osmophobia) can accompany both types, and intensification with movement of the head is common. If the pain is severe, the patient prefers to lie down in a quiet, darkened room and tries to sleep. The hemicranial and the throbbing (pulsating) aspects of migraine and the preceding visual aura are its most characteristic features in comparison to other headache types. Each patient displays a proclivity for the pain to affect one side or the other of the cranium, but not exclusively, so that some bouts are on the other side or on both sides.

The heritable nature of migraine with aura is apparent from its occurrence in several members of the family of the same and successive generations in 40 or more percent of cases; the familial frequency of common migraine (without aura) is lower. Twin and sibling studies suggest against a mendelian pattern in either form. In genome-wide association studies, approximately 40 susceptibility sites have been identified with many risk variants being associated with genes active in vascular smooth muscle tissue (Gormley P, et al). Certain other rare forms of migraine, such as familial hemiplegic migraine, appear to be monogenic disorders but the role of these genes, most of which code for ion channels, in other forms of migraine is still speculative.

Migraine is a remarkably common condition, with an estimated 1-year overall prevalence of approximately 15 percent in the Global Burden of Disease Study (Stovner, 2018). A study in the United States showed differences in the prevalence of migraine between individuals of white, African, and Asian origin of approximately 20, 16, and 9 percent, respectively, among women, and 9, 7, and 4 percent for men (Stewart and colleagues, 1996; see also Lipton et al, 2007). One-third of migraineurs have more than three attacks monthly if untreated and many require bed rest or severe curtailment of daily activities. Migraine may have its onset in childhood but usually begins in adolescence or young adulthood; in more than 80 percent of patients, the onset is before 30 years of age, and the physician should be cautious in attributing headaches that appear for the first time after this age to migraine, although there are many exceptions.

In younger women, the headaches may occur during the premenstrual period; in approximately 15 percent of such migraineurs, the attacks are exclusively perimenstrual. *Menstrual migraine* (also termed *catamenial migraine*) discussed further on, had been considered to be solely related to the withdrawal of estradiol (based on the work of Somerville). It is now acknowledged that the influence of sex hormones on headache is more complex. Migraine tends to cease during the second and third trimesters of pregnancy in 75 to 80 percent of women, and in others they continue at a reduced frequency; less often, attacks of migraine or the associated neurologic symptoms first appear during pregnancy, usually in the first trimester.

Although migraine commonly diminishes in severity and frequency with age, it may actually worsen in some postmenopausal women, and estrogen therapy may either increase or, paradoxically, diminish the incidence of headaches. The use of birth control pills is associated with an increased frequency and severity of migraine and in rare instances has resulted in a permanent neurologic deficit (see further on and Chap. 33).

Some patients link their attacks to certain dietary items—particularly chocolate, cheese, fatty foods, oranges, tomatoes, and onions—but these connections have proved inconsistent in most carefully done studies but there may be persuasive individual instances. Some of these foods are rich in tyramine, which has been incriminated as a provocative factor in migraine. Alcohol, particularly red wine or port, regularly provokes an attack in some persons; in others, headaches are fairly consistently induced by exposure to glare or other strong sensory stimuli, sudden jarring of the head in concussion ("footballer's migraine"), or by rapid changes in barometric pressure. A common trigger is excess caffeine intake or withdrawal of caffeine.

Migraine with aura may occur at any time of day, in some individuals, arising frequently after awakening. The temporal pattern, as stated, is the visual phenomena followed in minutes or less than an hour by unilateral throbbing headache. During the preceding hours, there may have been mild changes in mood, sometimes a surge of energy or a feeling of well-being, hunger or anorexia, drowsiness, or frequent yawning. Then, abruptly, there is a disturbance of vision consisting usually of unformed patterns of flashing, shimmering, or rotating white, or silver, or, rarely, of multicolored lights. This may be followed by an enlarging blind spot with a shimmering edge (*scintillating scotoma*), or formations of dazzling zigzag lines (arranged like the battlements of a castle, hence the term *fortification spectra,* or *teichopsia*). Hubert Airy's description and drawings of his own auras over 20 min are instructive (Fig. 9-1). Similar descriptions and drawings were later published by Lashley. In both, the expansion and movement across the

Figure 9-1. Drawings by Hubert Airy of his own expanding scotoma with fortification spectra at the edges. "O" indicates the point of visual fixation in each image. The visual aberration expanded over approximately 20 minutes and slowly moved peripherally. Reproduced with permission from H. Airy, "I. On a distinct form of transient hemiopsia," Proceedings of the Royal Society of London, vol. 18, no. 114–122, pp. 212–216, Jan. 1870.

visual field of the scotoma and the fortification, maintaining a consistent but expanding shape, are notable.

Other patients complain instead of blurred or shimmering or cloudy vision, as though they were looking through thick or smoked glass or through the wavy distortions produced by heat rising from asphalt. These luminous hallucinations move slowly across the visual field for several minutes and may leave an island of visual loss in their wake, a scotoma, usually homonymous (involving corresponding parts of the field of vision of each eye), pointing to its origin in the visual cortex. Patients often attribute these visual symptoms to originating in one eye rather than to parts of both fields. Ophthalmologic abnormalities of retinal and optic nerve vessels have been described in some cases but are not typical.

Other neurologic symptoms associated with migraine, less common than visual ones, include numbness and tingling of the lips, face, and hand (on one or both sides) that spreads over minutes; slight confusion; weakness of an arm or leg; mild aphasia or dysarthria, dizziness, and uncertainty of gait or drowsiness. Only one or a few neurologic phenomena are present in any given patient and they tend to occur in more or less the same combination in each attack. If weakness or paresthetic numbness spreads from one part of the body to another, or if one neurologic symptom follows another, this occurs relatively slowly over a period of minutes (not over seconds, as in a seizure, or virtually simultaneously in all affected parts as in a transient ischemic attack).

The visual or neurologic symptoms usually last for less than 30 min, sometimes longer. As they recede, a unilateral dull pain develops of slowly increasing intensity that progresses to a throbbing headache (usually but not always on the side of the cerebral disturbance). At the peak of the pain, within minutes to an hour, the patient may be forced to lie down and shun light (photophobia) and noise (phonophobia). Light is irritating and may be painful to the globes, or it is perceived as overly bright (dazzle), and strong odors are disagreeable. Nausea and, less often, vomiting may occur. The headache lasts for hours and sometimes for a day or even longer and is often the most disabling feature of the illness. The temporal scalp vessels may be tender and the headache is worsened by strain or jarring of the body or head. Pressure on the scalp vessels or carotid artery may momentarily reduce the pain and releasing pressure accentuates it.

Between attacks, the migrainous patient is normal. In the past, it was believed that there was a migrainous personality, characterized by tenseness, rigidity of attitudes and thinking, meticulousness, and perfectionism. Further analyses, however, have not established a particular personality type in the migraineur. A relationship of migraine to epilepsy in general is also tenuous; however, the incidence of seizures may be slightly higher in migrainous patients and their relatives than in the general population, and there are syndromes that encompass both disorders. In surveys, affective disorders, particularly depressive and anxiety disorders, are more common in patients with migraine than would be expected by chance.

Some patients note that their attacks of migraine tend to occur during the "let-down period," after many days of hard work or tension. There is an overrepresentation of motion sickness or a vague instability of vision or accommodation, sensitivity to striped patterns, fainting, and of fleeting sensory symptoms on one side of the body in migraineurs. Moreover, as appreciated by Graham, migraine has a lifetime profile and is a familial disease that includes some or many of the following: colic in infancy, motion sickness, episodic abdominal pain, fainting, alcohol sensitivity, exercise-induced headaches, "sinus headaches," "tension headaches," and menstrual headaches. These, to varying degrees, can be markers of the disease, and their absence in the patient or family members should at least cause the consideration of alternative explanations for cranial pain before attributing headache to migraine.

Alternative Patterns of Migraine

The patterns of migraine can vary. As already alluded to, the headaches need not be unilateral and the pulsatile aspect may not be prominent. The headache may be exceptionally severe and abrupt in onset ("crash migraine" or "thunderclap headache"), raising the specter of subarachnoid hemorrhage. Careful questioning in these cases sometimes reveals that the headache did not truly attain its peak rapidly but evolved over several minutes. The distinction of this type of "headache from that caused by subarachnoid hemorrhage can sometimes be made only by examination of the CSF and imaging of the brain (see further on).

A headache may at times precede or accompany, rather than follow, the neurologic abnormalities of a migraine aura. Although typically hemicranial (the French word *migraine* is said to be derived from *megrim*, which, in turn, is from the Latin *hemicrania,* and its corrupted forms *hemigranea* and *migranea*), the pain may be frontal,

temporal, or, quite often, generalized. Furthermore, throbbing or pulsating pain is not an inviolate feature.

Any two of the three principal components—neurologic abnormality, headache, and gastrointestinal upset—may be absent. With advancing age, for example, in some instances there is a tendency for the headache and nausea to become less severe, finally leaving only the episodic neurologic abnormality, which simulates a transient ischemic attack (TIA) and eventually recurs with decreasing frequency. One common configuration is a full-blown visual aura without subsequent headache (migraine without headache, or migraine dissocié). Visual and other neurologic disturbances differ in detail from patient to patient; numbness and tingling of the lips and the fingers of one hand are probably next in frequency after visual displays, followed by transient dysphasia or thickness of speech and rarely, hemiparesis as mentioned earlier. Episodes of sudden, transient blindness or hemianopia at the onset of a migraine attack, accompanied by only mild headache are also known. Furthermore, there are several special forms of migraine that do not conform to the usual patterns discussed above, and are discussed in the following section.

In addition to variability in the pattern of conventional migraine detailed just above, there are several distinctive syndromes that have been allied with migraine. They are so classified because they have as main features recurrent migrainous headache with reversible neurologic deficits or visual displays that are identifiable as aura components of typical migraine. What sets them apart from conventional migraine is paralysis, stupor, ophthalmoplegia, or monocular visual loss. Furthermore, patients or their families may display both typical migraine and one of these variants.

Migraine With Brainstem Aura (Basilar Migraine)

An uncommon form of the migraine syndrome with prominent premonitory brainstem symptoms was described by Bickerstaff. These patients, usually children with a family history of migraine, first develop visual phenomena like those of typical migraine except that they occupy much or the whole of both visual fields (temporary cortical blindness may occur as mentioned above). There may be associated vertigo, staggering, incoordination of the limbs, dysarthria, and tingling in both hands and feet, and sometimes around both sides of the mouth but curiously, rarely is there paralysis. These symptoms last 10 to 30 min and are followed by headache, which is usually occipital. Some patients, at the stage when the headache would have been likely to begin, may faint, and others become confused or stuporous, a state that may persist for several hours or longer. Exceptionally, there is an alarming period of coma or quadriplegia. The symptoms closely resemble those caused by ischemia in the territory of the basilar-posterior cerebral arteries—hence the name *basilar,* or *vertebrobasilar migraine*. Subsequent studies have indicated that basilar migraine, although more common in children and adolescents, affects men and women more or less equally over a wide age range, and that the condition is not always benign and transient because of rare instances with residual deficits.

The initial attack is not easily identifiable as a benign condition and various forms of imaging are reasonably performed to exclude basilar artery and upper brainstem disease. The issue of risk of causing stroke from the administration of intrarterial contrast is often raised and is unresolved. With recurrent similar attacks, the diagnosis becomes clearer and the use of imaging becomes less necessary.

Childhood Periodic Syndrome

Episodes of *cyclic vomiting* or periodic recurrent abdominal pain have been linked to migraine as a result of the frequent co-occurrence of these symptoms with headache or typical migraine at other times. Pallor, lethargy, and mild headache are common. This disorder seems to be a problem almost exclusively in children. The results of diagnostic investigation are normal but one cannot be faulted for pursuing some form of testing with the initial occurrence of the syndrome.

Migrainous Vertigo

Dizziness is certainly a common accompaniment of migraine and its auras. A less certain syndrome associates episodic vertigo with migraine, mainly in children but also in some adults who are known migraineurs. Patients report varying degrees and types of dizziness, are disturbed by highly patterned or crowded visual environments, and can be disabled by imbalance but the examination during a symptomatic period is most often normal. Many of these features align with anxiety but the episodic occurrence of symptoms and interspersed attacks of conventional migraine headache or visual phenomena make the connection plausible. Bedside vestibular testing is normal, however, a proportion of patients is found to have minor central or peripheral deficits on more elaborate laboratory testing (see Chap. 14). Similarly, a tenuous relationship between an episodic vertigo syndrome and migraine in children, as described by Basser, is discussed in Chap. 14.

Ophthalmoplegic Migraine

Ophthalmoplegic migraine in the current terminology of the International Headache Society is "recurrent painful ophthalmoplegic neuropathy" rather than migraine but it is most conveniently described here. It consists of a recurrent unilateral headaches associated with weakness of extraocular muscles. Transient third-nerve palsy with ptosis, with or without involvement of the pupil, is the usual picture; rarely, the sixth nerve is affected. This disorder almost exclusively occurs in children. As a general rule, the diagnosis should not be made in adults unless there had been recurrent bouts in childhood. The ocular paresis often outlasts the headache by days or weeks; after many attacks, a slight mydriasis and some degree of ophthalmoparesis may remain permanently. We and others have encountered instances of gadolinium enhancement of the proximal, cisternal portion of the third nerve during and after an attack. However, in adults the syndrome of headache, unilateral ophthalmoparesis, and loss of vision may have more serious causes, including temporal (cranial) arteritis.

Retinal Migraine

In another entity that is more clearly allied with migraine than the ophthalmoplegic variety above, *retinal*, or *ocular migraine,* there are purely monocular visual symptoms of

scintillations or scotoma. The visual loss can be quite severe or complete but is transient and recovers fully. Often in our experience, there is no headache but if one is present, it is of the typical migraine type, not ocular pain. In some cases of uniocular visual disturbance with scotoma, fortuitous examination during an attack may reveal attenuation of the retinal arterioles (Berger and colleagues). Most often, there are no funduscopic changes. Either the retinal or the ciliary circulation is probably involved but there is always difficulty in differentiating the experience of what is called retinal migraine from a very incongruous hemifield cortical migraine. Knowledge of this syndrome in a young healthy person may prevent excessive evaluation and unnecessary treatment, although antiphospholipid antibody syndrome and other hypercoagulable states are considerations. In older persons, carotid disease and giant cell arteritis merit investigation.

Hemiplegic Migraine (Familial Hemiplegic Migraine)

In *hemiplegic migraine*, a condition mostly in infants and children (rarely adults), there are episodes of unilateral paralysis that may long outlast the headache. Other unusual clinical features have been unilateral massive brain swelling with recovery, putatively in some cases triggered by minor head injury.

Families have been described in which this condition is the result of a mutation in an ion channel (*familial hemiplegic migraine; alternating hemiplegia of childhood*). Of the known loci, which together account for more than half of cases, the most common one is in the gene coding for the P/Q-type calcium channel α subunit (*CACNA1A*). A second locus is in the gene for the Na^+/K^+-adenosine triphosphatase (ATPase) channel (*ATP1A2*) and a rarer subtype is caused by mutations in a sodium channel α-subunit gene (*SCNA1*). These, however, do not account for all cases, indicating that other mutations will inevitably be discovered. It is reasonable to surmise that many of the nonfamilial cases of hemiplegic migraine are also caused by these mutations.

By their nature, these channelopathies would be expected to have clinical and genetic overlap with other neurologic diseases. Indeed, there are shared traits between some of the genetic forms of familial hemiplegic migraine and both episodic and degenerative cerebellar diseases (Goadsby, 2007). A variety of other neurologic features have been found in these families, including persistent cerebellar ataxia and nystagmus in 20 percent; others had attacks of coma and hemiplegia from which they recovered (Ducros). Also notable because of genetic overlap are an acetazolamide-responsive ataxia that has in common other mutations in the *CACNA1A* gene, and the cerebrovascular disorder known as CADASIL, discussed in Chap. 33, which, in rare families, presents with hemiplegic migraine but instead is related to the *Notch3* gene on the same chromosome 19.

Complicating the situation is the undoubted existence of sporadic migraine with transient hemiplegia that has no familial trait (see further on under Transient Ischemic Attacks and Stroke with Migraine). Neurologic symptoms lasting more than an hour or so should prompt investigation for alternative causes, but none may be found. Instances of hemiplegic migraine may account for some of the inexplicable strokes in young women and older adults of both sexes, as also discussed further on. The treatment of these conditions is discussed in a later section.

Status Migrainosus

In some individuals, migraine attacks, for unaccountable reasons, may increase in frequency for several months. As many as three or four attacks may occur each week, leaving the scalp on one side continuously tender. When this occurs for more than half of the days in a month, the International Headache Society terms the condition *chronic* migraine.

An even more difficult clinical problem is posed by migraine that lapses into a debilitating condition of severe continuous headache (*status migrainosus*; defined by the Headache Society as lasting greater than 72 h). The pain is initially unilateral, later more generalized, more or less throbbing, but with a constant superimposed ache and is disabling; vomiting or nausea is common at the outset but abates. The absence of prior headaches should raise concern about a more serious cause. Status migrainosus sometimes follows a head injury or a viral infection, but most cases have no explanation.

Relief is often sought by increasing the intake of ergot or serotonin agonist preparations or even opioids, often to an alarming degree, but with only temporary relief, serving at times to perpetuate the condition. In the diagnosis of such persistent cases, the possibility should be considered that migraine has been complicated by this type of overuse of symptomatic medications with subsequent ("rebound") worsening of headache. This cycle may produce a transformation of previously intermittent migraine into a low-grade continuous headache with superimposed migrainous exacerbations. Narcotic and other analgesic dependence is a concern in these cases. In cases of status migrainosus, it is our practice to discontinue narcotic medications, and administer any of the following: intravenous hydration, metoclopramide, rapidly acting nonsteroidal anti-inflammatory drugs, magnesium, glucocorticoids, or dihydroergotamine intravenous infusion in selected patients (see further on for details of treatment). In all likelihood, the patient has already been treated unsuccessfully with several medications and furthermore, the widely used serotonin agonist ("triptan") medications are less likely to be helpful at this later stage of migraine.

Migraine-Like Headaches With CSF Pleocytosis

An intriguing problem arises in the patient with migraine who is found to have a slight lymphocytic pleocytosis in the spinal fluid (the CSF examination having been performed because of concern for meningitis or subarachnoid hemorrhage). Most of these cases in our experience have proved to be simply instances of aseptic meningitis, presumably viral, that have precipitated migraine in susceptible individuals. In others, a few cells are found in the spinal fluid during an attack of migraine without obvious explanation; probably a minor cellular reaction of 3 to 10 white blood cells (WBCs)/mL may be innocuous if there is no fever or meningismus.

A more extensive syndrome was described under the title "A migrainous syndrome with cerebrospinal

fluid pleocytosis." (Bartleson et al) A subsequent series (Berg and Williams) introduced the acronym *HaNDL* (headache with neurologic deficits and CSF lymphocytosis). An extensive report (Gomez-Aranda and colleagues) described 50 adolescents and young adults, predominantly males, who developed multiple widely separated episodes of transient neurologic deficits lasting hours, accompanied by migraine-like headaches, sometimes with slight fever but no stiff neck. One-quarter of this group had a history of past migraine and a similar number had a viral-like illness within 3 weeks of the neurologic problem. The CSF contained from 10 to 760 lymphocytes per cubic millimeter, and the total protein was elevated. The transient neurologic deficits were mainly sensorimotor, often involving the hand and lips, and aphasia; only six patients had visual symptoms. The patients were asymptomatic between attacks and in none did the entire illness persist beyond 7 weeks. We have observed several cases, all in otherwise healthy middle-aged men and we found corticosteroids to be helpful.

In these circumstances, it is important to exclude an immune reaction to nonsteroidal anti-inflammatory medications or to intravenous immunoglobulin, which are among the agents that cause otherwise unexplained aseptic meningitis and headache but generally not with migraine features.

The causation and pathophysiology of the HaNDL syndrome and its relation to migraine are uncertain but may relate to a hypothesized neurogenic inflammation basis of migraine discussed further on. The distinction between this syndrome and the recurrent aseptic meningitis of Mollaret and other chronic meningitic syndromes as well as cerebral vasospasm or vasculitis is difficult (see "Chronic Persistent and Recurrent Meningitis" in Chap. 32).

Migraine Following Head Injury

In addition to acute and chronic forms of generalized post-traumatic headache, cranial trauma of almost any degree may precipitate a migraine in persons prone to the condition. A particularly troublesome variant occurs in a child or adolescent who, after a trivial or mild head injury, may lose vision, suffer severe headache, vomit, or be plunged into a state of confusion, with belligerent behavior that lasts for hours or several days before clearing. The possible relationship of this syndrome to familial hemiplegic migraine and channelopathy has been mentioned earlier. In yet another variant, there is an abrupt onset of either one-sided paralysis or aphasia after virtually every minor head injury (we have seen this condition several times in college athletes) but without visual symptoms and little or no headache. Although a family history of migraine is frequent in such cases, there has been no history of hemiplegia in other family members. Of course, more treacherous conditions such as carotid artery dissection and subdural hematoma can simulate post-traumatic migraine, for which reason brain imaging is often undertaken in the circumstances.

Migraine in Young Children

This may present special difficulties in diagnosis, as a young child's capacity for accurate description is limited. Instead of complaining of headache, the child appears limp and pale and complains of abdominal pain; vomiting is more frequent than in the adult, and there may be slight fever. Recurrent attacks were referred to in the past by pediatricians as the *periodic syndrome* as discussed in an earlier section. Another variant in the child is episodic vertigo and staggering (paroxysmal disequilibrium) followed by headache, probably a type of basilar migraine (Watson and Steele). Also, there are puzzling patients with bouts of fever or transient disturbances in mood ("psychic equivalents") and abdominal pain (*abdominal migraine*), that had been attributed to migraine.

Infants and young children may have attacks of hemiplegia (without headache), first on one side then the other, every few weeks. Recovery is usually complete, and arteriography in one child seen by our colleagues, after more than 70 attacks, was normal. Alternating hemiplegia of childhood may terminate in a dystonic state. There is probably a relationship of this condition to familial hemiplegic migraine (see earlier). One advantage of considering such attacks as migrainous is that it may protect some patients from repeated diagnostic procedures and surgical intervention; but, by the same token, it may delay appropriate investigation and treatment.

Menstrual (Catamenial) Migraine and Other Headaches Linked to the Hormonal Cycle

The relation of headache to a drop in estradiol levels during the late luteal phase of ovulation was mentioned in section "Migraine." There it was also indicated that the mechanism is probably more complex. In practice, factors such as sleep deprivation are probably important in triggering perimenstrual headaches. Premenstrual headache, taking the form of migraine or a combined tension-migraine headache, usually responds to the administration of an NSAID begun 3 days before the anticipated onset of the menstrual period; oral sumatriptan (25 to 50 mg qid) and zolmitriptan (2.5 to 5 mg bid) are also equally effective. Manipulation of the hormonal cycle with danazol (a testosterone derivative) or estradiol has also been effective but is rarely necessary.

The management of migraine during pregnancy poses special problems because one wishes to restrict the exposure of the fetus to medications. Beta-adrenergic compounds and tricyclic antidepressants may be used safely in the small proportion of women whose headaches persist or intensify during pregnancy. From a limited registry of patients who were given sumatriptan during pregnancy, and from several small trials summarized by Fox and colleagues, no teratogenic effects or adverse effects on pregnancy arose, but serotonin agonist drugs should be used advisedly until their safety is further confirmed. Ergots (DHE) are obviously interdicted because of their capacity to precipitate uterine contractions or labor. For those women who use antiepileptic drugs as a means of headache prevention, it is recommended that the drugs be stopped prior to pregnancy or as soon as it is known that pregnancy has begun.

In the special circumstance of true and debilitating status migrainosus during pregnancy, infusions of magnesium and metoclopramide (in doses previously mentioned in this chapter) are often used but repeated administration and monitoring of blood pressure and tendon reflexes may

be needed. This should probably precede resorting to opioids, which may nevertheless become necessary in some cases. In all instances of headache in late pregnancy, the possibilities of toxemia and cerebral venous thrombosis should be considered.

Migraine in Pregnancy

There are many causes of headache during pregnancy, as discussed further on, but among the most frequent and important is migraine. Also, migraine may make its first appearance during pregnancy, particularly in the first trimester. During pregnancy, migraines in most women tend to abate, although there are notable exceptions, especially in the third trimester. It is not unusual to hear reports of auras dissociated from headache during pregnancy but a marked change of headache pattern during pregnancy should lead to consideration of alternative diagnoses such as toxemia or cerebral venous sinus thrombosis. The causes of headache have been described in a single-center study of pregnant women (Robbins and colleagues) as detailed further on, who emphasize that migraine remains the most common, followed by hypertensive disorders. The treatment of migraine during pregnancy presents special issues that are discussed further on.

Transient Ischemic Attacks and Stroke With Migraine (See Also Chap. 33.)

Migraine complicated by stroke Rarely, migrainous neurologic symptoms, instead of being transitory, leave a prolonged or even permanent deficit (e.g., homonymous hemianopia), indicative of an ischemic stroke. A small number of these are attributed to *migrainous infarction* rather than being attributable to conventional mechanisms of stroke. Platelet aggregation, edema of the arterial wall, increased coagulability, dehydration from vomiting, and intense, prolonged spasms of vessels have all been implicated (on rather uncertain grounds) in the pathogenesis of arterial occlusion and strokes that complicate migraine (Rascol et al).

Furthermore, attacks of migraine, particularly with prominent neurologic symptoms that simulate TIA, instead of beginning in childhood, may have their onset later in life, and Fisher provided support for the hypothesis that some of the transient aphasic, hemianesthetic, or hemiplegic attacks of later life may be of migrainous origin ("late-life migraine accompaniments"). With careful questioning, many of these patients with TIA syndromes will recall a history of migraine headaches in youth.

The reported incidence of stroke complicating migraine has varied. At the Mayo Clinic, in a group of 4,874 patients, aged 50 years or younger with a diagnosis of migraine, migraine equivalent, or vascular headache, 20 patients had migraine-associated infarctions (Broderick and Swanson). Caplan described seven patients in whom attacks of migraine were complicated by strokes in the vertebrobasilar territory. A study by Wolf and colleagues collected 17 instances of stroke and migraine. Most had a prolonged aura, either visual, sensory, or aphasic and over two-thirds of the strokes, demonstrated by diffusion restriction on MRI, were in the posterior circulation territory and occurred in younger women. There is a paucity of useful pathology by which to interpret the mechanism of migraine-associated stroke. The uncertain but potential role of antimigraine medications in producing stroke by causing vasospasm or a vasculopathy is discussed further on in the section on treatment. Estrogen medications have also been implicated in stroke in some women migraineurs. The complex relationship between acute stroke and the use of triptans or ergots for the treatment of migraine is addressed in a later section.

In children and young adults with the mitochondrial disease MELAS (mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes) and in adults with the rare cerebral vasculopathy CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy), migraine may be a prominent feature. Chapter 33 addresses these issues further.

The special problem of focal cerebral disorders associated with segmental or diffuse vasospasm, including the form that follows treatment with the "triptan" (serotonin agonist) drugs and Call-Fleming syndrome, is discussed further on in the section on treatment and under "Diffuse and Focal Cerebral Vasospasm" in Chap. 33.

Epidemiologic association between migraine and stroke A separate set of observations, mainly epidemiologic, pertain to the risk of strokes, particularly in women with migraine. Despite variability in conclusions between studies, meta-analyses have suggested that there is an up to two-fold increase in lifetime incidence of ischemic stroke in individuals with migraine and aura (Spector et al). The risk may increase with increasing migraine attack frequency and particularly with oral contraceptive use and smoking, which together may confer a nine-fold increase in stroke risk. For example, in the Northern Manhattan Study (Monteith and colleagues), migraine was associated with future stroke but only in smokers. There may be a similar increase in cardiovascular events later in life but the evidence for this is uncertain and difficult to disengage from confounding risk factors. A meta-analysis of case control and cohort studies conducted by Schüks and colleagues were unable to demonstrate an increased risk for cardiovascular events. Other investigators, again depending on various population databases and few patient-level studies, have come to the opposite conclusion (Bigal et al) and have suggested that all-cause mortality is increased in migraine patients (Gudmundsson et al). There are also emerging but tentative connections between genetic variants and shared risks for stroke and migraine.

The issue of oral contraceptives as a risk for stroke in migraineurs is a matter that has not been entirely resolved except that the risk of stroke with these agents may be greater in women who have migraine with aura. Oral contraception is not interdicted in migraineurs but some guidelines suggest against their use of oral contraceptives if there is migraine with aura. Perhaps lower estrogen compounds are advisable in migraine without aura as formulations with high estrogen concentrations have been associated with clotting in the venous circulation.

Finally, there has long been implication of an association between migraine and patent foramen ovale, especially associated with migraine with aura. A few physicians in the past favored a causal role and advocated closure of

the foramen in an attempt to alleviate migraine but several trials have failed to sustain this concept. However, large cross-sectional (Rundek et al) and case-control (Garg et al) studies have not affirmed these associations and the issue, while still under discussion, has been of waning interest.

Imaging changes in migraine There are cerebral imaging changes in migraineurs that are suggestive of small ischemic lesions. A number of cross-sectional population studies, (Kurth and colleagues, Scher et al, and Kruit and coworkers 2004, 2010), have indicated that MRI changes in both the deep and subcortical white matter are more frequent in women migraine patients who experienced auras than in those without auras and in the general population. A high frequency of migraine headaches is also associated in some studies with an increased number of white matter lesions including, according to some observers, lesions in the cerebellar white matter.

The implications of these frequently encountered small white matter lesions in migraineurs that are familiar to neurologists are unclear. The findings are often cause for neurologic consultation, sometimes with the question of multiple sclerosis. Several studies indicate that migraineurs with these changes have no greater cognitive decline over time than those in the general population. In discussion with patients, we tend to underemphasize these lesions and the risk of stroke but point out the importance of the usual stroke risk factors: smoking, hypertension, hyperlipidemia, and cardiac rhythm abnormalities.

Pathogenesis of Migraine

It has not been possible to determine from the many clinical observations and investigations, a unifying theory the cause of migraine with certainty. Clearly, an underlying genetic factor is implicated, as noted earlier, although it is expressed mainly as a polygenic risk. How this genetic predisposition is translated periodically into a regional neurologic deficit, unilateral headache, or both is unknown. For many years, our thinking about the pathogenesis of migraine was dominated by the views of Harold Wolff and others—that the headache was caused by the distention and excessive pulsation of branches of the external carotid artery. Certainly, the throbbing, pulsating quality of the headache and its relief by compression of the common carotid artery supported this view, as did the early observation of Graham and Wolff that the headache and amplitude of pulsation of the extracranial arteries diminished after the intravenous administration of ergotamine.

The potential importance of vascular factors continues to be emphasized by some recent findings, but not in the way envisaged by Wolff. For example, in a group of 11 patients with classic migraine, (Olsen and colleagues) using the xenon inhalation method, noted a regional reduction in cerebral circulation spreading forward from the occipital region during the period when neurologic symptoms appear. They concluded that the reduction in blood flow was consistent with the cortical spreading depression syndrome described below. In a subsequent study, Woods and colleagues described a patient who, during positron emission tomography (PET), fortuitously had an attack of common migraine with blurred vision. Sophisticated measurements showed a reduction in blood flow that started in the occipital cortex and spread slowly forward on both sides, in a manner much like spreading cortical depression (see below), and perfusion-weighted MRI has corroborated the finding of diminished occipital cerebral blood flow during the aura (Cutrer and colleagues 1998). However, a study using single-photon emission computed tomography (SPECT) in 20 patients during and after attacks of migraine without aura disclosed no focal changes of cerebral blood flow; also, no changes occurred after treatment of the attacks with 6 mg of subcutaneous sumatriptan (Ferrari et al, 1995).

In reference to the extracranial vessels, Iversen and associates, by means of ultrasonography, documented a dilatation of the superior temporal artery on the side of the migraine during the headache period. The same dilatation in the middle cerebral arteries has been inferred from observations with transcranial Doppler insonation. The complication of cerebral infarction with migraine is also in keeping with a vascular hypothesis, but it involves only a tiny proportion of migraineurs. The vascular hypothesis for migraine must be regarded as uncertain but clearly, there is frequently a reduction in posterior cortical blood flow during an aura. What is not established is whether the blood flow changes are fundamental or simply the result of a reduction in cortical activity. The original opinion expressed by Wolff that a vascular element is responsible for the cranial pain of migraine is also unconfirmed.

The relationship between the vascular changes and evolving neurologic symptoms of migraine are noteworthy. Lashley, who as noted earlier plotted his own visual aura, calculated that the cortical impairment progressed at a rate of 2 to 3 mm/min over the surface of the brain. The site of activity putatively begins in one occipital lobe and extends forward slowly (2.2 mm/min) as a wave of "spreading oligemia" that does not respect arterial boundaries (Lauritzen and Olesen). Both of these events are intriguingly similar to the above-mentioned phenomenon of "spreading cortical depression," observed by Leão in experimental animals. He demonstrated that a noxious stimulus applied to the rat cortex was followed by vasoconstriction and slowly spreading waves of inhibition of the electrical activity of cortical neurons, moving at a rate of approximately 3 mm/min. Lauritzen and Olesen attribute both the aura and spreading oligemia to the *spreading depression*, and considerable work since then has corroborated this idea. These observations, however, apply only to the aura.

These vascular mechanisms and origin of aura with spreading depression aside, two competing views of migraine headache pathogenesis have emerged. One hypothesis links both the aura and the painful phase of migraine to a peripheral neural mechanism originating in the trigeminal nerve, termed the trigeminovascular complex, as proposed by Moskowitz. This has been subsumed under the category of a peripheral mechanism of migraine and is based on the innervation of extracranial and intracranial vessels by small unmyelinated fibers of the trigeminal nerve that subserve both pain and autonomic functions. This model is widely accepted and provides an explanation for migraine pain as originating in

the trigeminal ganglion. Activation of these fibers releases substance P, calcitonin gene-related peptide (CGRP), and other peptides into the vessel wall, which serves to sensitize the trigeminal system to the pulsatility of cranial vessels, and to increase their permeability, thereby promoting an inflammatory response. The small molecules released from nerve endings adjacent to the cortex would then incite spreading depression in this model. The effects of recently developed treatments that target these molecules support the trigeminovascular hypothesis. Perhaps somewhat against this hypothesis is the occurrence of headache as often as not on the side opposite the side of generation of the aura.

A second view, not as well established, might be called the "central hypothesis" of migraine. It is largely based on neuroimaging findings and relates migraine to brainstem and diencephalic dysfunction that indirectly affects pain-sensitive pathways, perhaps by sensitizing them ("central sensitization"). Supportive data has been mainly in the form of activation of the hypothalamus during aura and activation of brainstem structures during the headache. The recurrent nature of migraine has been attributed to periodic activation of hypothalamic structures. In some models this mechanism begins with cortical spreading depression and subsequently activates hypothalamic and rostral brainstem structures involved in pain generation. Both the peripheral and central hypotheses can accommodate the aforementioned vascular changes but consider these secondary or downstream effects. Moreover, both implicate various signaling molecules but the trigeminovascular model is more prominent at the moment.

Finally, the involvement of the delta opioid receptor (as opposed to the canonical mu-receptor) has been shown in experimental models to trigger many phenomena associated with migraine and antagonists of this receptor mute the effects. Whether this is a primary process in migraine or acts indirectly through CGRP receptors, is even more speculative.

In part to address the action of the serotonin agonist drugs on migraine (see below), a body of evidence has been assembled that serotonin (5-HT) acts as a humoral mediator in the neural and vascular components of migraine headache. Serotonin is discharged from platelets at the onset of headache and the headache is reduced by the injection of 5-HT. This led to the development by Humphrey of sumatriptan, which acted selectively on 5-HT1B/D receptors to reduce side effects. This was the forerunner of the large group of "triptans." More recently, nitric oxide generated by endothelial cells has been implicated as the cause of the pain of migraine headache, but the reason for its release and the relationship to changes in blood flow is unclear.

The opinion has been expressed that the presence or absence of headache does not depend solely on extracranial vascular factors (Blau and Dexter and Drummond). These authors point to their findings that occlusion of blood flow through the scalp or common carotid circulation fails to alleviate the pain of migraine in one-third to one-half of the patients. Others have suggested that the trigeminal pathways are in a state of persistent hyperexcitability in the migraine patient and that they discharge periodically, perhaps in response to hypothalamic stimulus acting on the endogenous pain control pathways (Lance and Goadsby). This is in keeping with current theories regarding the trigeminovascular complex discussed earlier, as well as with evolving ideas on central sensitization to pain because of repeated noxious stimulation from one body region that may produce a type of centrally mediated allodynia. The role of alternative factors in migraine has been reviewed in the monograph by Lance and Goadsby.

The foregoing observations leave many questions unanswered. Is one to conclude that migraine with and without aura are different diseases, involving mainly extracranial arteries in one instance and intracranial ones in another? Is the circulatory change the primary cause of headache, or is it a secondary or coincidental phenomenon? Is diminished neuronal activity (spreading depression) the primary cause of neurologic symptoms (it seems so, at least for scintillations and subsequent scotomas) and headache (unclear), and is the diminished regional blood flow secondary to reduced metabolic demand? Why are the posterior portions of the brain (visual auras) so often implicated (perhaps because of richer trigeminal innervation of the posterior vessels)? The neural mechanisms that underlie these changes and precisely what is altered by the genetic predisposition to migraine are unresolved. No final reconciliation of all these data is possible and migraine remains incompletely explained.

Diagnosis

Migraine with aura should occasion no difficulty in diagnosis if a proper history is obtained. Most often, the symptoms begin as "positive," that is, scintillation, paresthesia, as opposed to the later "negative" scotoma, numbness, aphasia, or paresis. The difficulties come from a lack of awareness that a progressively unfolding neurologic syndrome may be migrainous in origin and may occur without headache. Furthermore, recurrent migraine headaches take many forms, some of which may prove difficult to distinguish from the other common types of headache, and it should be recognized that migraine headaches need not be severe or disabling. Some of these problems merit elaboration because of their practical importance.

The neurologic part of the migraine syndrome may resemble a transient ischemic attack, focal epilepsy, the clinical effects of a slowly evolving hemorrhage from an AVM, or a thrombotic or embolic stroke. It is the pace of the neurologic symptoms of migraine that distinguish it from epilepsy and most cases of stroke. Furthermore, the positive rather than negative nature of the symptoms assists in distinguishing it from the usual stroke syndromes.

Recurrent painful ophthalmoplegic cranial neuropathy (formerly ophthalmoplegic migraine, mentioned earlier) may suggest a carotid-cavernous or supraclinoid aneurysm. Transient monocular blindness from carotid stenosis is infrequent in the age group affected most by migraine, but the antiphospholipid syndrome, which has some ill-defined relationship to migraine, does cause episodic unilateral visual loss in this group and should be sought as the explanation for transient monocular blindness with or without headache.

One accepts that the headache of migraine may be almost exclusively on one side of the head but the invariant occurrence of migraine-like headache on the same side of the head increases the likelihood of an underlying AVM or other structural lesion. R.D. Adams, who studied more than 1,200 patients with AVM found that the headaches, which occurred in more than 30 percent of these individuals, usually did not include the other features of either migraine or cluster headache. However, in about 5 percent, the headaches were associated with visual aura, making them indistinguishable from migraine with aura. In most, the AVM was in the occipital region and on the side of the headache. Approximately half of the patients with AVM and migraine had a family history of migraine. It is unclear to us if AVM can be regarded as an acknowledged cause of recurrent migraine-like headache but headaches or visual phenomena that are invariably on one side over a long period raises the possibility of a structural lesion such as AVM. It is, of course, possible that given the ubiquity of migraine in the population, the association is coincidental.

Treatment of Migraine

This topic may be divided into two parts—control of the individual acute attack, and prevention that includes both the use of medications and of lifestyle modifications. The time to initiate treatment of an acute attack is during the neurologic (visual) prodrome or at the very onset of the headache (see below). If the headaches are mild, the patient may already have learned that aspirin, acetaminophen, or another nonsteroidal anti-inflammatory drug (NSAID) will suffice to control the pain and these are considered first-line therapy. Insofar as a good response may be obtained from one type of NSAID and not another, it may be advisable to try two or three preparations in several successive attacks of headache and to use moderately high doses if necessary. This class of medications, however, has the potential for inducing "medication overuse headache" in a cycle of relief followed by worsened headache, followed by relief, and so on. Numerous other medications have proved effective and each has had a period of popularity among neurologists and patients including medications that contain butabarbital, which have the potential for dependence, and the general approach has been to avoid this medication and others that combine agents.

For severe attacks of migraine headache, one of the serotonin agonist "triptans," or the ergot alkaloids, ergotamine tartrate, and particularly dihydroergotamine (DHE), are effective forms of treatment and are best administered early in the attack, ideally just after a visual aura or just at the onset of headache. Patients with waning visual auras have been advised to wait to self-administer subcutaneous serotonin agonists until the headache begins. Clinical experience and the study by Bates and colleagues suggest that the subcutaneous triptans are ineffective in preventing headache if given during the aura; they are however, probably safe during this period (see further on). In contrast, the slightly slower-acting nasal spray or the even slower-acting oral formulations are often ineffective if given too long after the start of headache. Patients have therefore learned to administer the nasal and oral preparations during the aura and the subcutaneous drugs as close to the onset of headache as possible.

A single of triptan, given subcutaneously, is an effective and well-tolerated treatment for migraine attacks (see Subcutaneous Sumatriptan Study cited in the references). When successful, it eliminates or reduces the accompanying symptoms of nausea, vomiting, photophobia, and phonophobia. An advantage of the serotonin agonist drugs, aside from their relative safety, is the ease of self-administration using prepackaged injection kits, thus avoiding frequent and inconvenient visits to the emergency department. Sumatriptan can also be given orally in a 25-, 50-, or 100-mg tablet and as a nasal spray (20 mg per spray), zolmitriptan in a 2.5- or 5-mg tablet or 5-mg nasal spray, and rizatriptan in a 5- or 10-mg dose tablet, repeated, if needed, in 2 h. For oral preparations, latency for headache relief is longer than with subcutaneous injection or inhalation. As with the oral non-steroidal anti-inflammatory agents, if one serotonin agonist is found to be ineffective, another drug or an alternative route of administration, such as intranasal, may be tried. These medications are summarized in Table 9-2.

An often cited meta-analysis of the available drugs in 53 separate trials (Ferrari and colleagues 2001) found modest differences in overall efficacy between drugs. Loder has given a tabulated comparison of the main drugs for migraine and a review of their use in routine situations.

Ergotamine is probably an equally effective agent, but its peripheral and coronary vasoconstricting side effects and risks, including nausea, have greatly reduced its use. This is an alpha-adrenergic agonist with strong serotonin receptor affinity and vasoconstrictive action. The drug is taken as an uncoated 1 to 2-mg tablet of ergotamine tartrate, held under the tongue until dissolved (or swallowed), or in combination with caffeine. Repeat use is not advisable as it may lead to prolonged or daily headache. A single oral dose of promethazine 50 mg, or of metoclopramide 20 mg, given with the ergotamine, allays the potential nausea and vomiting from ergotamine and may have independent effects on reducing the severity of headache. Patients in whom vomiting prevents oral administration may be given ergotamine by rectal suppository or DHE by nasal spray or inhaler (one puff at onset and another at 30 min)

Table 9-2

TRIPTANS FOR ORAL USE

TRIPTANS	TABLET SIZES, mg	OPTIMUM DOSES, mg	MAXIMUM SINGLE DOSES, mg	MAXIMUM DAILY DOSES, mg
Almotriptan	6.25 and 12.5	12.5	12.5	25
Eletriptan	20 and 40	20	40	80
Frovatriptan	2.5	2.5	2.5	7.5
Naratriptan	1 and 2.5	2.5	2.5	5
Rizatriptan	5 and 10	10	10	30
Zolmitriptan	2.5 and 5	2.5	5	10
Sumatriptan*	25, 50, and 100	50	100	200

*Also available as 20 mg nasal spray and 6 mg subcutaneous injection.

or can learn to give themselves a subcutaneous injection of DHE (usual dosage, 1 mg). Caffeine, 100 mg, is thought, on slim evidence, to potentiate the effects of ergotamine and other medications for migraine. When ergotamine is administered early in the attack, the headache will be abolished or reduced in severity and duration in 70 to 75 percent of patients.

An important problem pertains to the risk of stroke from serotonin agonists in patients with prolonged visual aura or other focal neurologic symptoms associated with the headache. What evidence exists suggests the risk of stroke is low or nonexistent as, for example, in an epidemiologic study (Hall and colleagues). As a matter of course, however, serotonin agonists and ergots are generally avoided if there is an ongoing and prolonged aura of any type, including visual, but particularly with hemiparesis, aphasia, or features such as vertigo, drowsiness, or diplopia, referable to the basilar artery. Not all experts agree with this proscription and some small series, among them 13 patients (Klapper and colleagues), have found triptans safe to use if a headache with neurologic signs has commenced, but this issue has not been resolved. As previously noted, although this class of drugs may not be helpful during the visual aura, they also seem to do no harm (Bates et al).

Rare cases of severe but reversible cerebral vasospasm have been reported after the use of ergotamine or a serotonin agonist drug, but most of these patients in fact had not had neurologic features as part of their initial headache syndrome. Of particular danger, however, is the often unnoticed, concurrent use of other sympathomimetic drugs such as phenylpropanolamine (Singhal and colleagues and by Meschia and associates) (see discussion of Call-Fleming syndrome, "Diffuse Vasoconstriction," "Diffuse and Focal Cerebral Vasospasm" in Chap. 33). Cerebral hemorrhage is another rare complication of serotonin agonist use that possibly relates to hypertension induced by triptans or ergots. Ergot drugs and triptans are contraindicated in symptomatic and asymptomatic coronary artery disease and poorly controlled hypertension.

For severely ill patients who arrive in the emergency department or physician's office, having failed to obtain relief from a prolonged headache with the above medications, metoclopramide 10 mg IV, followed by DHE 0.5 to 1 mg IV every 8 h for 2 days, may be effective (Raskin 1986). We also use this approach as well as intravenous magnesium infusions, starting with 1 g, in cases of status migrainosus. The administration of intravenous DHE can be combined with a lidocaine infusion; this combination having not been exposed to a rigorous clinical trial. The potential success of metoclopramide alone should not be dismissed, as we and others have occasionally found that the headache abates after this initial injection. A wide array of other drugs including almost all of the conventional nonsteroidal anti-inflammatory medications has been recommended as adjunctive therapy, for example, prochlorperazine, ketorolac, and intranasal lidocaine. Each of these drugs, given alone, is effective in alleviating the headache in about half of patients, emphasizing the need for blinded placebo-controlled trials for any drug that is introduced for the treatment of headache.

Intravenous and oral corticosteroids have been found anecdotally to be useful in refractory cases and as a means of terminating migraine status. A randomized trial of intravenous dexamethasone 10 mg in an emergency department setting (Friedman et al) found no benefit. As an alternative to steroids and more commonly used nonsteroidal agents, Weatherall and colleagues used intravenous aspirin (lysine acetylsalicylate, 1 g, repeated up to five times) with reasonably good effect in inpatient management of migraine and other headache disorders. We have determined that this agent is difficult to obtain from our hospital pharmacies.

Based on the action of peptides in the trigeminovascular complex, novel antagonists of CGRP receptor have been investigated for migraine. These small molecule drugs, called "-gepants", and 5-HT 1F antagonists called "ditans," are superior to placebo in aborting attacks but have a relatively low rate of success compared to other drugs in the sense that approximately 20 percent of patients have relief of headache several hours after treatment and a higher proportion have relief from bothersome symptoms such as nausea. Their use may be limited to individuals who cannot tolerate or have no response to nonsteroidal agents and triptans but this is an emerging field. [Lipton NEJM, 2019; Dodick NEJM 2019].

Preventive Treatment

In individuals with frequent migrainous attacks, efforts at prevention are worthwhile. A survey by Lipton and colleagues, found approximately one-fourth of patients were appropriate for some form of prophylactic treatment on the basis of the frequency and severity of their headaches, usually more than one severe episode per week. The most used agents have been beta-adrenergic blockers, antiepileptic drugs, and tricyclic antidepressants. Often, comorbidities such as depression, hypertension, epilepsy, or coronary artery disease guide the choice among these three classes of drugs. Some headache specialists have expressed the opinion that amitriptyline may be more effective if headaches are very frequent and that propranolol is more effective if severity of headaches is the concern. Ziegler and colleagues found propranolol and amitriptyline to be equally effective as preventive measures.

Some success has been obtained with propranolol, beginning with 10 to 20 mg two to three times daily and increasing the dosage gradually to as much as 240 mg daily, probably best given as a long-acting preparation in the higher dosage ranges. Under-dosing is a major reason for ineffectiveness. If propranolol is unsuccessful or not tolerated, one of the other beta-blockers, specifically those that lack agonist properties—atenolol (40–160 mg/d), timolol (20–40 mg/d), or metoprolol (100–200 mg/d)—may be effective. Many practitioners have found that particularly young patients do not tolerate the fatigue and other side effects of these medications.

Alternatives, depending on other comorbidities, are an antiepileptic medication, or our preference, a tricyclic antidepressant. Valproic acid 250 mg taken three to four times daily (avoided in pregnant women), other antiepileptic drugs, or amitriptyline, 25 to 125 mg nightly may be tried. The newer antidepressants (e.g., specific

serotonin reuptake inhibitors) seem not to be as effective and may even cause headache in our experience. If these three main approaches are unsuccessful, calcium channel blockers (e.g., verapamil, 320 to 480 mg/d; nifedipine, 90 to 360 mg/d) are also reportedly effective in decreasing the frequency and severity of migraine attacks in some patients, but there is typically a lag of several days or weeks before benefit is attained and our success with them has been limited. Indomethacin, 150 to 200 mg/d; and cyproheptadine, 4 to 16 mg/nightly are found to be helpful in some patients and may be particularly useful in preventing predictable attacks of perimenstrual migraine.

To these preventive medications, which have been used for decades, a class of monoclonal antibodies targeting CGRP or its receptor, agents mentioned above for acute treatment, have also demonstrated effectiveness in reducing migraine attacks. A reduction by approximately an average of 3 to 4 headache days per month has been shown, compared to approximately 2 days for placebo (Goadsby, 2019; Silberstein, 2017). At this time, evidence is being accumulated to determine their place in preventive treatment.

Another putative treatment for chronic or frequently repeating headaches, both migraine and tension, is the injection of botulinum toxin (Botox) into sensitive temporalis and other cranial muscles. Elimination of headaches for 2 to 4 months has been reported—a claim that justifies further study. Similarly, injection blockade of one or both greater occipital nerves or upper cervical roots has reportedly been helpful. Surgical decompression of sensory nerves in the scalp and related techniques have also been advocated but without documentation.

Some patients report that certain items of food induce attacks (chocolate, peanuts, hot dogs, smoked meats, oranges, and red wine are the ones most commonly mentioned), and it is obvious enough that they should avoid these foods if possible. Limiting caffeinated beverages may be helpful. In certain cases, the correction of a refractive error, an elimination diet, or behavioral modification is said to have reduced the frequency and severity of migraine and of tension headaches. However, the methods of study and the results have been so poorly controlled that it is difficult to evaluate them. All experienced physicians appreciate the importance of helping patients rearrange their schedules with a view to controlling tensions and hard-driving lifestyles. There is no single program to accomplish this. The claims for sustained improvement of migraine with chiropractic manipulation are unsubstantiated and do not accord with our experience. Meditation, acupuncture, and biofeedback, craniosacral therapy, and similar approaches all have their advocates, some supported by trials but again, the results, while not to be entirely discounted, are difficult to interpret.

Indomethacin Responsive Headaches

This is a group of relatively uncommon syndromes that were mentioned earlier and have the special characteristic that they respond well and perhaps specifically to indomethacin both acutely and as prophylaxis, so much so that some authors have defined a category of *indomethacin-responsive headaches*. These include orgasmic migraine, chronic paroxysmal hemicrania (see further on), hemicrania continua, exertional headache, hypnic headache, brief head pains (jabs and jolts and "icepick" headaches), and some instances of premenstrual migraine, (which respond to many nonsteroidal anti-inflammatory agents). These are summarized in Table 9-3 and discussed further on.

Table 9-3

INDOMETHACIN RESPONSIVE HEADACHES

Valsalva related headaches
Headache associated with sexual activity*
Exertional (exercise induced, weight lifters) headache*
Cough headache
Trigeminal-autonomic cephalgias
Chronic paroxysmal hemicrania
Episodic paroxysmal hemicrania
Hemicrania continua*
Stabbing headaches
"Jabs and jolts"
Idiopathic stabbing (ice pick) headache

*These headache syndromes may improve with drugs other than Indomethacin

Cluster Headache

This type of headache has been described in the past under a variety of names, including *paroxysmal nocturnal cephalalgia*, *migrainous neuralgia*, *histamine cephalalgia* (Horton's headache), and others. Kunkle and colleagues, who were impressed with the characteristic temporal "cluster pattern" of the attacks, coined the term in current use—*cluster headache*. This headache pattern occurs predominantly in adult men (age range: 20 to 50 years; male-to-female ratio approximately 5:1) and is characterized by a severe consistent unilateral orbital localization. The pain is felt deep in and around the eye, is very intense and nonthrobbing as a rule, and often radiates into the forehead, temple, and cheek—less often to the ear, occiput, and neck. Its denominative feature is the nightly recurrence, between 1 and 2 h after the onset of sleep, or several times during the night for several or more consecutive days; thus "cluster." Less often, it occurs during the day or early evening, unattended by aura or vomiting. The headache has been called the "alarm clock headache" because it may recur with remarkable regularity each night for periods extending as long as many weeks, followed thereafter by complete freedom for many months or even years. However, in approximately 10 percent of patients, the headache becomes chronic, persisting over days, months, or even years.

There are several associated vasomotor phenomena by which cluster headache can be identified: a blocked nostril, rhinorrhea, injected conjunctivum, lacrimation, miosis, and a flush and edema of the cheek, all lasting on average for 45 min (range: 15 to 180 min). Some of our patients, when alerted to the sign, also report slight ptosis on the side of the orbital pain; in a few, the ptosis has become permanent after repeated attacks. The ipsilateral temporal artery may become prominent and tender during an attack, and the skin over the scalp and face may be hyperalgesic.

Most patients arise from bed during an attack and sit in a chair and rock or pace the floor, holding a hand to the

side of the head. The pain of an attack may leave as rapidly as it began or may fade away gradually. Almost always the same side is involved during a cluster of headaches as well as in recurring bouts. During the period of freedom from pain, alcohol, which commonly precipitates headaches no longer has the capacity to do so. The picture of cluster headache, including the patient's nocturnal behavior in response to it, is usually so characteristic that it cannot be confused with any other disease, although those unfamiliar with it may entertain a diagnosis of migraine, trigeminal neuralgia, carotid aneurysm, or temporal arteritis. Treatment is discussed further on.

Trigeminal Autonomic Cephalgias (Cluster Variants)

Cases of paroxysmal pain behind the eye or nose or in the upper jaw or temple—associated with blocking of the nostril or lacrimation and described in the past under the titles of *sphenopalatine* (referred to as Sluder's sphenopalatine neuralgia), *petrosal*, *vidian*, and *ciliary neuralgia*—probably represent variants of cluster headache. A similar head pain may occasionally be confined to the lower facial, postauricular, or occipital areas. Yet another variant, "lower cluster headache" syndrome, is distinguished by infraorbital radiation of the pain, an ipsilateral partial Horner syndrome, and ipsilateral hyperhidrosis. There is no evidence to support the separation of these neuralgias as distinct entities, and they have collectively been called *trigeminal autonomic cephalgias*. They are important, however, because of the frequency of underlying intracranial lesions. In other words, these are not always primary headache disorders. Favier and colleagues collected 4 of their own cases and 27 from the literature to emphasize the range of underlying diseases, including intracranial aneurysms, peritentorial or parasellar meningiomas, or other tumors and nasopharyngeal cancers surrounding the carotid artery. We have encountered a case of Wegener granulomatosis of the soft palate that presented as a paroxysmal trigeminal autonomic neuralgia. The headache syndrome disappeared with cyclophosphamide treatment of the underlying granulomatous disorder.

Chronic paroxysmal hemicrania was the name given by Sjaastad and Dale to a primary headache consisting of rapidly repetitive unilateral form of headache that resembles cluster headache in many respects but has several distinctive features. These are of much shorter duration (2 to 45 min) than cluster and usually affect the temporoorbital region of one side, accompanied by conjunctival hyperemia, rhinorrhea, and in some cases a partial Horner syndrome. Even periorbital ecchymosis may accompany a severe attack. Unlike cluster headache, however, the paroxysms occur many times each day, recur daily for long periods (the patient described by Price and Posner had an average of 16 attacks daily for more than 40 years), and, most important, respond dramatically to the administration of indomethacin, 25 to 50 mg tid. Unlike cluster headache, chronic paroxysmal hemicrania is more common in women than in men (ratio of 3:1).

The acronym SUNCT (short-lasting unilateral neuralgiform attacks with conjunctival injection and tearing), another primary headache, has been applied to an episodic condition with attacks of even briefer duration, but otherwise similar to paroxysmal hemicrania in which the supraorbital or temporal pain lasts up to 4 min or so and is frequent; it does not usually respond to indomethacin.

A similar hemicrania but without autonomic features, may be symptomatic of lesions near the cavernous sinus (mainly pituitary adenoma) or in the posterior fossa, but most cases are idiopathic. The typical episode of pain lasts approximately 20 min. Also known is a recurrent nocturnal headache in elderly individuals ("hypnic headache"), as described further on.

The relationship of cluster headache and its variants to migraine remains conjectural. No doubt the headaches in some persons have some of the characteristics of both, hence the terms *migrainous neuralgia* and *cluster migraine* (Kudrow). Lance and others, however, have pointed out differences that seem important to us: flushing of the face on the side of a cluster headache and pallor in migraine; increased intraocular pressure in cluster headache, normal pressure in migraine; increased skin temperature over the forehead, temple, and cheek in cluster headache, decreased temperature in migraine; and notable distinctions in sex distribution, age of onset, rhythmicity, and other clinical features, but prominently by differences among them in response to specific treatments. Cluster may be triggered in sensitive patients by the use of nitroglycerin and as mentioned, by alcohol.

The cause and mechanism of cluster headache syndrome are unknown. Gardner and coworkers originally postulated a paroxysmal parasympathetic discharge mediated through the greater superficial petrosal nerve and sphenopalatine ganglion. These authors obtained inconsistent results by cutting the nerve, but others (Kittrelle et al) reported that application of cocaine or lidocaine to the region of the sphenopalatine fossa (via the nostril) consistently aborts attacks of cluster headache. Capsaicin, applied over the affected region of the forehead and scalp, may have the same effect. Stimulation of the ganglion is said to reproduce the syndrome. Kunkle, on the basis of a large personal experience, concluded that the pain arises from the internal carotid artery, in the canal through which it ascends in the petrous portion of the temporal bone. In the course of an arteriogram, during which a patient with cluster headaches fortuitously developed an attack, others have noted a narrowing of the artery that was interpreted as being caused by swelling of the arterial wall, which, in turn, compromised the pericarotid sympathetic plexus and caused the Horner syndrome. (Ekbom and Greitz) This remains to be confirmed.

The cyclic nature of the attacks has been linked to a hypothalamic mechanism that governs the circadian rhythm. At the onset of the headache, the region of the suprachiasmatic nucleus appears to be active on PET (May et al). Hypothalamic activation has also been found in migraine, SUNCT, chronic paroxysmal hemicrania, and hemicrania continua. Moreover, stimulation of the hypothalamus has proved effective, although highly experimental, in stopping chronic cluster headache and SUNCT (Leone et al; Bartsch et al).

Much was made in the past of the fact that cluster headaches could be reproduced by the intravenous injection of 0.1 mg histamine, but the effect was probably nonspecific.

Goadsby (2002) has reviewed the pathophysiology of the cluster headache syndrome.

Treatment of Cluster Headache

Inhalation of 100 percent oxygen via mask for 10 to 15 min at the onset of cluster headache may abort the attack, but this is not always practical. Termination of a cycle of cluster can also be achieved with verapamil, starting with 80 mg qid and increasing the dose over days, but electrocardiogram (ECG) monitoring is recommended in the older individual. The usual nocturnal attacks of cluster headache can be treated with a single anticipatory dose of ergotamine at bedtime (2 mg orally) or with possibly lesser efficacy, an equivalent dose of serotonin agonist. Intranasal lidocaine or sumatriptan (or zolmitriptan as for migraine, see above) can also be used to abort an acute attack. In other patients, ergotamine given once or twice during the day, before an attack of pain is expected, has been helpful.

With regard to prevention of cluster headache, if ergotamine and sumatriptan are ineffective or become ineffective in subsequent bouts, many headache experts prefer to use verapamil, up to 480 mg/d. Ekbom introduced lithium therapy for cluster headache (600 mg, up to 900 mg daily), and Kudrow has confirmed its efficacy in chronic cases. Lithium and verapamil may be given together, but lithium toxicity is a frequent problem. A course of prednisone, beginning with 75 mg daily for 3 days and then reducing the dose at 3-day intervals, has been beneficial in many patients. Usually, it can be decided within a week if any one of these medications is effective. In brief, no method is effective in all cases, but the best initial approach probably involves the use of one of the triptan compounds. Rare cases of intractable cluster headache, in which the syndrome persists for weeks or longer without remission, have been treated by partial section of the trigeminal nerve, as described by Jarrar and colleagues, but these ablative measures are now always a last resort, especially when hypothalamic stimulation has been shown to be possibly effective, as mentioned earlier.

As with treatment for migraine noted above, the class of monoclonal antibodies against CGRP or its receptor has been successful in reducing the frequency of cluster headache. The mean number of weekly cluster episodes was approximately halved in a clinical trial of an antibody to CGRP administered subcutaneously, whereas the placebo group had a reduction of approximately one-third (Goadsby, 2019).

Tension-Type Headache (Tension Headache)

This, said to be the most common variety of headache, is usually bilateral, with occipitonuchal, temporal, or frontal predominance, or diffuse extension over the top of the cranium. The pain is usually described as dull and aching, but questioning often uncovers other sensations, such as fullness, tightness, or pressure (as though the head were surrounded by a band or clamped in a vise) or a feeling that the head is swollen and may burst. On these sensations, waves of aching pain are superimposed. These may be interpreted as paroxysmal or throbbing and, if the pain is slightly more on one side, the headache may suggest a migraine without aura. However, absent in tension headache are the persistent throbbing quality, nausea, photophobia, phonophobia, and clear lateralization of migraine. Nor do most tension headaches seriously interfere with daily activities, as migraine does. The onset is more gradual than that of migraine, and the headache, once established, may persist with only mild fluctuations for days, weeks, months, or even years. In fact, this is the only one of the few types of headache that exhibits the peculiarity of being present throughout the day, day after day, for long periods of time for which the term *chronic tension-type headache* is used. There is often self-acknowledged anxiety and depression, as noted below. Although sleep is usually undisturbed, the headache develops soon after awakening, and the common analgesic remedies have limited effect if the pain is of more than mild to moderate severity.

The incidence of tension headache is certainly greater than that of migraine. However, most patients treat tension headaches themselves and do not seek medical advice. Like migraine, tension headaches are more common in women than in men. Unlike migraine, they infrequently begin in childhood or adolescence but are more likely to arise in middle age and coincide with anxiety, fatigue, and depression in the trying times of life. In the large series (Lance and Curran), about one-third of patients with persistent tension headaches had readily recognized symptoms of depression. They carried out a controlled and blinded trial that demonstrated benefit from amitriptyline even in those patients who were not depressed. In our experience, chronic anxiety or depression of varying degrees of severity is present in the majority of patients with protracted headaches. Migraine and traumatic headaches may, of course, be complicated by tension headache, which, because of its persistence, often arouses fears of a brain tumor or other intracranial disease. However, as Patten points out, not more than one or two patients out of every thousand with tension headaches will be found to harbor an intracranial tumor, and its discovery has been most often incidental (see further on).

In a substantial group of patients with chronic daily headache, the pain, when severe, develops a pulsating quality, to which the term tension-migraine or tension vascular headache has been applied. Observations such as these have tended to blur the sharp distinctions between migrainous and tension headaches in some cases.

For many years, it was thought that tension headaches were a result of excessive contraction (tension) of craniocervical muscles and an associated constriction of the scalp arteries. However, it is not clear that either of these mechanisms contributes to the genesis of tension headache, at least in its chronic form. In most patients with tension headache, the craniocervical muscles are quite relaxed (by palpation) and show no evidence of persistent contraction when measured by surface electromyographic (EMG) recordings. Some investigators found no difference in the degree of muscle contraction between migraine and tension headache. (Anderson and Frank) By contrast, using a laser device, Sakai and associates have reported that the pericranial and trapezius muscles are hardened in patients with tension headaches. Nitric oxide has been implicated

in the genesis of tension-type headaches, specifically by creating a central sensitization to sensory stimulation from cranial structures. The strongest support for this concept comes from several reports that an inhibitor of nitric oxide reduces muscle hardness and pain in patients with chronic tension headache (Ashina et al). At present, these are interesting but speculative ideas.

Treatment of Tension Headache

Simple analgesics, such as aspirin or acetaminophen or other NSAIDs, may be helpful, if only for brief periods. Persistent or frequent tension headaches respond best to the cautious use of one of several drugs that relieve anxiety or depression such as amitriptyline given as a single dose at night, especially when symptoms of these conditions are present. Stronger analgesic medication should be avoided. Some clinicians have reported success with calcium channel blockers, phenelzine, and cyproheptadine. Ergotamine and propranolol are ineffective unless there are symptoms of both migraine and tension headache. Some patients respond to ancillary measures such as massage, meditation, and biofeedback techniques. Relaxation techniques may be helpful in teaching patients how to deal with underlying anxiety and stress. Gradual withdrawal of daily doses of analgesics, ergotamines, or triptan medications is an important aspect of treating chronic daily headache.

Hemicrania Continua

This is a moderately severe cranial pain that remains on one side and may fluctuate in severity. It is accompanied by autonomic features such as conjunctival injection or lacrimation, nasal congestion and runny nose, or ptosis. As mentioned earlier, it is responsive in most instances to indomethacin but escalating doses may be required, or a partial response may be expected from other nonsteroidal agents if gastrointestinal side effects are excessive. The clinical similarities to cluster headache are evident.

New Daily Persistent Headache

This awkward term describes an unremitting generalized headache with a distinct and fairly rapid onset the inception of which can be clearly recalled by the patient. Many cases follow a viral illness, stressful situation, or non-cranial surgery (Li and Rozen). The IHSS classification requires that it last for over 3 months. It has a female preponderance but no special clinical, imaging, or CSF features. The laterality and cephalic autonomic features of hemicrania continua are lacking. Treatment is largely unsatisfactory but antiepileptic agents may be tried.

HEADACHES ASSOCIATED WITH INCITING EVENTS AND MEDICAL CONDITIONS

Headaches in the Elderly

In several surveys, headache with onset in the elderly age period was found to be a prominent problem in as many as 1 of 6 persons, and more often to have serious import than headache in a younger population. In a series reported by Pascual and Berciano, more than 40 percent were classified as having tension headaches (women more than men), and there was a wide variety of diseases in the others (posttraumatic headaches, cerebrovascular disease, intracranial tumors, cranial arteritis, severe hypertension, and in our experience, subdural hematomas). Cough-induced headaches and cluster headaches were present in some of the men. New-onset migraine in this age group was a rarity.

Raskin described a headache syndrome in older patients that shares with cluster headache a nocturnal occurrence (*hypnic headache*). It also may occur with daytime naps. However, it differs in being bilateral and unaccompanied by lacrimation and rhinorrhea. He has successfully treated a number of his patients with 300 mg of lithium carbonate or 75 mg of sustained-release indomethacin at bedtime. The nosologic position of this hypnic headache syndrome is undetermined.

Despite these considerations, the most hazardous cause of headache in the elderly is temporal (cranial) arteritis with or without polymyalgia rheumatica, as discussed further on.

Headache With Psychiatric Disease

A common cause of generalized persistent headache, both in adolescents and adults, is probably mild depression or anxiety in one of its several forms. A small group of older patients has delusional symptoms involving pain and physical distortion of cranial structures. As the psychiatric symptoms subside, the headaches usually disappear. Odd cephalic pains, for example, a sensation of having a nail driven into the head (*clavus hystericus*), may occur in hysteria or psychosis and raise perplexing problems in diagnosis. The bizarre character of these pains, their persistence in the face of every known therapy, the absence of other signs of disease, and the presence of other manifestations of psychiatric disease provide the basis for correct diagnosis. Older children and adolescents sometimes have peculiar behavioral reactions to headache: screaming, looking dazed, clutching the head with an agonized look. Usually, migraine is the underlying disorder in these cases, the additional manifestations responding to therapeutic support and suggestion.

Posttraumatic Headache

Severe, chronic, continuous, or intermittent headaches lasting several days or weeks appear as the cardinal symptom of several cranial posttraumatic syndromes, separable in each instance from the headache that immediately follows head injury that may be due to scalp laceration, cranial or cerebral contusion, or increased intracranial pressure. These cranial pains are also differentiated from the more mundane postconcussive headaches detailed below. The *headache of chronic subdural hematoma* is deep-seated, dull, steady, mainly unilateral and may be accompanied or followed by drowsiness, confusion, and fluctuating hemiparesis. In *acute subdural hematomas*, we have been impressed with the positional worsening of pain in some patients after lying down or leaning the head to

one side. Tentorial hematomas produce the additional feature of pain in the eye. The head injury that gives rise to a subdural hematoma may have been minor, as described in Chap. 34, and forgotten by the patient and family. Typically, the headache increases in frequency and severity over several weeks or months. Patients who have received anticoagulation are particularly at risk. Diagnosis is established by CT or MRI.

Chronic headache is certainly a prominent feature of the *postconcussion syndrome*, comprising dizziness, fatigability, insomnia, nervousness, irritability, and inability to concentrate. This type of headache and associated symptoms, which resemble the tension headache syndrome, are described fully in Chap. 34, "Craniocerebral Trauma." The International Headache Society has classified persistence in this context as headache for longer than 3 months after injury. The patient with postconcussion syndrome requires supportive therapy in the form of repeated reassurance and explanations of the benign nature of the symptoms, a program of increasing physical activity, and the use of drugs that allay anxiety and depression. The early settlement of litigation, which is often an issue, works to the patient's advantage.

Tenderness and aching pain sharply localized to the scar of a long previous scalp laceration or surgical incision represent in a different problem and raise the question of a traumatic neuralgia or neuroma. Tender scars from scalp lacerations may be treated by repeated subcutaneous injections of local anesthetics, which also may act as a diagnostic test.

With *whiplash injuries* of the neck, there may be unilateral or bilateral retroauricular or occipital pain, probably as a result of stretching or tearing of ligaments and muscles at the occipitonuchal junction or of a worsening of a preexisting cervical arthropathy. Much less frequently, cervical intervertebral discs and nerve roots are involved. However, it is questionable if chronic headache can be attributed to whiplash (Malleson); nevertheless, the International Headache Society retains post whiplash headache as a category, while noting that it has no typical characteristics.

One should also be alert to headache as a sign of carotid or vertebral artery dissection after head or neck injury.

Headaches of Brain Tumor

It remains a popular notion that headache is a significant symptom in brain tumor but it is actually infrequent, particularly as the heralding symptom of a tumor in an adult. While headache is sometimes stated to occur in one-third of brain tumor cases, this is certainly in part the result of the high frequency of cranial imaging in headache patients. Headache probably only arises if the tumor displaces major cerebral vessels or blocks the flow of CSF, but we have seen exceptions. The pain has no specific features; it tends to be deep-seated, usually nonthrobbing (occasionally throbbing), and is described as aching or bursting. However, a major change in the pattern of an accustomed headache syndrome should raise suspicion of a structural lesion in the cranium. Physical activity and changes in position of the head may provoke pain, whereas rest sometimes diminishes it. Nocturnal awakening because of pain occurs in only a small proportion of brain tumor patients and is by no means diagnostic. Most headaches that awaken people at night are cluster-like headaches, hypnic headaches in the elderly, or those caused by caffeine withdrawal. Unexpected forceful (projectile) vomiting may punctuate brain tumor headache in its later stages, particularly in children, or as an early feature if the tumor is in the posterior fossa.

If unilateral, the headache is nearly always on the same side as the tumor. Pain from supratentorial tumors is felt anterior to the interauricular circumference of the skull; from posterior fossa tumors, it is felt behind this line. Bifrontal and bioccipital headaches from tumor coming on after unilateral headaches probably signify the development of increased intracranial pressure or hydrocephalus.

Having stated that headache is not to be equated with brain tumor, one cannot help but be impressed with its frequency in association with *colloid cysts*, and we have several times stumbled on the diagnosis when an odd, unexplained bilateral headache led to brain imaging. The mechanism of headache in cases of colloid cyst, if such a relationship is valid at all, is not simply one of blocking the flow of CSF at the foramina of Monro, as it is not predicated on the development of hydrocephalus. Restated, the presence of a colloid cyst does not assure that it is explanatory of a headache syndrome; furthermore, many cases of colloid cyst found on imaging or autopsy are not associated with headache. In addition, Harris described exceptional headaches of paroxysmal type with intra- and periventricular brain tumors, and others have commented on the same type of headache with parenchymal tumors. These are severe headaches that reach their peak intensity in a few seconds, last for several minutes or as long as an hour, and then subside quickly. When they are associated with vomiting, transient blindness, leg weakness causing "drop attacks," and loss of consciousness, there is a possibility of brain tumor with greatly elevated intracranial pressure. With respect to its onset, this headache almost resembles that of subarachnoid hemorrhage, but the latter is far longer-lasting and even more abrupt in onset. In its entirety, this paroxysmal headache is most typical of the aforementioned colloid cyst of the third ventricle, but it can occur with other tumors as well, including craniopharyngiomas, pinealomas, and cerebellar masses.

Headaches of Temporal Arteritis (Giant Cell Arteritis) (See Also Chap. 33)

This type of inflammatory disease of cranial arteries is an important cause of headache in older persons. All of our patients have been older than 55 years, most of them older than age 65. From a state of normal health, the patient develops an increasingly intense throbbing or nonthrobbing headache, often with superimposed sharp, stabbing pains. In a few patients the headache has had an almost explosive onset. The pain is usually unilateral, sometimes bilateral, and often localized to the site of the affected arteries in the scalp. The pain persists to some degree throughout the day and is particularly severe at night. It lasts for many months if untreated. The superficial temporal and other scalp arteries are frequently thickened and

tender and without pulsation. Jaw claudication and ischemic nodules on the scalp, with ulceration of the overlying skin, have been described in severe cases.

Many of the patients feel generally unwell and have lost weight; some have a low-grade fever and anemia. Usually the sedimentation rate is greatly elevated (>50 mm/h and typically >75 mm/h) but elevation of the C-reactive protein (CRP) level is a more sensitive indicator of this inflammatory condition and is particularly helpful when the sedimentation rate is only mildly elevated. A few patients have a peripheral neutrophilic leukocytosis. Half of patients have generalized aching of proximal limb muscles, reflecting the presence of polymyalgia rheumatica (see Chap. 45, "Polymyalgia Rheumatica"). A relation of temporal arteritis to herpes zoster has been proposed.

The importance of early diagnosis relates to the threat of blindness from thrombosis of the ophthalmic or posterior ciliary arteries. This may be preceded by several episodes of amaurosis fugax (transient monocular blindness). Ophthalmoplegia may also occur but is less frequent, and its cause, whether neural or muscular, is not settled. Masticatory claudication is a specific but not particularly sensitive symptom of cranial arteritis. The large intracranial vessels are occasionally affected, thereby causing stroke. Once vision is lost, it is seldom recoverable. For this reason, the earliest suspicion of cranial arteritis should lead to the administration of corticosteroids and then to biopsy of the appropriate scalp artery. Microscopic examination discloses an intense granulomatous or "giant cell" arteritis. If biopsy on one side fails to clarify the situation and there are sound clinical reasons for suspecting the diagnosis, the other side should be sampled. Arteriography of the external carotid artery branches is probably the most sensitive test but is seldom used, because of its relatively higher risk. Ultrasonographic examination of the temporal arteries may display a dark halo and irregularly thickened vessel walls. This technique has not been incorporated into routine evaluation because its sensitivity has not been established; our own experience suggests that it may miss cases, but it could be useful in choosing the site for biopsy of the temporal artery.

Treatment

The administration of prednisone, 45 to 60 mg/d in single or divided doses over a period of several weeks, is indicated in all cases, with gradual reduction to 10 to 20 mg/d and maintenance at this dosage for several months or years, if necessary, to prevent relapse. The headache can be expected to improve within a day or two of beginning treatment; failure to do so brings the diagnosis into question. When the sedimentation rate or CRP is elevated, its return to normal, usually over months, is a reliable index of therapeutic response. Whether symptoms or the blood tests are a better guide to reducing the steroid dose is unclear, one should probably be cautious in lowering the medication if the erythrocyte sedimentation rate (ESR) and CRP remain high.

More recently, the effect of the interleukin-6 inhibitor, tocilizumab, administered subcutaneously has been investigated and found to be effective in allowing a reduction in prednisone dose without recurrence of the disorder. [Stone NEJM 2017].

Headaches of Pseudotumor Cerebri (Benign or Idiopathic Intracranial Hypertension, see Chap. 29)

The headache of pseudotumor cerebri assumes a variety of forms. Most typical is a feeling of occipital pressure that is greatly worsened by lying down, but many patients have—in addition, or only—headaches of migraine or tension type. Indeed, some of them respond to medications such as propranolol and ergot compounds. None of the proposed mechanisms for pain in pseudotumor cerebri seems to be adequate as an explanation, particularly the idea that cerebral vessels are displaced or compressed, as neither has been demonstrated. It is worth noting that facial pain may also be a feature of the illness, albeit rare. Chapter 29 has a more complete description of the clinical features and treatment.

After successful treatment for pseudotumor, some patients have persistent headaches that have the flavor of migraine or tension headache.

Cough and Exertional Headache

A patient may complain of very severe, transient cranial pain on coughing, sneezing, laughing heartily, lifting heavy objects including weight lifting, stooping, and straining at stool. Pain is usually felt in the front of the head, sometimes occipitally, and may be unilateral or bilateral. As a rule, it follows the initiating action within a second or two and lasts a few seconds to a few minutes. The pain is often described as having a bursting quality and may be of such severity as to cause the patient to cradle his head in his hands, thereby simulating the headache of acute subarachnoid hemorrhage.

Most often this syndrome is a benign idiopathic state that recurs over a period of several months to a year or two and then disappears. Many decades ago, Sir Charles Symonds emphasized the benignity of the condition. In a report of 103 patients followed for 3 years or longer, Rooke found that additional symptoms of neurologic disease developed in only 10. The cause and mechanism have not been determined. During the headache, the CSF pressure is normal. Bilateral jugular compression may induce an attack, possibly because of traction on the walls of large veins and dural sinuses. In a few instances, we have observed this type of headache after LP or after a hemorrhage from an AVM.

Patients with cough or strain headache will only occasionally be found to have serious intracranial disease; when present, particularly if a first attack, subarachnoid hemorrhage may be suspected. In other infrequent cases, this type of headache has been traced to lesions of the posterior fossa and foramen magnum, AVM, subdural hematoma, Chiari malformation, or tumor. It may be necessary, therefore, to supplement the neurologic examination by appropriate LP, CT, and MRI. Far more common, of course, are the temporal and maxillary pains that are caused by dental or sinus disease, which may also be worsened by coughing.

A variant of exertional headache is "weightlifter's headache." It occurs either as a single event or repeatedly over

a period of several months, but each episode of headache may last many hours or days, again raising the suspicion of subarachnoid hemorrhage. The pain begins immediately or within minutes of heavy lifting. If the pain resolves in an hour or less and there is no meningismus or sign of bleeding on the CT, we have foregone LP and angiography but have suggested that weightlifting not be resumed for several weeks. Athletes and runners in general seem to suffer exertional headaches quite often in our experience, and the episodes usually have migrainous features.

Indomethacin, as already mentioned, is usually effective in controlling exertional headaches; this has been confirmed in controlled trials. Useful alternatives are NSAIDs, ergot preparations, and propranolol. In a few of our patients, LP appeared to immediately resolve the problem in some inexplicable way.

Headaches Related to Sexual Activity ("Orgasmic Headache")

Lance (1976) described 21 cases of this type of headache, 16 in males and 5 in females. The headache took one of two forms: one in which pain typical of tension headache developed as sexual excitement increased, and another in which a severe, throbbing, "explosive" headache occurred at the time of orgasm and persisted for several minutes or hours (orgasmic headache). The latter headaches were of such abruptness and severity as to suggest a ruptured aneurysm but the neurologic examination was negative in every instance, as was arteriography in seven patients who were subjected to this procedure. In 18 patients who were followed for a period of 2 to 7 years, no other neurologic symptoms developed. Characteristically, the headache occurred on several consecutive occasions and then disappeared. In cases of repeated coital headache, indomethacin has been effective. Of course, so-called orgasmic headache is not always benign; a hypertensive hemorrhage, rupture of an aneurysm or vascular malformation, carotid artery dissection, or myocardial infarction may occur during the exertion of sexual intercourse. While there is no authoritative direction, it is justified to perform a spinal tap if a sexual-related headache is the first occurrence of headache in a patient's history.

Thunderclap Headache

This is a severe headache of very abrupt onset and numerous causes, most being less serious than the nature of the symptoms suggest. Of course, the headache of subarachnoid hemorrhage caused by rupture of a saccular (berry) aneurysm is among the most abrupt and dramatic of cranial pains (see Chap. 33). It was in relation to headaches of this nature that the term *thunderclap* was introduced by Day and Raskin. They attributed the symptoms to an unruptured cerebral aneurysm but the term is now used to denote headache of this description from various causes.

Patients have offered colorful descriptions, such as "being kicked in the back of the head." Thunderclap headache, has been a symptom of pituitary apoplexy, cerebral venous thrombosis, cervical arterial dissection, nonaneurysmal perimesencephalic hemorrhage, or hypertensive crisis (Dodick 2002) (Table 9-4). To this list should be added diffuse idiopathic arterial spasm (Call Fleming syndrome; see "Diffuse and Focal Cerebral Vasospasm" in Chap. 33) and cerebral vasospasm as the result of the administration of sympathomimetic or serotonergic drugs, including cocaine and the triptan group of medications for the treatment of migraine. The coital and exertional headaches described above may also be considered of this nature. *Recurrent thunderclap* pain may be particularly indicative of multifocal or diffuse vasospasm, (Chen and colleagues), as this vasculopathy was found in 39 percent of patients with recurrent thunderclap pain in one series.

Table 9-4

CAUSES OF THUNDERCLAP HEADACHE

Migraine
Subarachnoid hemorrhage
Cerebral venous thrombosis
Diffuse cerebral vasospasm (Call-Fleming syndrome)
Accelerated hypertension
Pituitary apoplexy
Cocaine and adrenergically active drugs
Perimesencephalic non-aneurysmal subarachnoid hemorrhage

Because the pain of thunderclap headache may be indistinguishable from that caused by subarachnoid hemorrhage, even to the extent of being accompanied by vomiting and acute hypertension, the diagnosis is clarified after LP and cerebral imaging, and the pain resolves in hours or less. Most cases turn out to be idiopathic. Wijdicks and colleagues confirmed that thunderclap headache is usually a benign condition; among 71 patients followed for more than 3 years they found no serious cerebrovascular lesions. For this reason, these idiopathic thunderclap headaches have been presumed by some workers to be a form of migraine ("crash migraine"). This opinion is based in part on a history of preceding or of subsequent headaches and migrainous episodes in affected individuals; however, in our experience not all of such patients have had migraine in the past. There is a notable tendency for thunderclap headaches to recur as mentioned above.

Chiari Malformation and Headache

All manner of headache has been attributed to Chiari type I malformation (with tonsils descended at least 3 mm below the lip of the foramen magnum), but with limited justification. However, some instances of exertional and Valsalva-induced suboccipital pain can be attributed to this developmental abnormality. In the survey by Pascual and colleagues of 50 patients with Chiari type I malformations, approximately a quarter described a fairly specific pattern of pain consisting of bursting, dull, throbbing, or lancinating discomfort for seconds to far longer following Valsalva-related activities, either in the occipital or frontal region and radiating to one or both shoulders. Only the degree of tonsillar descent correlated with the presence of exertional headache and skull abnormalities such as basilar impression were not clearly associated with this type of headache. It follows that suboccipital decompressive operations for headache in this condition should be

undertaken only selectively. Chiari malformation is discussed further in Chap. 37.

Erythrocyanotic Headache

An intense, generalized, throbbing headache may occur in conjunction with flushing of the face and hands and numbness of the fingers (erythromelalgia). Episodes tend to be present on awakening from sound sleep. This condition, called erythrocyanotic, has been reported in a number of unusual settings: (1) in mastocytosis (infiltration of tissues by mast cells, which elaborate histamine, heparin, and serotonin); (2) with carcinoid tumors; (3) with serotonin-secreting tumors; (4) with some tumors of the pancreatic islets; and (5) with pheochromocytoma. Seventy-five percent of patients with pheochromocytoma reportedly have vascular-type headaches coincident with paroxysms of hypertension and release of catecholamines (Lance and Hinterberger) but the flushing phenomenon has been rare in our experience.

Headache Related to Various Medical Diseases

A cardinal feature of meningitis of varied causes is headache. When accompanied by fever and stiff neck, the diagnosis is almost assured. However, severe headache may occur with several infectious illnesses caused by banal viral infections, by organisms such as *Mycoplasma,* and particularly by influenza. There is often accompanying neck pain and slight stiffness. The suspicion of meningitis is raised, even subarachnoid hemorrhage, but there is no reaction in the CSF ("meningism"). The mild aseptic meningitis that accompanies HIV seroconversion may also be accompanied by headache. When persistent and moderately severe, the headache may be classified with "new daily persistent headache" described above.

Approximately 50 percent of patients with chronic and essential hypertension complain of headache, but the relationship of one to the other is probably coincidental. Minor elevations of blood pressure may be a result rather than the cause of headaches. Severe (accelerated) hypertension, with diastolic pressures of more than 120 mm Hg is, however, associated with headache, and measures that reduce the blood pressure relieve the cranial pain. In preeclampsia, the headaches occur at minor degrees of hypertension or normal levels in a woman who has otherwise low blood pressure. Abrupt elevations of blood pressure, as occur in patients who take monoamine oxidase inhibitors and then ingest tyramine-containing food, can cause headaches that are severe enough to simulate subarachnoid hemorrhage. However, it is the individual with moderately severe hypertension and frequent severe headaches that typically confronts the practitioner. In some of these patients, the headaches are of the common migrainous or tension type, but in others, they defy classification. The acute headache of pheochromocytoma correlates with the rate of increase in blood pressure rather than its absolute value. Curiously, headaches that occur toward the end of renal dialysis or soon after its completion are associated with a fall in blood pressure (as well as a decrease in blood sodium levels and osmolality).

Headaches frequently follow a seizure, having been recorded in half of one large series of epileptic patients analyzed by Schon and Blau but the pain was infrequently severe. In migraineurs, the postseizure headache may reproduce a typical migraine attack.

Experienced physicians are aware of many other conditions in which headache may be a principal symptom. These include fevers of any cause, carbon monoxide exposure, chronic lung disease with hypercapnia (headaches often nocturnal or early morning), sleep apnea, hypothyroidism, thrombocythemia, Cushing disease, withdrawal from corticosteroid medication or alcohol, mountain (altitude) sickness, exposure to nitrates, cyanotic heart disease, occasionally in adrenal insufficiency, and acute anemia with hemoglobin well below 10 g.

No attempt is made here to discuss the symptomatic treatment of headache that may accompany these many medical conditions. Obviously, the guiding principle is to address the underlying disease.

Headache Related to Diseases of the Cervical Spine

Headaches that accompany diseases of the upper cervical spine are well recognized, but their mechanism is obscure and their frequency possibly overestimated. Recent writings have focused on a wide range of causative lesions, such as apophyseal (facet) arthropathy, C2 dorsal root entrapment, calcified ligamentum flavum, hypertrophied posterior longitudinal ligament, and rheumatoid arthritis of the atlantoaxial region. The most credible evidence for this group of disorders comes from systematic injection of anesthetics into cervical structures and effecting complete relief of headache (Bogduk and Govind). Even this is not uniformly successful in patients whose cranial pain has been attributed to a cervicogenic mechanism. CT and MRI have divulged a number of these abnormalities. One special variety is discussed further under "'Third Occipital Nerve' Headache," in this chapter and further in Chap. 10.

OTHER CRANIOFACIAL PAINS (SEE CHAP. 44)

Trigeminal Neuralgia (Tic Douloureux)

This chronic, recurrent disorder of middle age and later life consists of paroxysms of intense, stabbing pain in the distribution of the mandibular and maxillary divisions (rarely the ophthalmic division) of the fifth cranial nerve. The pain is typically triggered by minor stimuli on the face and seldom lasts more than a few seconds or rarely a minute or two, but it is often so intense that the patient winces involuntarily; hence the term *tic*. It is uncertain whether the tic is reflexive or quasivoluntary. The paroxysms recur frequently, both day and night, for several weeks or months at a time. A characteristic feature is the initiation of a jab or a series of jabs of pain by stimulation of certain areas of the face, lips, or gums, as in shaving or brushing the teeth, or by movement of these parts in chewing, talking, or yawning, or even by a breeze—the so-called trigger factors. Sensory or motor loss in the distribution of the fifth nerve

cannot be demonstrated, though there are exceptions. In addition to the paroxysmal pain, some patients complain of a more or less continuous discomfort, itching, or sensitivity of restricted areas of the face, features regarded as atypical even though not infrequent.

In studying the relationship between stimuli applied to the trigger zones and the paroxysms of pain, touch and possibly tickle are more likely to be precipitants rather than painful or thermal stimulus. Usually a spatial and temporal summation of impulses is necessary to trigger a paroxysm of pain, which is followed by a refractory period of up to 2 or 3 min.

The *diagnosis* of tic douloureux rests on the clinical criteria enumerated above, so that the condition can be distinguished from other forms of facial and cephalic neuralgia and pain arising from diseases of the jaw, teeth, or sinuses. Many cases of trigeminal neuralgia are the result of compression by an intracranial vascular loop, called "classic" and described below. An uncertain number are truly *idiopathic*) and a small number are *symptomatic*, in which paroxysmal facial pain is because of involvement of the fifth nerve by some other disease: multiple sclerosis (may be bilateral), aneurysm of the basilar artery, or tumor (acoustic or trigeminal schwannoma, meningioma, epidermoid) in the cerebellopontine angle. The symptomatic forms of trigeminal neuralgia may give rise only to pain in the distribution of the trigeminal nerve, or it may produce a loss of sensation as well. A proportion of patients, perhaps as high as half, have continuous fluctuating facial pain in the distribution of their neuralgia. The discomfort may be aching, throbbing, or burning. Several hypotheses have been offered for the mechanism of this pain, not entirely satisfactory.

Glossopharyngeal Neuralgia

This syndrome is much less common than trigeminal neuralgia but resembles the latter in many respects. The pain is intense and paroxysmal; it originates in the throat, approximately in the tonsillar fossa, and is provoked most commonly by swallowing but also by talking, chewing, yawning, laughing, etc. The pain may be localized in the ear or radiate from the throat to the ear, implicating the auricular branch of the vagus nerve. For this reason, White and Sweet several decades ago suggested the term *vagoglossopharyngeal neuralgia*. This is the main craniofacial neuralgia that may be accompanied by bradycardia and even by syncope, presumably because of the triggering of cardioinhibitory reflexes by afferent vagal pain impulses. There is no demonstrable sensory or motor deficit.

Rarely, tumors, including carcinoma, lymphoma or epithelioma of the oropharyngeal-infracranial region or peritonsillar abscess may give rise to pain that is clinically indistinguishable from glossopharyngeal neuralgia.

Cranial Herpes Zoster and Postherpetic Neuralgia

The common pain and herpetic eruption caused by herpes zoster infection of the gasserian ganglion are practically always limited to the first division (herpes zoster ophthalmicus). Ordinarily, the rash appears within 4 to 5 days or less after the onset of the pain, thereby making the clinical diagnosis difficult; however, treatment should be instituted (see below) based on the clinical likelihood of zoster infection. If the eruption does not appear, some cause other than herpes zoster will almost invariably declare itself; nevertheless, a few cases have been reported in which the characteristic location of pain with serologic evidence of herpes zoster infection was not accompanied by skin lesions.

The acute discomfort associated with the herpetic eruption usually subsides after several days or weeks, or it may linger for several months. It is mostly in the elderly that the pain becomes chronic and intractable. Usually it is described as a constant burning, with superimposed waves of stabbing pain, and the skin in the territory of the preceding eruption is exquisitely sensitive to the slightest tactile stimuli, even though the threshold of pain and thermal perception is elevated. This unremitting *postherpetic neuralgia* of long duration represents one of the most difficult pain problems with which the physician must deal. Some relief may be provided by the application of capsaicin cream, use of a mechanical or electrical cutaneous stimulator, or administration of one of the antiepileptic drugs.

Neuralgia associated with a vesicular eruption caused by the herpes zoster virus may affect the external auditory meatus and pinna and sometimes of the palate and occipital region—with or without deafness, tinnitus, and vertigo—is combined with facial paralysis. This syndrome, since its original description by Ramsay Hunt, has been known as geniculate herpes, and also *Ramsay Hunt syndrome* (see also Chap. 44). It is clear that the skin of the external ear canal, tympanic membrane and in some patients, the skin behind the ear are supplied by somatic sensory branches that travel with the chorda tympani and greater superficial petrosal nerves and have their cell bodies in the geniculate ganglion.

Treatment

Treatment with acyclovir, along the lines indicated in Chap. 32, will shorten the period of eruption and the acute pain, but the drug does not prevent its persistence as a chronic pain. There is little data on which to judge the utility of corticosteroids but they are generally not used (whereas they do provide benefit in Bell's palsy and antiviral agents are not clearly useful).

Antidepressants such as amitriptyline and fluoxetine are helpful in some patients, and Bowsher has suggested, on the basis of a small placebo-controlled trial, that treatment with amitriptyline during the acute phase may prevent persistent pain. The use of preemptive measures, such as gabapentin or pregabalin administered at the outset, may be effective but a properly performed clinical trial is lacking. The addition of amitriptyline up to 75 mg at bedtime has proved to be a useful measure. Probably equivalent results are obtained by a combination of valproic acid and an antidepressant (Raftery). Ketamine cream has been suggested as an alternative. Extensive trigeminal rhizotomy or other destructive procedures should be avoided, as these surgical measures are not long successful and may

lead to a superimposed diffuse refractory dysesthetic component on the original neuralgia (anesthesia dolorosa).

Trochlear Headache

Under the heading of "primary trochlear headache," a periorbital pain has been described that emanates from the superomedial orbit in the region of the trochlea (the pulley of the superior oblique muscle) (Yanguela and colleagues). Most of their patients were women. The pain was worsened by adduction and (paradoxically for the superior oblique) upgaze of the globe on the affected side, in the direction of action of the superior oblique muscle. The authors describe a diagnostic method of examination that begins by having the patient look downward so that the trochlea can be palpated and compressed; the patient then looks upward, eliciting or exaggerating the pain, while the examiner continues compression. Injection of the trochlea with corticosteroids relieved the pain in almost all of these patients. The authors made a distinction between primary trochlear headache and "trochleitis," which seems to us an ambiguous difference. There is no limitation of ocular movement or autonomic change and imaging of the orbit is normal. This syndrome, with which we have no experience, brings to mind the entity of the Brown syndrome of trochlear entrapment with diplopia and pain (see Chap. 13). The above authors were also of the opinion that the trochlea may be a trigger point for migraine.

Otalgia

Pain localized in and around one ear is occasionally a primary complaint. It is commonly the incipient symptom of Bell's palsy or an outbreak of shingles but there are a number of different causes and mechanisms. During neurosurgical operations in awake patients, stimulation of cranial nerves V, VII, IX, and X causes ear pain, yet interruption of these nerves usually causes no or limited demonstrable loss of sensation in the ear canal or the ear itself (superficial sensation in this region is supplied by the great auricular nerve, which is derived from the C2 and C3 roots). The neurosurgical literature cites examples of otalgia that were relieved by section of the nervus intermedius (sensory part of VII) or of nerves IX and X. In otalgic cases, one is also prompted to search for a nasopharyngeal tumor, vertebral artery aneurysm or dissection or to anticipate an outbreak of zoster as mentioned. Formerly, lateral sinus thrombosis was a common cause in children. When these possibilities are eliminated by appropriate studies, there always remain examples of primary idiopathic otalgia, lower cluster headache, and glossopharyngeal neuralgia. Some patients with migraine have pain centered in the ear region and occiput, but we have never observed a trigeminal neuralgia in which the ear was the predominant site of pain. Occasionally, temporomandibular joint disease is the cause (see below).

Occipital Neuralgia

Paroxysmal pain may occur in the distribution of the greater or lesser occipital nerves (suboccipital, occipital, and posterior parietal areas). While tenderness may be localized to the region where these nerves cross the superior nuchal line, there is only questionable evidence of an occipital nerve lesion at this site. The finding of hypesthesia in the distribution of the occipital nerves makes the possibility of an entrapment neuropathy more convincing. Carbamazepine or gabapentin may provide some relief. Blocking the nerves with lidocaine may abolish the pain and encourage attempts to section one or more occipital nerves or the second or third cervical dorsal root, but the results of the sectioning procedure have had variable success, and several such patients who had these procedures were later referred to us with disabling anesthesia dolorosa. Experts advise repeated injections of local anesthetic agents and the use of steroids, botulinum toxin, and analgesic and anti-inflammatory drugs. The pain at times may be difficult to distinguish from that arising in the upper three cervical facet joints, one type of which is discussed below. The approach of treating migraine by injection of the occipital nerves, mentioned earlier, is controversial.

"Third Occipital Nerve" Headache

This condition, a unilateral occipital and suboccipital ache, may be a prominent symptom in patients with neck pain, particularly after neck injuries (a prevalence of 27 percent, according to Lord et al). It has been attributed to a degenerative or traumatic arthropathy involving the C2 and C3 facet joints with impingement on the "third occipital nerve" (a branch of the C3 dorsal ramus that crosses the dorsolateral aspect of the facet joint (Bogduk and Marsland). Elimination of the neck pain and headache by percutaneous blocking of the third occipital nerve near the facet joint under fluoroscopic control is diagnostic and temporarily therapeutic. More sustained relief (weeks to months) has been obtained by radiofrequency coagulation of the nerve or steroid injections in and around the joint. NSAIDs also may provide some relief.

Carotidynia and Extracranial Artery Dissection

Carotidynia was coined by Temple Fay in 1927 to designate a special type of cervicofacial pain that could be elicited by pressure on the common carotid arteries of patients with atypical facial neuralgia. Compression of the artery in the neck in these patients, or mild electrical stimulation at or near the bifurcation, produced a dull ache that was referred to the ipsilateral face, ear, jaws, and teeth or down the neck. This type of carotid sensitivity occurs as part of cranial (giant cell) arteritis and of the rare condition known as Takayasu arteritis (see Chap. 33), and during attacks of migraine or cluster headache. It has also been described with displacement of the carotid artery by tumor and dissecting aneurysm of its wall; among these causes, the last is of greatest concern. The idiopathic variety of carotidynia may have to do with a swelling or inflammation of the tissue surrounding the carotid bifurcation, a change that has been demonstrated on MRI (Burton and colleagues) but the problem has been seen most frequently in migraineurs.

Roseman has described a variant of carotidynia that has a predilection for young adults. This syndrome takes the form of recurrent, self-limited attacks of pain and tenderness at the carotid bifurcation lasting a week or two. Dissection of the carotid artery, as discussed below, is always a concern. During the attack, aggravation of the pain by head movement, chewing, and swallowing is characteristic. This condition is treated with simple analgesics. Yet another possible variety of carotidynia appears at any stage of adult life and recurs in attacks lasting minutes to hours in association with throbbing headaches indistinguishable from common migraine (Raskin and Prusiner). This form responds favorably to the administration of ergotamine and other drugs that are effective in the treatment of migraine.

Although most pain of carotid or vertebral artery dissection is localized to the site of injury in the anterior or posterior neck. The frequency with which ipsilateral headache, and not neck pain, was the sole feature has been emphasized by some authors (Arnold and colleagues). Some had a paroxysmal ("thunderclap") onset but most had throbbing and progressive pain over days, sometimes bilaterally. The combination of focal neck pain and localized headache over an eye is particularly suggestive of carotid dissection and, of course, if there are corresponding symptoms of fluctuating or static regional brain ischemia, Horner syndrome, or lower cranial nerve palsies, the diagnosis is likely.

Temporomandibular Joint Pain (Costen Syndrome)

This is a form of craniofacial pain from dysfunction of one temporomandibular joint. Malocclusion because of ill-fitting dentures or loss of molar teeth on one side with alteration of the normal bite may lead to distortion of and ultimately degenerative changes in the joint and to pain in front of the ear, with radiation to the temple and over the face (Guralnick et al). Most patients report deviation of the mandible to the affected side on jaw opening and clicking noises emanating from the joint (Scrivani and colleagues). Locking of the jaw in either the open or closed position is another feature. The diagnosis is supported by the findings of tenderness over the joint, crepitus on opening the mouth, and limitation of jaw opening. The favored diagnostic maneuver involves palpating the joint from its posterior aspect by placing a finger in the external auditory meatus and pressing forward. The diagnosis can be made with some confidence only if this entirely reproduces the patient's pain. CT and plain films are rarely helpful, but effusions have been shown in the joints by MRI. Management consists of careful adjustment of the bite by a dental specialist. Small doses of amitriptyline at bedtime may be helpful. In our experience, most of the putative diagnoses of Costen syndrome that reach the neurologist have been uncertain, and the number of headaches and facial pains that are attributed to "temporomandibular joint dysfunction" is probably excessive, especially if judged by the response to treatment. The temporomandibular joint may also be the source of pain when involved with rheumatoid arthritis and other connective tissue diseases.

Facial Pain of Dental or Sinus Origin

Maxillary and mandibular discomfort is a common effect of nerve irritation from deep caries, abscess, dental pulp degeneration, or periodontal disease. The pain of dental nerve origin is usually most severe at night, slightly pulsating, and often associated with local tenderness at the root of the tooth in response to heat, cold, or pressure. The diagnosis can be confirmed by infiltrating the base of the tooth with lidocaine, and the pain is eradicated by proper dental management.

Trigeminal neuritis following dental extractions or oral surgery is another vexing problem. There may be sensory loss in the tongue or lower lip and weakness of the masseter or pterygoid muscle.

Sometimes the onset of "atypical facial pain" (see below) can be dated to a dental procedure such as tooth extraction, and, as usually happens, neither the dentist nor the neurologist is able to find a source for the pain or any malfunction of the trigeminal nerve. Roberts and coworkers, as well as Ratner and associates, have pointed out that residual microabscesses and subacute bone infection account for some of these cases. They isolated the affected region by using local anesthetic blocks, curetted the bone, and administered antibiotics, following which the pain resolved. The removed bone fragments showed vascular and inflammatory changes and infection with oral bacterial flora, but there was no control material.

Facial Pain of Uncertain Origin (Idiopathic, "Atypical" Facial Pain)

There remains, after all the aforementioned facial pain syndromes, a fair number of patients with pain in the face for which no cause can be found. These patients describe the pain as constant and unbearably severe, deep in the face, or at the angle of cheek and nose, and unresponsive to all varieties of analgesic medication. Because of the failure to identify an organic basis for the pain, one is tempted to attribute it to psychologic or emotional factors. Depression of varying severity is found in some. Some such patients, with or without depression, may respond to tricyclic antidepressants and selective serotonin reuptake inhibitors (SSRI) medications. Differentiated from this group is the condition of trigeminal neuropathy with facial numbness, described in Chap. 44.

Facial pain of the "atypical type," like other chronic pain of indeterminate cause, requires close observation of the patient, looking for lesions such as nasopharyngeal carcinoma or apical lung carcinoma to become apparent. The pain can be managed by the conservative methods outlined in the preceding chapter and not by destructive surgery. Antidepressants may be helpful, especially if the patient displays obsessive characteristics in relation to the pain; some European neurologists favor clomipramine for various facial and scalp pains.

Other Rare Types of Facial Pain

Neuralgia may arise in the terminal branches of the trigeminal, ciliary, nasociliary, and supraorbital nerves; some of

which have already been mentioned. Some of these are vague entities at best and merely descriptive terms given to pains localized around the eye and nose. The Tolosa-Hunt syndrome of pain behind the eye and granulomatous involvement of some combination of cranial nerves III, IV, VI, and ophthalmic V, responsive to steroids, is discussed in Chap. 44.

A kind of *reflex sympathetic dystrophy of the face* is postulated as another rare form of persistent facial pain that may follow dental surgery or penetrating injuries to the face. It is characterized by severe burning pain and hyperpathia in response to all types of stimuli. Sudomotor, vasomotor, and trophic changes are lacking, unlike causalgia that affects the limbs. Nevertheless, this form of facial pain is said to respond to repeated blockade or resection of the stellate ganglion.

Under the title of *neck–tongue syndrome*, Lance and Anthony have described the occurrence of a sharp pain and tingling in the upper neck or occiput with numbness of the ipsilateral half of the tongue on sudden rotation of the neck. They attribute the syndrome to stretching of the C2 ventral ramus, which contains proprioceptive fibers from the tongue; these fibers run from the lingual nerve to the hypoglossal nerve and thence to the second cervical root.

A problem that has gone by the self-evident name *burning mouth syndrome (stomatodynia)* occurs mainly in middle-aged and older women, as commented in Chap. 11. The tongue or other oral sites may be most affected or the entire oral mucosa may burn. A few patients are found to have diabetes, vitamin B_{12} deficiency, or Sjögren syndrome as possible causes. A hint to the last diagnosis is the inability to feel food in the mouth. The oral mucosa is normal when inspected, and no one treatment has been consistently effective, but gabapentin combined with antidepressants or clonazepam may be tried (Grushka et al). One of our patients with a limited form of this condition, which affected only the upper palate and gums, benefited from dental nerve blocks with lidocaine.

Pain in the Back, Neck, and Extremities

Back pain is among the most frequent medical complaints. Neurologists are often called upon, perhaps not always appropriately as expertise in this field is distributed among orthopedists, neurosurgeons, physical medicine experts, rheumatologists, pain specialists, and neurologists to offer an opinion as to diagnosis and treatment. Up to 80 percent of adults have low back pain at some time in their lives, and an even larger percentage will be found at autopsy to have degenerative spinal disease (Kelsey and White). One task is to determine whether a disease of the spine has compressed the spinal cord or the spinal roots. This requires a clear understanding of the structures involved.

The parts of the back that possess the greatest freedom of movement and hence are most frequently subject to injury and degeneration, are the lumbar, lumbosacral, and cervical segments. In addition to bending, twisting, and other voluntary movements, many actions of the spine are reflexive in nature and are the basis of erect posture. As pains in the lower part of the spine and legs are caused by different types of disease than those in the neck, shoulder, and arms, they are considered separately in this chapter.

ANATOMY AND PHYSIOLOGY OF THE SPINAL COLUMN

The bony spine is a complex structure, roughly divisible into anterior and posterior parts. The anterior component consists of cylindric vertebral bodies, articulated by the intervertebral discs and held together by the anterior and posterior longitudinal ligaments. The posterior elements are more delicate and extend from the bodies as pedicles and laminae, which form the borders of the *spinal canal* by joining with the posterior aspects of the vertebral bodies and ligaments. Large transverse and spinous processes project laterally and posteriorly, respectively, and serve as the origins and insertions of the muscles that support and protect the spinal column. The bony processes are also held together by sturdy ligaments, the most important being the ligamentum flavum, which runs along the ventral surfaces of the posterior elements and is applied to the inner surface of the laminae. The posterior longitudinal ligament lies opposite it on the dorsal surfaces of the vertebral bodies. These two ligaments bound the posterior and anterior structures of the spinal canal, respectively.

The posterior parts of the vertebrae articulate with one another at the diarthrodial *facet joints* (also called apophyseal or zygapophyseal joints), each of which is composed of the inferior facet of the vertebra above and the superior facet of the one below. The facet and sacroiliac joints, which are covered by synovia, the compressible intervertebral discs, and the collagenous and elastic ligaments, permit a limited degree of flexion, extension, rotation, and lateral motion of the spine. Figure 10-1 illustrates these anatomic features in representative sections of the lumbar spine. The size and shape of thoracic and cervical vertebrae and their posterior elements differ, but the essential relationships between adjacent vertebral bodies are similar. The first cervical vertebral body, the atlas, has special articular relationships to the base of the skull just above it and the cervical vertebral segments have a broad component at the anterior laminae, just under the facet joints, termed lateral mass.

Although the ligamentous structures are quite strong, neither they nor the vertebral body–disc complexes have sufficient integral strength to resist some of the enormous forces that may act on the spinal column. Consequently, the stability of the lower back is also dependent on the voluntary and reflex activity of the sacrospinalis, abdominal, gluteus maximus, quadratus lumborum, and hamstring muscles, and on the integrity of the ligamentum flavum and posterior longitudinal ligament.

The vertebral and paravertebral structures derive their innervation from the meningeal branches of the spinal nerves (also known as recurrent meningeal or sinuvertebral nerves). These branches spring from the posterior divisions of the spinal nerves just distal to the dorsal root ganglia, reenter the spinal canal through the intervertebral foramina, and supply pain fibers to the intraspinal ligaments, periosteum of bone, outer layers of the annulus fibrosus (which enclose the disc), and capsule of the articular facets. The A-δ and C pain fibers extending into the inner layers of the annulus and even into the nucleus pulposus (Coppes and associates). Although the spinal cord itself is insensitive, many of the conditions that affect it produce pain by involving these adjacent structures. For example, the sensory fibers from the lumbosacral and sacroiliac joints enter the spinal cord via the fifth lumbar and first sacral roots.

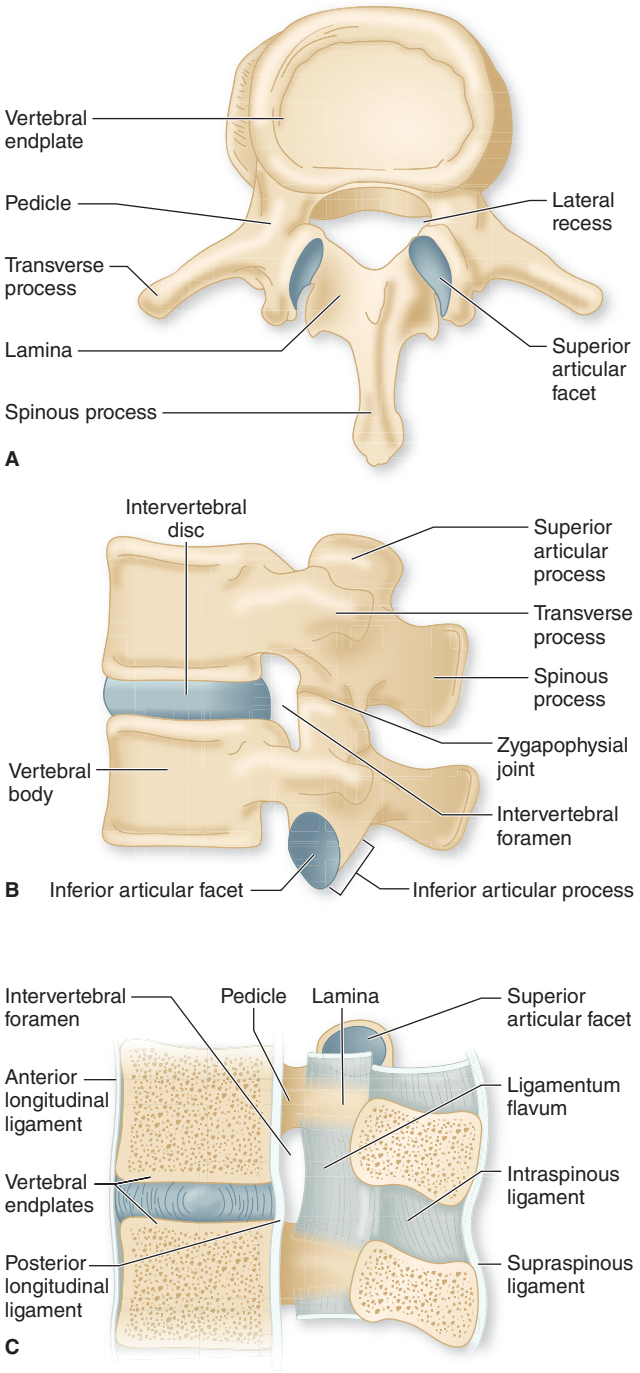

Figure 10-1. *A*. The lumbar vertebrae viewed from above *B* from the side and *C* mid-sagittally. *A* and *B* show the bony structures and their relationships to the disc space, facet joints, and intervertebral foramina. *C* demonstrates, in a cutaway mid-sagittal view, the main ligamentous structures of the spine in relation to the bones and discs. The ligaments and articulations are critical to the mechanical integrity of the spinal column.

This explains some of the patterns of pain referral from these joints.

The spinal roots in the lumbar region (cauda equina) angulate sharply to exit horizontally through the intervertebral foramina. Prior to entering the short foraminal canal, the lumbar spinal root lies in a shallow furrow along the inner surface of the pedicle, the *lateral recess*. This is a common site of root entrapment by disc fragments and osteophytic bony overgrowth. Because the thoracic and cervical discs do not have to travel downward and laterally to their points of exit at the foramina, they exit horizontally from their points of formation in the spinal subarachnoid space.

Aging Changes in Spinal Structures

Degeneration in the intervertebral discs and ligaments is a consequence of aging and the succession of inevitable minor traumas to the spine. Deposition of collagen and elastin and alterations of glycosaminoglycans combine to decrease the water content of the nucleus pulposus; concomitantly, the cartilaginous endplate becomes less vascular (Hassler). The dehydrated disc thins out and becomes more fragile. Similar changes occur in the annulus of the disc, which frays with the passage of time and with minor trauma, permitting the nucleus pulposus to bulge and, sometimes with injury, to extrude into the spinal canal. This process can be observed by MRI, which shows a gradual reduction in the high signal of the nucleus pulposus with aging in most individuals. For example, among women who had MRI for gynecologic reasons, the frequency of lumbar disc degeneration and bulging approaching 70 percent by age 50 (Powell and coworkers).

The problem of degenerative spinal disease has been conceptualized as being initiated by shrinkage of the disc that subsequently alters the alignment of the articular facets and vertebral bodies, leading to facet arthropathy and bony spur formation across the disc space (called spondylitic "bar"). These reactive changes conspire to create stenosis of the spinal canal and compromise the lateral recesses and the inter-vertebral foramina, where they impinge on lumbar nerve roots and, at higher levels, on the spinal cord, but the process of spinal degeneration is probably more complex and has genetic components. Osteoporosis, especially in older women, is a further important cause of vertebral flattening or collapse, additionally narrowing the spinal canal.

PAIN IN THE LOWER BACK AND LEGS

The lower parts of the spine and pelvis, with their massive muscular attachments, are relatively inaccessible to palpation and inspection. Although some physical signs and imaging studies are helpful, diagnosis often depends on the patient's description of the pain and his behavior during the execution of certain maneuvers. Seasoned clinicians appreciate the need for a systematic inquiry and method of examination.

Clinical Features of Low Back Pain

The symptoms of spinal disease are pain, stiffness, limitation of movement, and deformity, but pain is foremost. Several types of spinal pain may be distinguished: local, referred, radicular, and that arising from secondary muscular spasm.

The origin of pain can often be discerned from the patient's description, reliance being placed mainly on the character of the pain, its location, and conditions that modify it.

Local pain is steady and aching, but it may be intermittent and sharp and, although not well circumscribed, is felt in or near the affected part of the spine. Local pain is caused by any pathologic process that impinges on structures containing sensory endings, including the periosteum of the vertebral body, capsule of facet joints, annulus fibrosus, and ligaments. The archetypal local spinal pain is produced by an epidural abscess; the pain is felt over the region of the abscess, is deep, aching, and tends to be worse at night. Destruction of the nucleus pulposus alone produces little or no pain, but the annulus is innervated with small nerve fibers and may produce considerable pain when disrupted in the immediate region of the disc. Such local discomfort often accompanies the moment of disc rupture through the annulus before the subsequent pain of nerve root compression arises. Pathologic change arising in spinal structures may also evoke discomfort in regions that share common innervation and thereby vaguely simulate the pain of radicular disease. These areas of referred projection may be considered similarly to the referred pain of the "sclerotomes" discussed in Chap. 7 and below.

Referred pain may be projected from the spine to viscera and other structures lying within the territory of the lumbar and upper sacral dermatomes, or conversely, projected from pelvic and abdominal viscera to the spine. For example, pain caused by disease of the upper part of the lumbar spine may be referred to the medial flank, lateral hip, groin, and anterior thigh. This has been attributed to irritation of the superior cluneal nerves, which are derived from the posterior divisions of the first three lumbar spinal nerves and innervate the superior portions of the buttocks. Pain from the lower part of the lumbar spine is usually referred to the buttock and posterior thigh and is a result of irritation of lower lumbar spinal nerves, which activate the same pool of intraspinal neurons as the nerves that innervate the posterior thighs. Pain of this type is usually diffuse and has a deep, aching quality, but it tends to be more superficially projected. In general, the intensity of referred pain parallels that of local pain and maneuvers that alter local pain have a similar effect on referred pain. These areas of reference have been established by the pain induced by injection of hypertonic saline into the facet joints and their projection to sclerotomes (McCall and colleagues; Kellgren), as discussed in Chap. 7; however, others have pointed out that the sites of referred pain are inexact and cannot be relied on for precise anatomic localization (Sinclair and coworkers).

The opposite situation, in which pain from visceral diseases is referred to the lumbar spine, is usually modified by the state of activity of the viscera and sometimes by assuming an upright or supine posture. What is notable in comparison to pain referred from the spine to the viscera is that the character and temporal relationship of the pain have little relationship to movement of the spine.

Radicular or root pain has some of the characteristics of referred pain but differs in its greater intensity, distal radiation along the course of the nerve containing the affected root, and factors that excite it. The mechanism is stretching, irritation, or compression of a spinal root at any site within or proximal to the intervertebral foramen. The pain is sharp, often intense, and usually superimposed on the dull ache of referred pain; it nearly always radiates from a paracentral position near the spine or the buttock to some part of the lower limb. Coughing, sneezing, and straining characteristically evoke this sharp radiating pain, although each of these actions may also jar or move the spine and enhance local pain. Any maneuver that stretches the nerve root—for example, "straight-leg raising" or bending at the waist in cases of sciatica—evokes radicular pain. The patterns of radicular pain are described in the sections on herniation discs further on in the chapter, and the distribution of cutaneous innervation of the spinal roots is shown in Figs. 8-2 and 8-3. The most common pattern of root nerve pain is *sciatica*, which originates in the buttock and is projected along the posterior or posterolateral thigh. It results from irritation of the L5 or S1 nerve root (Ropper and Zafonte). Paresthesia or superficial sensory loss, soreness of the skin, tenderness in certain regions along the nerve, and loss of a tendon reflex usually accompany radicular pain. If the anterior roots are involved as well, there is weakness, atrophy, or muscular twitching.

In patients with severe circumferential constriction of the cauda equina due to spondylosis (*lumbar spinal stenosis*), sensorimotor impairment and referred pain are elicited by standing and walking. The symptoms are projected to the calves and the backs of the thighs thereby simulating the exercise-induced symptoms of iliofemoral arterial insufficiency—hence the term *spinal claudication* has been applied to the activity-induced symptoms of lumbar stenosis [see "Lumbar Stenosis (Spondylotic Caudal Radiculopathy)" later in this chapter].

A useful tenet is that referred pain from structures of the lower back (sometimes called *pseudoradicular*) does not usually project below the knees and is not accompanied by neurologic changes other than sometimes a vague numbness without demonstrable sensory impairment. This is in contrast to the pain of root compression. Pain resulting from *muscular spasm* usually occurs in relation to local spinal irritation and may be thought of as a nocifensive reflex for the protection of the diseased parts against injurious motion. Chronic muscular contraction may give rise to a dull, sometimes cramping ache. One can sometimes feel the tautness of the sacrospinalis and gluteal muscles and demonstrate by palpation that the pain is localized to them. However, except for the most severe degrees of acute injuries of the back, the spasms are difficult to detect and their contribution to low back pain has appeared to us to be relatively small.

In addition to assessing the character and location of the pain, one should determine the factors that aggravate and relieve it, its constancy, and its relationship to activity and to rest, posture, forward bending, coughing, sneezing, and straining. Frequently, the most important lead comes from knowledge of the mode of onset and the circumstances that initiated the pain. Inasmuch as many painful conditions of the back are the result of injuries incurred during work or in accidents, the possibility of exaggeration or prolongation of pain for purposes of compensation must

be kept in mind. The attribution of chronic back pain to anxiety or depression may at times be incorrect, but chronic back pain can certainly lead to these disorders, especially if sleep is disrupted (see further on under Obscure Low Back Pain and Psychiatric Disease).

Examination of the Lower Back

The main goals of the examination of the back are to differentiate pain that is caused by nerve root compression from musculoskeletal strains, metastatic spinal tumors, and infectious and inflammatory diseases of the spine and hips.

Some information may be gained by inspection of the back, buttocks, and lower limbs in various positions. The normal spine shows thoracic kyphosis and lumbar lordosis in the sagittal plane, which in some individuals may be exaggerated. In the coronal plane, the spine is normally straight or shows a slight curvature, particularly in women. One should observe the spine for excessive curvature, a list, flattening of the normal lumbar lordosis, presence of a gibbus (a sharp, kyphotic angulation usually indicative of a fracture), pelvic tilt or obliquity (Trendelenburg sign), and asymmetry of the paravertebral or gluteal musculature. A sagging gluteal fold suggests involvement of the S1 root. In sciatica, one may observe a flexed posture of the affected leg, presumably to reduce tension on the irritated nerve. Another configuration occurs in patients with a free fragment of lumbar disc material that has migrated posterolaterally, causing them to be unable to lie down and extend the spine.

The next step in the examination is observation of the spine, hips, and legs during motion. No advantage accrues from determining how much pain the patient can tolerate. More important is to determine when and under what conditions the pain begins or worsens. Observation of the patient's gait may disclose a subtle limp, a pelvic tilt, a shortening of step, or a stiffness of bearing—indicative of a disinclination to bear weight on a painful leg. One looks for limitation of motion while the patient is standing, sitting, and reclining. When standing, the motion of forward bending normally produces flattening and reversal of the lumbar lordotic curve and exaggeration of the thoracic curve. With lesions of the lumbosacral region that involve the posterior ligaments, articular facets, or sacrospinalis muscles and with ruptured lumbar discs, protective reflexes prevent flexion, which stretches these structures ("splinting"). Asa consequence, the sacrospinalis muscles remain taut and prevent motion in the lumbar part of the spine. Forward bending then occurs at the hips and at the thoracolumbar junction; also, the patient bends in such a way as to avoid tensing the hamstring muscles and putting undue leverage on the pelvis. In the presence of degenerative disc disease, straightening up from a flexed position is performed with difficulty.

Lateral bending is usually less instructive than forward bending but in unilateral ligamentous or muscular strain, bending to the opposite side aggravates the pain by stretching the damaged tissues. With unilateral sciatica, the patient may list to one side and strongly resists bending to the opposite side, and the preferred posture in standing is with the leg slightly flexed at the hip and knee. When the herniated disc lies lateral to the nerve root and displaces it medially, tension on the root is reduced and pain is relieved by bending the trunk to the side opposite the lesion; with herniation medial to the root, tension is reduced by inclining the trunk to the side of the lesion. An antalgic posture, referred to as *sciatic scoliosis*, is maintained by reflex contraction of the paraspinal muscles, which can be both seen and palpated. In walking, the knee is slightly flexed, and weight bearing on the painful leg is brief and cautious on the ball of the foot, giving a limp. It is particularly painful for the patient to go up and down stairs.

In the sitting position, flexion of the spine can be performed more easily, even to the point of bringing the knees in contact with the chest. The reason for this may be that knee flexion relaxes tightened hamstring muscles and relieves the stretch on the sciatic nerve. With lumbosacral disc lesions and sciatica, passive lumbar flexion causes little pain and is not limited as long as the hamstrings are relaxed and there is no stretching of the sciatic nerve. Thus, with the knees flexed to 90 degrees, sitting up from the reclining position is unimpeded and not painful; with knees extended, there is pain and limited motion (Kraus-Weber test). With vertebral disease, passive flexion of the hips is free, whereas flexion of the lumbar spine may be impeded and painful. Examination with the patient in the reclining position yields much the same information as in the standing and sitting positions.

The most helpful signs in detecting L5 or S1 nerve root compression are elicitation of sciatic pain with passive *straight-leg raising* when the patient is supine (Lasègue sign), which is possible up to almost 90° in normal individuals without hip disease; and variations of this test. Raising the straight leg places the sciatic nerve and its roots under tension, thereby producing radicular, radiating pain from the buttock through the posterior thigh if there is compression of these neural structures. During straight-leg raising, the patient can usually distinguish between the discomfort of ordinary tautness of the hamstring and the sharper, less familiar root pain, particularly when asked to compare the experience with that on the normal side. However, the straight leg raising may also cause an anterior rotation of the pelvis around a transverse axis, increasing stress on the lumbosacral joint and causing milder radiating pain if this joint is arthritic or otherwise diseased. *Straight raising of the opposite leg* ("crossed straight-leg raising," Fajersztajn sign) may also cause pain on the affected side and is a more specific but less sensitive sign of herniated disc than the Lasègue sign (Hudgkins). The many derivatives of the straight-leg raising sign include accentuation of pain by dorsiflexion of the foot (Bragard sign) or of the great toe (Sicard sign). With the patient standing, forward bending of the trunk will cause flexion of the knee on the affected side (Neri sign). Sciatica may be provoked by forced flexion of the head and neck, coughing, or pressure on both jugular veins, all of which increase the intraspinal pressure (Naffziger sign). Marked inconsistencies in response to these tests raise the suspicion of psychologic factors or of referred muscular pain.

In cases of lumbar root compression, pain may also be provoked by pressure along the course of the sciatic nerve at the points of Valleix (sciatic notch, retrotrochanteric

gutter, posterior surface of thigh, and head of fibula). Pressure at one point may cause radiation of pain and tingling down the leg.

A patient with lumbosacral strain or disc disease (except in the acute phase or if the disc fragment has migrated laterally) can usually extend or hyperextend the spine with little or no aggravation of pain. If there is an active inflammatory process or fracture of the vertebral body or posterior elements, hyperextension may be markedly limited. In disease of the upper lumbar roots, hyperextension of the leg with the patient prone is the motion that is most limited and reproduces pain; however, in some cases of lower lumbar disc disease with thickening of the ligamentum flavum, this movement is also painful.

Maneuvers in the lateral decubitus position yield less information but may be useful in eliciting joint disease. In cases of sacroiliac joint disease, abduction of the upside leg against resistance reproduces pain in the sacroiliac region, sometimes with radiation of the pain to the buttock, posterior thigh, and symphysis pubis. Hyperextension of the upside leg with the downside leg flexed is another test for sacroiliac disease. Rotation and abduction of the leg evoke pain in a diseased hip joint and with *trochanteric bursitis*. A helpful indicator of hip disease as distinguished from spine disease is the *Patrick test*: With the patient supine, the heel of the offending leg is placed on the opposite knee and pain is evoked by depressing the flexed leg and externally rotating the hip.

Palpation and percussion of the spine are the last steps in the examination. It is preferable to first palpate the regions that are the least likely to evoke pain. At all times, the examiner should know what structures are being palpated (Fig. 10-2). Localized tenderness is seldom pronounced in disease of the spine because the involved structures are so deep, but there are exceptions, for example, tumor in the spinal bones and epidural abscess, and, pathologic or traumatic compression fracture, and occasionally disc herniation.

Tenderness over the interspinous ligaments or over the region of the articular facets between the fifth lumbar and first sacral vertebrae is consistent with lumbosacral disc disease (see Fig. 10-2, sites *2* and *3*). Tenderness in this region and in the sacroiliac joints is also a frequent manifestation of ankylosing spondylitis. Arthritic changes at a facet joint cause the same tenderness. Tenderness over the costovertebral angle often indicates genitourinary disease, adrenal disease, or an injury to the transverse process of the first or second lumbar vertebra (see Fig. 10-2, site *1*). Tenderness on palpation of the paraspinal muscles may signify a strain of muscle attachments or injury to the underlying transverse processes of the lumbar vertebrae. Focal pain in the same parasagittal line along the thoracic spine points to inflammation of the costotransverse articulation between spine and rib (*costotransversitis*). Other sites of tenderness and the structures implicated by disease are shown in the figure.

In palpating the spinous processes, one notes any deviation in the lateral plane (this may be indicative of fracture or arthritis) or in the anteroposterior plane. A "step-off" forward displacement of the spinous process and exaggerated lordosis are important clues to the presence of *spondylolisthesis* (see further on).

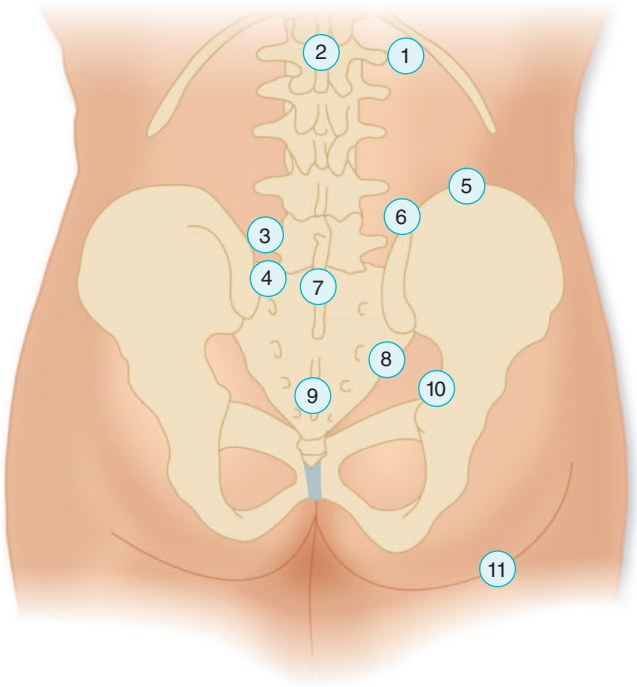

Figure 10-2. (*1*) Costovertebral angle. (*2*) Spinous process and interspinous ligament. (*3*) Region of articular facet (fifth lumbar to the first sacral). (*4*) Dorsum of sacrum. (*5*) Region of iliac crest. (*6*) Iliolumbar angle. (*7*) Spinous processes of fifth lumbar and first sacral vertebrae (tenderness = faulty posture or occasionally spina bifida occulta). (*8*) Region between posterior superior and posteroinferior spines. Sacroiliac ligaments (tenderness = sacroiliac sprain, often tender, with fifth lumbar or first sacral disc). (*9*) Sacrococcygeal junction (tenderness = sacrococcygeal injury; i.e., sprain or fracture). (*10*) Region of sacrosciatic notch (tenderness = fourth or fifth lumbar disc rupture and sacroiliac sprain). (*11*) Sciatic nerve trunk (tenderness = ruptured lumbar disc or sciatic nerve lesion).

Abdominal, rectal, and pelvic examinations may lead to the discovery of neoplastic or inflammatory diseases in these body parts that are referred to the lower part of the spine.

On completion of the examination of the back and legs, one turns to a search for motor, reflex, and sensory changes in the lower extremities (see "Herniation of Lumbar Intervertebral Discs," further on in this chapter).

Diagnostic Procedures

Depending on the circumstances, these may include a blood count, the acute phase reactants, erythrocyte sedimentation rate, and C-reactive protein (helpful in screening for spinal osteomyelitis, epidural abscess, or myeloma). Other useful blood tests are calcium, alkaline phosphatase, and prostate-specific antigen (if one suspects metastatic carcinoma of the prostate); serum protein immunoelectrophoresis (myeloma proteins); in special cases, a tuberculin test or serologic test for Brucella; a test for rheumatoid factor; and human leukocyte antigen (HLA) typing (for ankylosing spondylitis), all in the appropriate settings.

Conventional radiographs of the lumbar spine in the anteroposterior, lateral, and oblique planes (preferably with the patient standing) are not very useful in the routine

evaluation of low back pain and sciatica, but they can disclose some information. Readily demonstrable in plain films are narrowing of the intervertebral disc spaces, facet or vertebral overgrowth, displacement of vertebral bodies (spondylolisthesis), compression and other fractures of the spine, and most importantly, unsuspected infiltration of bone by cancer or myeloma. However, in cases of suspected disc herniation or tumor of the spine, one generally proceeds directly to MRI or CT if subsequent action is to be taken.

As mentioned at different points in this chapter, there is a high rate of inconsequential lumbar spine abnormalities in the general population who have no back or radicular symptoms, but disc herniation has been found on MRI in under 1 percent of people without back pain (Jensen and colleagues). Administration of gadolinium at the time of MRI enhances regions of inflammation and tumor but is not particularly helpful in cases of degenerative and disc disease of the spine. The decision to administer an intravenous contrast agent depends on the degree of suspicion of infiltration of the bones or spinal canal by cancer or the need to detect spinal nerve root tumors. MRI has replaced conventional myelography for the examination of spinal disease, but the latter examination, when combined with CT, provides detailed information about the dural sleeves that surround the spinal roots, disclosing subtle truncations caused by laterally situated disc herniations and at times revealing surface abnormalities of the spinal cord, such as arteriovenous malformations (AVMs). When MRI is precluded for technical reasons, CT, with or without myelography, remains useful for diagnosis.

Electromyography (EMG) is also very helpful in suspected root and nerve diseases as indicated further on in the discussion of lumbar disc disease. However, all the aforementioned tests must be interpreted in the context of the history and clinical examination; otherwise, they are subject to overuse and overinterpretation.

Conditions Giving Rise to Pain in the Lower Back

Back Pain from Visceral Disease

Peptic ulcer disease and carcinoma of the stomach and pancreas most typically induce pain in the epigastric region. However, if the posterior stomach wall is involved, particularly if there is retroperitoneal extension, the pain may be felt in the thoracic spine, centrally, or on one or both sides. If intense, it may seem to encircle the body. The back pain tends to reflect the temporal characteristics of the pain from the affected organ; for example, if caused by peptic ulceration, it appears about 2 h after a meal and is relieved by food and antacids. Diseases of the pancreas are apt to cause pain in the back, being more to the right of the spine if the head of the pancreas is involved and to the left if the body and tail are implicated. Retroperitoneal neoplasms—for example, lymphomas, renal cell tumors, sarcomas, and other malignancies—may evoke pain in the lower thoracic or lumbar spine with a tendency to radiate to the lower part of the abdomen, groins, anterior thighs, or flank. An aneurysm of the abdominal aorta may induce pain localized to an analogous region of the spine. The sudden appearance of lumbar pain in a patient receiving anticoagulants should arouse suspicion of retroperitoneal bleeding; this pain may also be referred to the groin. Retroperitoneal appendicitis may have an odd referral of pain to the low flank and back.

Gynecologic disorders may manifest themselves by back pain, and their diagnosis may prove difficult. Thorough abdominal palpation, as well as vaginal and rectal examination by an experienced physician, supplemented by ultrasonography and CT scanning or MRI, usually discloses the source of pain. The uterosacral ligaments are the most important pelvic source of chronic back pain. Endometriosis or carcinoma of the uterus (body or cervix) may invade these structures, causing pain localized to the sacrum either centrally or more to one side. In endometriosis, the pain begins premenstrually and often merges with menstrual pain, which also may be felt in the sacral region. Rarely, cyclic engorgement of ectopic endometrial tissue may give rise to sciatica and other radicular pain. Changes in posture may also evoke pain here when a fibroma of the uterus pulls on the uterosacral ligaments. Low back pain with radiation into one or both thighs is a common phenomenon during the last weeks of pregnancy.

Pain from *neoplastic infiltration of pelvic nerve plexuses* may be projected to the low back and is continuous, becoming progressively more severe; it tends to be more intense at night and may have a burning quality. The primary lesion can be inconspicuous and may be inevident on pelvic or rectal examination. Sarcoidosis may produce a similar painful plexopathy and diabetic infarction or inflammation of the lumbar roots and proximal plexus can project pain to the paraspinal or gluteal region (Chap. 31).

Traumatic Disorders of the Low Back

In severe acute lumbar injuries from direct impact, the examiner must be careful to avoid further damage and movements should be kept to a minimum until an approximate diagnosis has been made. If the patient complains of pain in the back immediately after impact and cannot move the legs, the spine may have been fractured and the cord or cauda equina, compressed or crushed. The neck should not be manipulated if there has been serious cervical or cranial injury, and the patient should not be allowed to sit up. (See Chap. 42 for further discussion of spinal cord injury.) Lesser degrees of injury, such as sprains and strains, are ubiquitous and can be handled with less caution because they do not involve compression of neural structures.

Acute sprains and strains The terms *lumbosacral strain* and *sprain* are used loosely and it is difficult to differentiate them. Furthermore, what was formerly referred to as “sacroiliac strain” or “sprain” is now known to be caused in some instances, by disc disease. The term *acute low back strain* may be preferable for minor, self-limiting injuries that are usually associated with lifting heavy loads when the back is in a mechanically disadvantaged position, or there may have been a fall, prolonged uncomfortable postures such as air travel or car rides, or sudden unexpected motion, as may occur in an auto accident.

Nonetheless, the discomfort of acute low back strain can be severe, and the patient may assume unusual postures related to spasms of the lower lumbar and sacrospinalis muscles. The pain is usually confined to the lower part of the back, in the midline, across the posterior waist, or just to one side of the spine. The diagnosis of lumbosacral strain is dependent on the biomechanics of the injury or activity that precipitated the pain. The injured structures are identified by the localized tenderness, augmentation of pain by postural changes—for example, bending forward, twisting, or standing up from a sitting position, and by the absence of signs of radicular involvement. In more than 80 percent of cases of acute low back strain of this type, the pain resolves in a matter of several days or a week, even with no specific treatment.

Sacroiliac joint and ligamentous strain is the most likely diagnosis when there is tenderness over the sacroiliac joint and pain vaguely radiating to the buttock and proximal posterior thigh, but this needs to be distinguished from the sciatica of a ruptured intervertebral disc. Strain is characteristically worsened by abduction of the thigh against resistance and may produce pain that is also felt in the symphysis pubis or groin. It, too, responds within days or a week or two to conservative management.

Treatment of acute low back strain and non-descript back pain The pain of muscular and ligamentous strains is usually self-limiting, responding to simple measures in a relatively short period of time. The basic principle of therapy in both disorders is to avoid reinjury and reduce the discomfort of painful muscles. As a result of several studies that have failed to demonstrate a benefit of bed rest, recent practice has been to allow activity if the patient is able and to prescribe exercises designed to stretch and strengthen trunk (especially abdominal) muscles, overcome faulty posture, and increase the mobility of the spinal joints (Hagen). Despite this modern approach, the authors can affirm from personal experience that some injuries produce such discomfort that arising from a bed or chair is simply not initially possible (Vroomen et al). Lying on the side with knees and hips flexed or supine with a pillow under the knees favor relief of pain. With strains of the sacrospinalis muscles and sacroiliac ligaments, the optimal position is mild hyperextension, which is effected by having the patient lie with a small pillow under the lumbar portion of the spine or by lying prone. Local physical measures—such as the application of ice in the acute phase and, later, heat and massage—may relieve pain temporarily. Nonsteroidal anti-inflammatory drugs (NSAIDs) may be given liberally during the first few days unless there are contraindications to these agents. It should be emphasized, however, the use of NSAIDs or narcotic analgesics for many months is hazardous and should also be avoided. Muscle relaxants (e.g., cyclobenzaprine, carisoprodol, metaxalone, and diazepam) serve mainly to make bed rest more tolerable. Traction, formerly a popular treatment, is no longer used. When weight bearing is resumed, discomfort may be diminished by a light lumbosacral support, but many orthopedists refrain from prescribing this aid.

The use of *spinal manipulation*—practiced by chiropractors, osteopaths, and others—has always been a contentious matter among neurologists and neurosurgeons, partly because of unrealistic therapeutic claims relating to spinal alignment and adjustment made in treating diseases other than low back derangements. When the supporting elements of the spine (pedicles, facets, and ligaments) are not disrupted, chiropractic manipulation of the lumbar spine has provided acute relief to several of our patients with low back strain or facet pain. At issue is the durability of the effect, particularly the need for repeated spinal adjustments. A type of slow muscle stretching and joint distraction (axial traction on a joint) administered by physiatrists and physical therapists is quite similar. It must be recognized that many patients seek chiropractic manipulation on their own for back complaints, often before seeing a physician and may not disclose this information to the physician. One randomized British trial has shown manipulation to be superior to analgesics and bed rest in returning patients to work after a minor back injury (Meade et al). Some other trials have corroborated this finding (Hadler et al), whereas others have not, or, often, the results have been ambiguous. For example, in a comparison of chiropractic, physical therapy (using the McKenzie method), and simple instruction to the patient from a booklet, manipulation yielded a slightly better outcome at the end of a month (Cherkin and colleagues).

Despite hypotheses offered by practitioners of spinal manipulation, the mechanism of pain relief is not known. The popping sound created by rapid and forceful distraction of the facet joints (and putatively due to nitrogen coming out of solution in the joint fluid) seems not to be necessary for pain relief. It seems unlikely that mundane low back pain represents minor subluxation.

Chronic and recurrent low back syndrome Often the symptoms of low back strain are recurrent and more chronic in nature, being regularly exacerbated by bending or lifting, suggesting that postural, muscular, and arthritic factors play a role. This is the most common syndrome seen in spine clinics, more often in men than in women.

Insidiously, or after some unusual activity that has the potential for producing spine trauma, the patient develops aching pain in the low back, increased by certain movements and attended by stiffness. The pain may additionally have a restricted radiation into the buttocks and posterior thigh, thereby simulating root compression. There are no motor, sensory, or reflex abnormalities. Imaging usually reveals some combination of osteoarthropathy, changes in vertebral discs, osteoarthritic changes in apophyseal joints, and sometimes osteoporosis or slight spondylosis, or they may be entirely normal. Treatment with short-duration bed rest, analgesics, and physiotherapy, as outlined for acute strains, helps to relieve the symptoms, and most patients recover within a few weeks, only to have a recurrence of similar pains in the future.

In the authors' experience, chronic low back pain, discussed below, has been less successfully treated by manipulative procedures, but there are some patients who testify to improvement in their clinical state, and admittedly, the medical profession has little to offer in most cases and the rate of spontaneous improvement is high. The results for acute and chronic back pain with another popular approach, acupuncture, have been even less beneficial,

most studies showing it to be no more effective than sham needle treatment (Tudler et al).

Recurrent attacks are typical of degenerative spine disease that affects the vertebrae and facet joints. Usually, the origin of the pain cannot be assigned with certainty to spinal, joint, or muscular injury. Quite often, changing the firmness of the mattress (in either direction) is helpful. Compensation relating to injuries at work or to an accident and related legal matters often prolong and intensify the reported disability, but there are, of course, many legitimate injuries that occur in these circumstances.

Vertebral fractures Fractures of lumbar vertebral bodies are usually the result of flexion injuries. Such trauma may occur in a fall or jump from a height (if the patient lands on his feet, the calcanei may also be fractured) or as a result of an auto accident or other violent impact. If the injury is severe, it may cause a fracture dislocation, a *burst fracture* of one or more vertebral bodies, or an asymmetrical fracture of a pedicle, lamina, or spinous process; most often, however, there is asymmetrical loss of height of a vertebral body (*compression fracture*), which may be extremely painful at the onset. When compression or other fractures occur with minimal trauma (or spontaneously), the bone has presumably been weakened by some pathologic process. Most of the time, particularly in older individuals, osteoporosis is the cause of such an event, but there are many other causes, including osteomalacia, hyperparathyroidism, prolonged use of corticosteroids, myeloma, metastatic carcinoma, and other conditions that are destructive of bone. Spasms of the lower lumbar muscles, limitation of all movements of the lumbar section of the spine, and the radiographic appearance of the damaged lumbar portion (with or without neurologic abnormalities) are the basis of clinical diagnosis. The pain is usually immediate, although occasionally it may be delayed for hours or exceptionally, days after injury.

A fractured transverse process, which is almost always the result of high-impact rotary injury of the spine causing the muscular attachments to pull the process off the pedicle, and also causes tearing of the paravertebral muscles and a local hematoma, producing deep tenderness at the site of the injury and limitation of all movements that stretch the lumbar muscles. The imaging findings, particularly MRI, confirm the diagnosis. In some circumstances, tears of the paravertebral musculature may be associated with extensive bleeding into the retroperitoneal space; this produces paraspinal or groin pain and proximal leg weakness with loss of the patellar reflex on the affected side. There may be a delayed subcutaneous hematoma in the flanks due to seepage of blood from the retroperitoneal space (Grey Turner sign).

For the mundane thoracic and lumbar fractures associated with osteoporosis, bed rest, and analgesics are usually adequate. In the past decades, several mechanical approaches to reducing pain have been investigated. The injection of various materials directly into the fracture site within the vertebral body (vertebroplasty) attained popularity because of reports of marked pain relief. Several large trials have addressed the use of vertebroplasty and given conflicting results. Perhaps one of the best conducted of these, with a placebo control group, concluded that there was no durable benefit; however, these two studies included patients with fractures up to a year old and the studies apply specifically to osteoporotic fractures (Buchbinder et al; Kallmes et al). Having witnessed a few patients with almost immediate and remarkable relief of severe pain, we are uncertain of the best course but acknowledge that vertebroplasty is probably not an effective treatment for the majority of patients. Further discussion can be found in reviews on the subject (Ensrud and Schousboe).

Herniation of Lumbar Intervertebral Discs (Table 10-1)

This condition is a major cause of severe and chronic or recurrent low back and leg pain. It occurs mainly during the third and fourth decades of life when the nucleus pulposus is still gelatinous and can rupture through a tear in the annulus. The disc between the fifth lumbar or first sacral vertebrae (L5-S1) is most often involved, and, with decreasing frequency, that between the fourth and fifth (L4-L5), third and fourth (L3-L4), second and third (L2-L3), and—quite infrequently—the first and second (L1-L2) lumbar vertebrae. Disc disease is less common but well described in the thoracic portion of the spine. It is frequent in the cervical spine, especially at the fifth and sixth and the sixth and seventh cervical vertebrae (see further on).

The likely cause of a herniated lumbar disc is a flexion injury, but a considerable proportion of patients do not recall a traumatic episode. Degeneration of the nucleus pulposus, the posterior longitudinal ligaments, and particularly the annulus fibrosus may have taken place silently or have been manifest by mild, recurrent lumbar ache. A sneeze, lurch, or other trivial movement may then cause the nucleus pulposus to herniate, pushing the frayed and weakened annulus posteriorly. A fragment of the nucleus protrudes through a tear in the annulus, usually to one side or the other (sometimes in the midline), where it impinges on a root or roots and causes the characteristic sciatic or other radicular pain and neurologic signs. In more severe cases of disc rupture, a small piece of the nucleus becomes entirely extruded as a "free fragment" and is mobile enough to affect a root at an adjacent level or to give rise to unusual changes in radicular pain with various body positions as noted below. Large protrusions cause pain by compressing the adjacent root against the articular apophysis or lamina. The protruded material may shrink over time, presumably from desiccation, but often there is continued chronic irritation of the root or later posterior osteophyte formation.

Clinical syndromes of lumbar disc herniation The fully developed syndrome of the common herniated (the terms ruptured and prolapsed are used equivalently) intervertebral lower lumbar disc consists of (1) pain in the sacroiliac region, radiating into the buttock, thigh, and the calf, a symptom termed *sciatica*; (2) a stiff or unnatural spinal posture; and often (3) some combination of paresthesia, weakness, and reflex impairment.

Sciatic pain is usually perceived by the patient as originating deep in the buttock or gluteal fold and radiating to the posterolateral thigh; it may progress to the calf and ankle—to the medial malleolus (L4), lateral malleolus (L5), or heel (S1). Distal radiation to the foot is infrequent and should

raise concern of an alternative process. Abortive forms may produce aching discomfort only in the lower buttock or proximal thigh and occasionally only in the lower hamstring or upper calf. With the most severe pain, the patient is forced to stay in bed, avoiding the slightest movement; a cough, sneeze, or strain is intolerable. The most comfortable position is usually lying on the back with legs flexed at the knees and hips and the shoulders raised on pillows to obliterate the lumbar lordosis. For some patients, a lateral decubitus position is more comfortable. Free fragments of disc that find their way to a lateral and posterior position in the spinal canal may produce the opposite situation, one whereby the patient is unable to extend the spine and lie supine. Sitting and standing up from a sitting position may be particularly painful in patients with a free fragment. The presence of lumbar disc disease, even frank rupture, bears an inconsistent relationship to low back pain.

Elongation of the nerve root by straight-leg raising or by flexing the leg at the hip and extending it at the knee (Lasègue maneuver, as discussed earlier) is the most consistent provoking sign. The signs of more severe spinal root compression are impairment of sensation, loss or diminution of tendon reflexes, and muscle weakness, as summarized in Table 10-1.

Generally, lumbar disc herniation compresses the root of the level just below the herniation (see below). Herniations of the intervertebral lumbar discs occur most often between the fifth lumbar and first sacral vertebrae (compressing the S1 root; Fig. 10-3) and between the fourth and fifth lumbar vertebrae (compressing the L5 root). *Lesions of the fifth lumbar root (L5)* produce pain in the region of the hip and posterolateral thigh (i.e., sciatica) and, in more than half such cases, lateral calf (to the lateral malleolus), and less often, the dorsal surface of the foot and the first or second and third toes. Paresthesia may be felt in the entire territory or only in its distal parts. The tenderness is in the lateral gluteal region and near the head of the femur. Weakness, if present, involves the extensors of the big toe and foot and the foot invertors (a distinguishing feature of foot drop originating from peroneal nerve damage, which spares inversion because it is a tibial nerve function). The ankle jerk may be diminished (more often it is normal), but the knee jerk is hardly ever altered unless there is an anomalous conjoined L4 and L5 root. In only a few patients is a foot drop (referable mainly to the L5 root) or weakness of plantar flexion (referable to the S1 root) the main feature of disc protrusion. Compression of the fourth, or sometimes fifth, lumbar root may occur without any change in the

Table 10-1

FEATURES OF THE MAIN ROOT-COMPRESSIVE SYNDROMES DUE TO CERVICAL AND LUMBAR DISC HERNIATION*

INTERVERTEBRAL DISC SPACE	ROOT AFFECTED	PAIN REFERRAL	WEAKNESS	REFLEX CHANGE	ADDITIONAL FEATURES
C4-C5	C5	Shoulder, trapezius	Supra- and infraspinatus deltoid, slight biceps weakness	Slightly diminished biceps reflex	
C5-C6	C6	Trapezius ridge and tip of shoulder, radiation to anterior upper arm, thumb, and index finger	Biceps, brachioradialis, extensor carpi radialis	Diminished biceps and supinator reflex	Tenderness over spine or scapula and suprascapular region; paresthesias in thumb and index finger
C6-C7	C7	Shoulder, axilla, posterolateral arm, elbow, and middle finger	Triceps, wrist extensors	Diminished or absent triceps jerk	Tenderness over medial scapula and supraclavicular region or triceps. May complain of paresthesias in most of the fingers
C7-T1	C8	Medial forearm	Intrinsic hand muscles	Slight or no decrease in triceps reflex	Mimics ulnar palsy
L2-L3	L3	Anterior thigh, over knee	Thigh adductor, quadriceps	Absent or diminished knee reflex	
L3-L4	L4	Anterolateral thigh, medial foreleg	Anterior tibial, sometimes with partial foot drop	Diminished or normal knee reflex	
L4-L5	L5	Posterolateral gluteal sciatica; lateral thigh, anterolateral foreleg, dorsal foot, lateral malleolus, and great or second and third toe	Extensor hallucis longus and extensor digitorum brevis; some weakness of anterior tibialis, sometimes with foot drop	Unaffected (except posterior tibial)	Pain with straight-leg raising and variant tests; tenderness over fourth lumbar lateral process and lateral gluteal region
L5-S1	S1	Midgluteal sciatica; posterior thigh, posterolateral leg, lateral foot, heel, or lateral toes	Plantar-flexor and hamstring weakness	Absent or diminished ankle reflex	Pain with straight-leg raising and variant tests; tenderness over lumbosacral (L5-S1) joint and sciatic notch; discomfort walking on heels

*For pattern of sensory loss, see dermatomal diagram in Figs. 8-3 and 8-4.

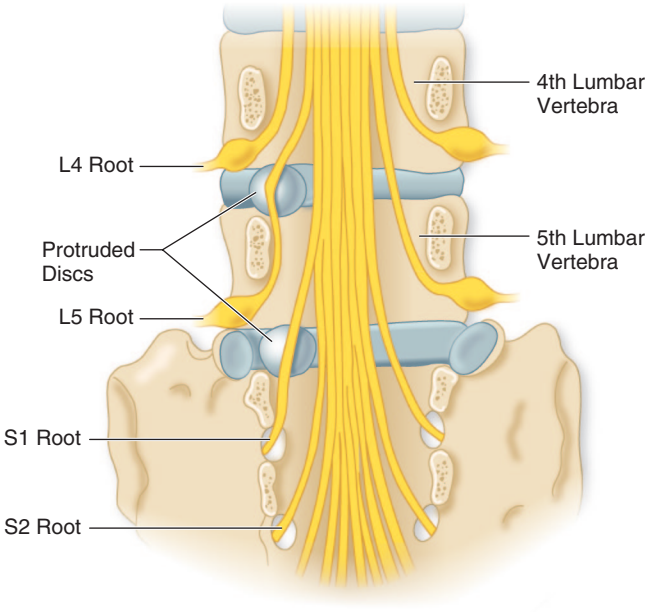

Figure 10-3. Mechanisms of compression of the fifth lumbar and first sacral roots. A lateral disc protrusion at the L4-L5 level usually involves the fifth lumbar root and spares the fourth; a protrusion at L5-S1 involves the first sacral root and spares the fifth lumbar root. Note that a more medially placed disc protrusion at the L4-L5 level (cross-hatched) may involve the fifth lumbar root as well as the first (or second and third) sacral root.

tendon reflexes. Bilaterality of symptoms and signs is rare, as is sphincteric paralysis, but they occur with large central protrusions that compress the cauda equina.

With *lesions of the first sacral root (S1)*, the pain is felt in the midgluteal region, mid-posterior part of the thigh, posterior region of the calf to the heel, outer plantar surface of the foot, and fourth and fifth toes. Tenderness is most pronounced over the midgluteal region. Paresthesia and sensory loss are mainly in the lower part of the leg and outer toes, and weakness, if present, involves the plantar flexor muscles of the foot and toes, abductors of the toes, and hamstring muscles. The Achilles reflex is diminished or absent in the majority of cases. In fact, loss of the Achilles reflex may be the only objective sign. Walking on the toes is more difficult and uncomfortable than walking on the heels because of weakness of the plantar flexors.

The less-frequent lesions of the *third (L3) and fourth (L4) lumbar roots* give rise to pain in the anterior part of the thigh and knee and anteromedial part of the leg (fourth lumbar), with corresponding sensory impairment in these dermatomal distributions. The knee jerk is diminished or abolished. Third lumbar (L3) motor root lesions may weaken the quadriceps, thigh adductor, and iliopsoas and reduce the knee jerk; L4 root lesions weaken the anterior tibial innervated muscles, sometimes with a mild foot drop and variably affect the knee jerk. First lumbar (L1) root pain is projected to the groin, and L2, to the lateral hip.

There may be a distinctive syndrome associated with extreme lateral disc protrusions, particularly those situated within the proximal portion of the intervertebral spinal foramina. Unremitting radicular pain without back pain and a tendency to worsen with extension of the back and torsion toward the side of the herniation is characteristic. Also, in rare instances of lumbar *intradural* disc rupture, there may not be sciatic pain because the free fragment in the subarachnoid space does not impinge on the roots of the cauda equina. Both of these configurations may confound clinical and imaging diagnosis and make surgery more difficult.

Rarer still, and often clinically obscure, are protrusions of *thoracic intervertebral discs* (0.5 percent of all surgically verified disc protrusions, according to Love and Schorn). The four lowermost thoracic interspaces are the most frequently involved. Trauma, particularly hard falls on the heels or buttocks, is an important causative factor. Deep boring spine pain; root pain circling the body or projected to the abdomen or thorax (sometimes simulating visceral disease); paresthesia below the level of the lesion; loss of sensation; both deep and superficial; and paraparesis or paraplegia are the usual clinical manifestations.

A herniated lumbar disc at one interspace may compress more than one root (see Fig. 10-3), and it follows that the symptoms reflect this. Furthermore, the above descriptions of single root compression refer mainly to signs and symptoms of typical posterolateral disc protrusion. Very large *central disc protrusions* may compress the entire cauda equina with a dramatic syndrome that includes intense low back and bilateral sciatic pain, incomplete paraparesis, loss of both ankle jerks, and, most characteristic, varying degrees of urinary retention and incontinence. This circumstance usually demands surgical attention.

Anomalies of the lumbosacral roots may lead to errors in localization (Postacchini et al). The combined rupture of two or more discs occurs occasionally and complicates the clinical picture. When both the L5 and S1 roots are compressed by a large herniated disc, the signs of the S1 lesion usually predominate.

Herniation may occur directly into the adjacent vertebral body, giving rise to a *Schmorl nodule*. In such cases, there are no signs of nerve root involvement although back pain may be present, sometimes recurrent and referred to the thigh. Most often, these circular radiographic densities adjacent to the endplate of the vertebral body are found incidentally on CT or MRI.

Diagnosis When all components of the lumbar disc syndrome are present, diagnosis is virtually assured. With persistent symptoms, many neurologists prefer to corroborate their clinical impression with an MRI of the spine from L3 to S1 (Fig. 10-4). This, of course, is not necessary if the pain is manageable and surgery is not contemplated (see further on). MRI is favored over CT because of the advantages of the sagittal image and the clarity of the anatomic relationships between discs and nerve roots (Epstein). MRI also excludes herniations at other sites or an unsuspected tumor. As indicated earlier, in cases in which MRI is not possible or has been unrevealing, we often turn to CT with myelography for a refined definition of the root sleeves and use the EMG to corroborate subtle findings. At the lumbosacral junction, there is a wide gap between the posterior margins of the vertebrae and the dural sac so that a lateral or central protrusion of the L5-S1 disc may fail to distort the dural margin and remain undetected on myelography.

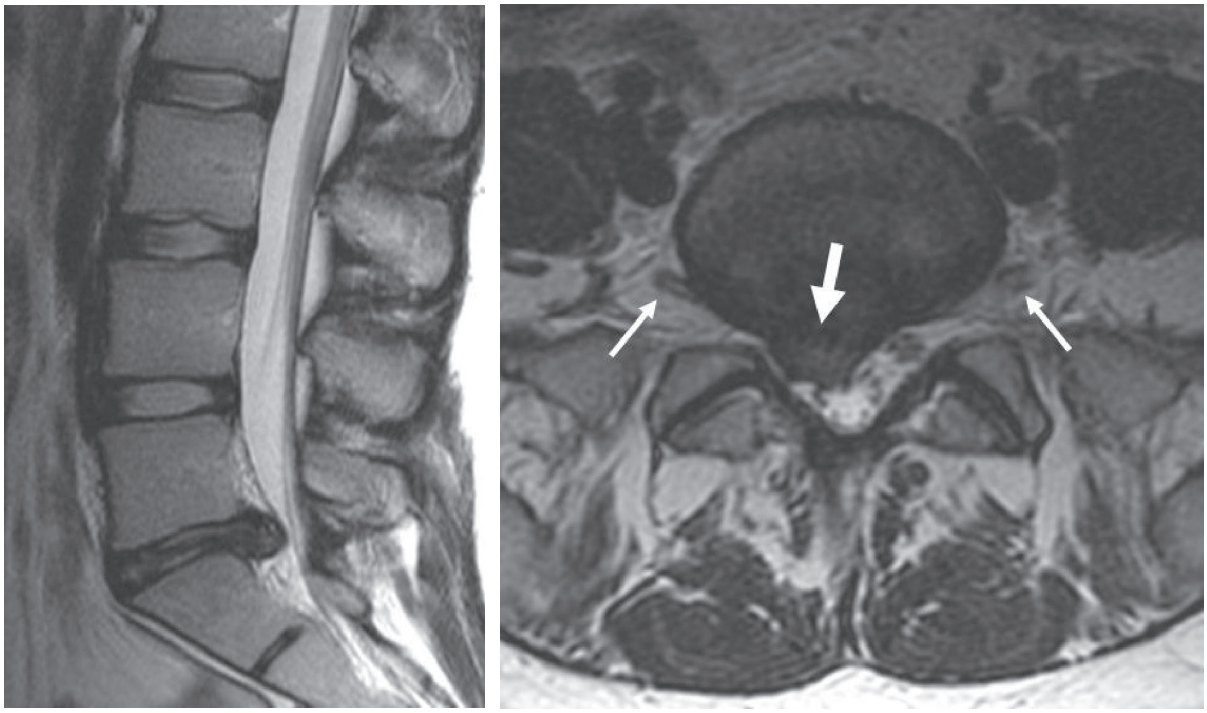

Figure 10-4. Lumbar disc herniation as shown by T2-weighted MRI. *A*. Sagittal view of a large herniated nucleus pulposus at L5-S1. The posteriorly protruding disc material indents and elevates the anterior thecal sac and narrows the spinal canal. The extruded material has the same signal characteristics of the parent disc. The disc space at this level is narrowed and the disc is less hyperintense than normal because of desiccation and the extruded component. *B*. Axial view showing the focal right paracentral posterior disc herniation (large arrow) protruding into the canal and compressing the traversing nerve root (the right S1 nerve root) at this level. The exiting L5 roots above are not affected and can be seen laterally to the disc (small arrows).

Many disc abnormalities observed on MRI and loosely referred to as "herniation" are actually disc bulges and can be considered incidental findings unrelated to the patient's symptoms. In an MRI study of the lumbar spine in 98 asymptomatic adults, more than half had a symmetrical extension of a disc (or discs) beyond the margins of the interspace that qualifies as bulging (Jensen and colleagues). In 27 percent, there was a focal or asymmetrical extension of the disc beyond the margin of the interspace (*protrusion*), and in only 1 percent was there more extreme extension of the disc (*extrusion*). These findings emphasize the importance of using precise terms in describing the imaging abnormalities and evaluating them strictly in the context of the patient's symptoms.

The needle EMG study in patients with compressive radiculopathy is abnormal, showing fibrillation potentials in denervated muscles referable to the affected root after 1 or 2 weeks of symptoms in more than 90 percent of cases in one study (Leyshon and colleagues) but less frequently in others. The sensory nerve action potentials remain normal, even in the presence of sensory symptoms, because the nerve root compression is proximal to the dorsal root ganglion. Loss or marked asymmetry of the H reflex is another useful indication of S1 radiculopathy, but this finding simply corroborates the loss of an Achilles reflex. The finding of denervation potentials in the paraspinal muscles (indicating root rather than peripheral nerve lesions) and in muscles that conform to a root distribution is also helpful, but at least 2 or 3 weeks must have elapsed from the onset of root pain for these findings to be present. We emphasize that, while useful information is gained from EMG, it is not routinely required and provides mainly corroborating data.

Treatment of Ruptured Lumbar Disc

In the treatment of an *acute or chronic rupture of a lumbar disc*, it seems reasonable to advise avoidance of physical activities and positions that cause pain and suggest bed rest if it appears to be helpful to the patient. But even this time-honored tenet has been strongly questioned by the results of several studies (Vroomen et al 1999). It would appear that the main benefit is simply that time has passed and the expected resolution of pain has taken its course in many patients. The patient may suffer minor recurrence of pain but should be able to continue some of his usual activities. The results of several surveys give guidance that is conservative in the treatment of sciatica in so far as sciatica resolves without treatment in one-third of patients within 2 weeks and in three-quarters of patients within 3 months (Vroomen et al 2002).

Analgesic medications, either NSAIDs or opioids, may be required for a few days. In a few patients with severe sciatica, we have been impressed with the temporary relief afforded by administration of oral dexamethasone (4 mg every 8 h) for several days, although this approach has

uncertain effects according to several systematic surveys (Ropper and Zafonte). The treatment of nerve root compression with repeated epidural injections of corticosteroids has enjoyed periods of popularity, but controlled studies have failed to confirm a sustained efficacy (White et al; Cuckler et al), and it is not without complications. As with many similar studies, short-term improvement with epidural steroid injection and the ultimate need for surgery was not altered (Carette and colleagues 1997). Nevertheless, we and many other neurologists and pain clinics have not discarded this form of treatment in view of notable success in selected patients, even if short-lived and only aiding in mobilizing the patient and relieving discomfort.

Surgical relief of lumbar disc disease After Mixter and Barr popularized the concept of prolapsed disc almost a century ago (now more properly called herniation), all sciatica and lumbar pains were ascribed to this condition. Operations became widely practiced, not only for frank disc protrusion but also for "hard discs" (unruptured) and related pathologies of the spine. In large referral centers, the surgical results became decreasingly satisfactory until approximately 25 years ago as many patients were being seen with unrelieved postlaminectomy pain as with unoperated ruptured discs. At one time, the role of surgery was much debated; now, it is mainly the timing of surgery that is a concern.

Urgent surgery is generally required or an acute compression of the cauda equina by massive disc extrusion causing bilateral sensorimotor loss and sphincteric paralysis. Although not necessarily the recommended course, it should be pointed out that there are infrequent instances where even a dramatic syndrome of cauda equina compression has resolved after weeks of observation.

If the pain and neurologic findings do not subside in response to conservative management or the patient suffers frequent disabling acute episodes, surgical treatment must be considered. Useful information regarding surgery and its timing can be ascertained from a randomized Dutch trial (Peul and colleagues), the Spine Patients Outcomes Research Trial (SPORT) (Weinstein and coworkers 2006), and others (Bailey et al). In the first mentioned trial, a large proportion of patients assigned to treatment with physical therapy and pain medications had enough pain that they nevertheless required surgery after several months. Patients assigned initially to surgery by microdiscectomy also had considerably faster relief of back and sciatic pain, but at the end of a year, both groups had minimal disability and similar degrees of minor pain. The implications of this study are that avoiding surgery initially does not have adverse consequences, but if pain relief and mobilization are the aims, surgery can be preferable. In the second cited trial, there was an even greater crossover between conservative and surgically assigned groups, but there was a slightly more favorable outcome in those who underwent early surgery. The third trial (Bailey et al) addressed sciatica that had persisted for 4 to 12 months, a not uncommon clinical situation. As with the other trials, there was a considerable crossover to surgery in the group assigned to conservative care and the outcome was that surgery was better at pain relief at 6 and at 12 months of follow-up.

Patients ask appropriate and predictable questions about choices of treatment for lumbar disc herniation. Surgery of the type described below has been associated with complications such as CSF leak or infection in approximately 1 to 2 percent of cases and even fewer patients require reoperation. Here, we can only express a broad opinion based on observing patients and their choices about surgery. Young and middle-aged healthy individuals with sciatica, and imaging that shows disc herniation consistent with the pattern of pain or other deficits, do better by performing surgery early and getting them back to normal activities. Because of the poor reputation of surgery from its overuse and now outdated procedures 40 and more years ago, there is still a propensity on the part of many patients to avoid it. As sciatica and lumbar disc herniation are not life-threatening, these patients are not making an error by waiting to see if the pain resolves. There is some evidence embedded in clinical trial data that outcomes may not be as good if patients wait weeks or months to have surgery, but this is uncertain. A related question that cannot be satisfactorily answered at the moment is whether waiting to operate on patients with weakness, such as foot drop, risks allowing the deficit to be permanent. All that can be said is that foot drop can undoubtedly resolve on its own over weeks. We have generally referred patients with more than trivial muscular weakness, such as foot drop, that does not improve in a week or so, for early surgery, but there is limited evidence on which to base this opinion. Our perspective can be summarized as patients with persistent radicular pain and many with weakness clearly attributable to compressive radiculopathy do somewhat better with surgery than those who persist with conservative care.

The surgical procedure most often indicated for lumbar disc disease is one of the variants of a hemilaminectomy with excision of the disc fragment. Questions relating to the relative merits of limited ("microdisc") excision of the lamina are often raised by patients, but no clear answer can be given except that individual surgeons excel at one or another technique and a minimal procedure is currently favored; the short-term outcomes are similar for most approaches. Eighty-five to 90 percent of cases with sciatic pain because of L4-L5 or L5-S1 disc ruptures are relieved by operation, are home in days or less, and resume activities within weeks. Rerupture of a lumbar disc occurs in fewer than 5 percent of operated cases (Shannon and Paul). Fusion of the involved segments may be indicated in cases in which there is substantial spondylolisthesis or instability. It is not known if delaying surgery in patients with foot or leg weakness from disc herniation risks irreversible damage. Similar issues pertain to the more complex issue of decompression of lumbar stenosis, discussed in a later section. It is of interest that the MRI findings on follow-up at a year or so after laminectomy for disc removal do not correspond to the clinical outcomes (Barzouhi and coworkers).

In our experience and that of our neurosurgical colleagues, the features that are predictive of a better outcome from decompressive surgery are the presence of radicular leg pain, younger age, a clear precipitating event for the back and sciatic pain, clinical features that are restricted

to compression of a single nerve root, and the absence of chronic or recurrent back pain. Psychological problems of various types and chronic smoking, because of poor bone structure, are risks for poorer outcomes.

Congenital Anomalies of the Lumbar Spine

Anatomic variations of the spine are frequent and, though infrequently themselves the source of pain and functional derangement, they predispose an individual to discogenic and spondylotic complications by virtue of altering the mechanics and alignment of the vertebrae, joints, or size of the spinal canal or by giving rise to traumatic fractures of the pedicles. Congenital scoliosis in particular is a complex matter in relation to secondary spinal disease and entire textbooks have been devoted to the analysis of this subject. It is not therefore discussed here except to point out that there is no obligatory relationship between mild degrees of scoliosis that carries over into adulthood and back derangements, and further that some instances of scoliosis occur in parallel with congenital anomalies of the spine and base of the brain such as Chiari malformation and syringomyelia.

A common anomaly is fusion of the fifth lumbar vertebral body to the sacrum ("sacralization") or, conversely, separation of the first sacral segment, giving rise to six rather than the usual five lumbar vertebrae ("lumbarization"). However, neither of these is consistently associated with any type of back derangement. Another less-common finding is a lack of fusion of the laminae of one or several of the lumbar vertebrae or of the sacrum (spina bifida). Occasionally, a subcutaneous mass, hypertrichosis, or hyperpigmentation in the sacral area betrays the condition, but in most patients, it remains occult until it is disclosed radiologically. The anomaly may be accompanied by malformation of vertebral joints and usually induces pain only when aggravated by injury. Many other congenital anomalies affect the lower lumbar vertebrae: asymmetrical facet joints, abnormalities of the transverse processes, are seen occasionally in patients with low back symptoms but apparently with no greater frequency than in asymptomatic individuals.

The neurologic aspects of defective fusion of the spine (dysraphism) are discussed in Chap. 37, with other developmental abnormalities of the nervous system.

Spondylolysis consists of a congenital and probably genetic bony defect in the pars interarticularis (the segment at the junction of pedicle and lamina) of the lower lumbar vertebrae. It is remarkably common, affecting approximately 5 percent of the North American population and is mainly a disease in children (peak incidence between 5 and 7 years of age). The defect assumes importance by predisposing to subtle fracture of the pars articularis, sometimes precipitated by slight trauma but often in the absence of an appreciated injury. In some young individuals, it is unilateral and may cause unilateral lumbar aching back pain that is accentuated by hyperextension and twisting. In the usual bilateral form, small fractures at the pars interarticularis allow the vertebral body, pedicles, and superior articular facets to move anteriorly, leaving the posterior elements behind. This leads to an anterior displacement of one vertebral body in relation to the adjacent one, namely *spondylolisthesis*. (The main cause of spondylolisthesis in older adults is degenerative arthritic disease of the spine as discussed further on.) Patients with progressive vertebral displacement and neurologic deficits require surgery. Reduction of displaced vertebral bodies before fusion and direct repair of pars defects are possible in special cases and back pain is usually reduced or relieved.

Other Causes of Sciatica and Low Back Pain

The authors have been impressed with the large number of such cases that have no clear cause. At one time, all they were classified under the vague and now untenable diagnoses of sciatic neuritis or "sacroiliac strain."

To explain cases of chronic sciatic pain, a number of pathologic entities have been described. Entrapment of lumbar roots may be the consequence not only of disc rupture but also of spondylotic spurs with *lateral recess stenosis*, cysts of the synovium derived from degenerative disease of the facet joint, hypertrophy of facets, and, rarely, arachnoiditis. Lateral recess stenosis in particular may be a cause of sciatica not relieved by disc surgery (see later, under "Lumbar Stenosis"). Synovial cysts arising from a facet joint are not uncommon, and even very small ones may be situated in the proximal portion of the foramen, thereby causing sciatica. If pain is intractable, surgical removal of the cyst is indicated. Another infrequent but surprising finding in imaging the spinal canal is a cyst-like dilatation of the perineural sheath (Tarlov cysts). One or more sacral roots may be involved at points where they penetrate the dura and may be associated with radicular symptoms. There are reports of relief from opening the cysts and freeing the roots, but the results seem more uncertain to us. Sciatica that is temporally linked to the premenstrual period is almost always a result of endometriosis involving the nerve at the sciatic notch ("catamenial sciatica"). We have also observed cases of sciatica that occurred with each pregnancy, presumably from uterine traction on the nerve.

Over the years, the notion of a piriformis syndrome, named by Kopell and Thompson, has become a putative cause of otherwise unexplained buttock pain or vague sciatica. The muscle overlies or, in a small proportion, embeds the peroneal trunk of the sciatic nerve. Hypertrophy, spasm, or simply the anatomic variation in which the nerve is entrapped in the tendinous origin of the muscle, have all putatively caused local and some degree of sciatic pain. Pain in these cases is ostensibly elicited by stretching the muscle through flexion, adduction, and internal rotation of the hip. The validity of this syndrome is uncertain and it has been the subject of polemical discussions in the literature. EMG data are ambiguous but reportedly show distal denervation, sparing more proximally innervated muscles. Our practice would be to avoid surgery in such cases but to endorse physical therapy, which may include injection of botulinum toxin or corticosteroids into the muscle.

Compression of the cauda equina by epidural tumor, as described further on, most often begins with back pain

or sciatica, as a result of deposits of prostatic or breast cancer or myeloma. The sciatic nerve or the plexus from which it originates may be implicated in tumor growths (lymphoma, neurofibrosarcoma). Several inflammatory diseases of the cauda equina produce back pain and *bilateral sciatica* and may be mistaken for the more usual types of cauda equina compression; cytomegalovirus infection in AIDS patients, Lyme disease (Bannwarth syndrome), herpetic infection, and neoplastic meningitis at times behave in this fashion. In all of these, the CSF shows a pleocytosis. The Guillain-Barré syndrome may also produce misleading back and radicular pain before weakness is apparent. The caudal roots in these diseases usually enhance with gadolinium on MRI. An unusual *lumbosacral plexus neuritis (Wartenberg plexitis*) is a unilateral (occasionally bilateral) disorder akin to brachial neuritis, which may cause sciatica, as does occasionally nerve infarction or damage from diabetes, herpes zoster, or a retroperitoneal mass (Evans et al) (see also Chap. 43).

Lumbar Stenosis (Spondylotic Lumbar Radiculopathy)

In the lumbar region, osteoarthritic and related degenerative changes, which together cause a spondylotic narrowing of the canal, lead to compression of one or more lumbar and sacral roots. The problem is more likely to occur if there is a congenitally narrow lumbar canal. The roots are typically compressed between the posterior surface of the vertebral body anteriorly, the facet joint laterally, and the ligamentum flavum posteriorly. Lateral recess stenosis, which is a common feature of spondylotic change (as mentioned above in relation to disc disease), also contributes to root compression and may be the main cause of compression in some patients. Even slight subluxation (spondylolistheses, as discussed below) may also contribute to the stenosis in the anteroposterior dimension. Later, the canal is also narrowed from side to side (reduced interpedicular distance).

The typical features are of fluctuating aching and sharp pain in the low back, buttock, and sciatic distribution, occasionally including femoral areas, and generally elicited by prolonged sitting, standing, or walking and relieved by rest. Some patients have virtually constant pain in these areas but still, have relief with rest in one or another body position.

In a distinctive presentation that occurs in some cases of lumbar stenosis, termed "neurogenic claudication," standing or walking causes a gradual onset of numbness and weakness of the legs, usually with asymmetrical sciatic, calf, or buttock discomfort that forces the patient to sit down. When the condition is more severe, the patient gains relief by squatting or lying with the legs flexed at the hips and knees. Often the numbness begins in one leg, spreads to the other, and ascends as standing or walking continues. The ankle tendon reflexes may disappear after walking a distance, only to return on flexing the spine. Pain in the low back and glutei is variable. Disturbances of micturition and impotence are infrequent unless there has been an additional more acute disc herniation. In some patients with lumbar stenosis, neurologic symptoms persist without relation to body position. The process is distinguished from vascular claudication of the legs by its appearance in the standing position, the prominence of numbness in some cases, relief by bending forward at the waist and elongating the lumbar spine, and, of course, by the preservation of distal leg pulses and loss of ankle reflexes. This "claudication of the cauda equina" was known to Dejerine and described by van Gelderen in 1948, and it was shown several years later by Verbiest to be caused not by ischemia but by encroachment on the cauda equina, for which reason his name has been attached to the syndrome.

A prominent feature of many cases of the degenerative spinal disorder is *spondylolisthesis*. This displacement and malalignment of one vertebral body in relation to the adjacent one may cause little difficulty at first, but eventually, the patient complains of limitation of motion and pain in the low back radiating into the thighs. In the extreme case, examination discloses tenderness near the segment that has "slipped" forward (most often L5, occasionally L4) or a palpable "step" of the spinous process forward and shortening of the trunk with protrusion of the lower abdomen (forward shift of L5 on S1, *spondyloptosis*). Compression of the corresponding spinal roots by the displaced vertebrae causes paresthesia and sensory loss, muscle weakness, and reflex impairment. These neurologic features, however, tend not to be severe. When spondylolisthesis is unstable, meaning the slippage between adjacent vertebrae increases with lumbar flexion or extension, or with standing, new symptoms may appear abruptly in the form of foot drop, urinary retention, or overflow incontinence. The instability is evidenced on conventional radiographs by a change in the diameter of the spinal canal as the patient moves between the flexed and extended position of the back.

A striking syndrome that has been attributed to lumbar stenosis consists of *painful legs–moving toes*, described by Spillane. There is burning leg pain and continuous and complex rhythmic movements of the toes, as the name implies. Symptoms may begin on one side but become bilateral. Lumbar nerve root compression, most often from stenosis but sometimes from other types of peripheral damage, underlie most cases.

It is worth comment from our own experience that certain symptoms are sometimes incorrectly attributable to lumbar stenosis; these include imbalance and falling, isolated Romberg sign, and painless progressive foot or leg weakness. Each of these may be embedded in an otherwise typical case of lumbar stenosis, but they are more often attributable to other problems such as polyneuropathy or cervical spondylosis.

Surgical treatment of lumbar stenosis Decompression of the spinal canal relieves the symptoms of lumbar stenosis in a large proportion of cases, but the results have been inconsistent. Patients must be chosen carefully for surgery, and success is likely if the clinical features conform to the typical syndrome, mainly pain that altered in various positions and at least partially relieved by rest, with definite evidence of root compression by imaging. In perhaps the most careful trial comparing surgery to conservative treatment for lumbar spinal stenosis, pain and overall function at 2 years was several-fold better in those who had operations (Weinstein et al 2008). However, interpretation was hampered by a large number of patients who crossed over between arms of the study.

Issues pertaining to the methodology of operation, particularly the need for fusion of the lumbar spine to limit mobility are of interest because of their increased cost over simple decompression but also because patients may query the neurologist about these matters. When there is spondylolisthesis and instability of adjacent segments, current opinion appears to favor fusion in order to reduce worsening spondylolisthesis and back pain. In the absence of slippage and instability, there is evidence from one trial that better patient satisfaction is attained with fusion after the second year compared to simple decompression (Ghogawala et al), but another series has shown little difference before that time (Försth et al). There is also concern about the rates of reoperation at the original level or at adjacent levels, which are destabilized by surgery and subject to spondylolisthesis and restenosis. Some cases of advanced lumbar stenosis have "autofused" adjacent segments may not benefit from the more extensive operation.

Epidural glucocorticoid injections have been used for some time as a temporizing treatment for the pain of lumbar stenosis, but a randomized trial (Friedly and colleagues) found no difference in disability or leg pain 6 weeks after one or two such injections. Nevertheless, the procedure is still widely used and some patients report relief, which is difficult to separate from the natural course of the process. A series of cases of meningitis that resulted from contaminated drug obtained wide attention decades ago but is less likely to occur in the future. Various physical therapy maneuvers and exercises may be helpful in the short run, but none has been validated in comparison to others.

Insofar as lumbar stenosis can cause a cauda equina syndrome, its differential diagnosis is also considered in Chap. 42 on diseases of the spinal cord.

Degenerative Osteoarthritis of the Spine

Chronic and recurring back pain caused by degenerative arthritic disease is among the most common disorders in general practice. It occurs in later life and may involve all or any part of the spine but is most prevalent in the cervical and lumbar regions. The pain is described as a stiffness that is centered in the affected part of the spine. It is increased initially by movement and is associated with limitation of motion but is often worse on arising in the morning. In contrast to the spinal claudicatory syndrome of lumbar stenosis, warming up and progressive mobilization make the pain better. There is a notable absence of systemic symptoms such as fatigue, malaise, or fever, and, more importantly, there are usually no features of radicular compression although vague aching may be felt in a sciatic distribution. In contrast to conventional lumbar root compression, the straight-leg raising tests do not elicit pain but may produce tightness in the hamstring muscle that the patient may report as sciatica. The sitting position is usually comfortable, although stiffness and discomfort are accentuated when the erect posture is resumed.

The severity of the symptoms often bears little relation to the radiologic changes; pain may be present despite minimal radiographic findings; conversely, marked osteophytic overgrowth with spur formation, ridging, bridging of vertebrae, narrowing of disc spaces, subluxation of posterior joints on flexion, and air in the disc spaces can be seen in both symptomatic and asymptomatic persons.

Facet Syndrome

The features of this syndrome remain imprecise. In one form, osteoarthritic degeneration of the facet joint gives rise to a focal parasagittal lumbar back pain, with variable tenderness over the joint but without signs of nerve root compression. The pain can be quite severe, worse at night, and prevent sleep if no comfortable position can be found. NSAIDs are helpful. Some patients have discovered that they may obtain temporary relief from facet pain by forcefully twisting or stretching the back and creating an audible pop at the affected joint, comparable to chiropractic manipulation. Over time, they acquire a laxity of the supporting structures of the joint, which may actually perpetuate the problem.

The diagnosis is confirmed when the pain is relieved for a variable period by injection of the joint with local anesthetic. Often one is uncertain whether it was the analgesic effect on the joint or the infiltration of the region around the nerve root that has relieved the pain. Two controlled studies have suggested the procedure of corticosteroid injections into the facet joints is ineffective, both in the short and long term (Carette et al, 1991; Lilius et al). Notwithstanding these reports, we have found the injection of analgesics and steroids in and around the facet to be a useful temporizing measure in some patients if the facet syndrome has been established by clinical means rather than for non-descript back and radicular pains. Epidural injections of steroids have no clear role in the treatment of this condition. If the diagnosis is established by local injection, many centers offer radiofrequency ablation of the small recurrent sensory nerves that innervate the joint as a means of permanent relief. This has met with some success but has not been studied systematically.

Some writers have used the term facet syndrome to describe a painful state from facetal hypertrophy that gives rise to a lumbar radiculopathy, indistinguishable from that caused by a ruptured disc or spondylotic disease (Reynolds and colleagues). At operation, the spinal root is compressed against the floor of the intervertebral canal by overgrowth of an inferior or superior facet. Foraminotomy and facetectomy, after exploration of the root from the dural sac to the pedicle, have relieved the pain in some operated cases.

Lumbar Adhesive Arachnoiditis

With the disappearance of oil-based media for myelography, this syndrome is now infrequently encountered. It is a thickening and opaqueness of the arachnoid membrane of the lumbar spinal cord or thickening of the arachnoidal sheaths around the individual roots (normal roots have essentially no epineurium). Lumbar arachnoiditis, even in the past, was uncommon Radiation damage is an occasional cause in current practice (Fig. 10-5). The clinical features are intractable low-back and leg pain and paresthesia, all positionally sensitive, in combination with neurologic abnormalities referable to lumbar spinal roots. Cervical-thoracic arachnoiditis is also known.

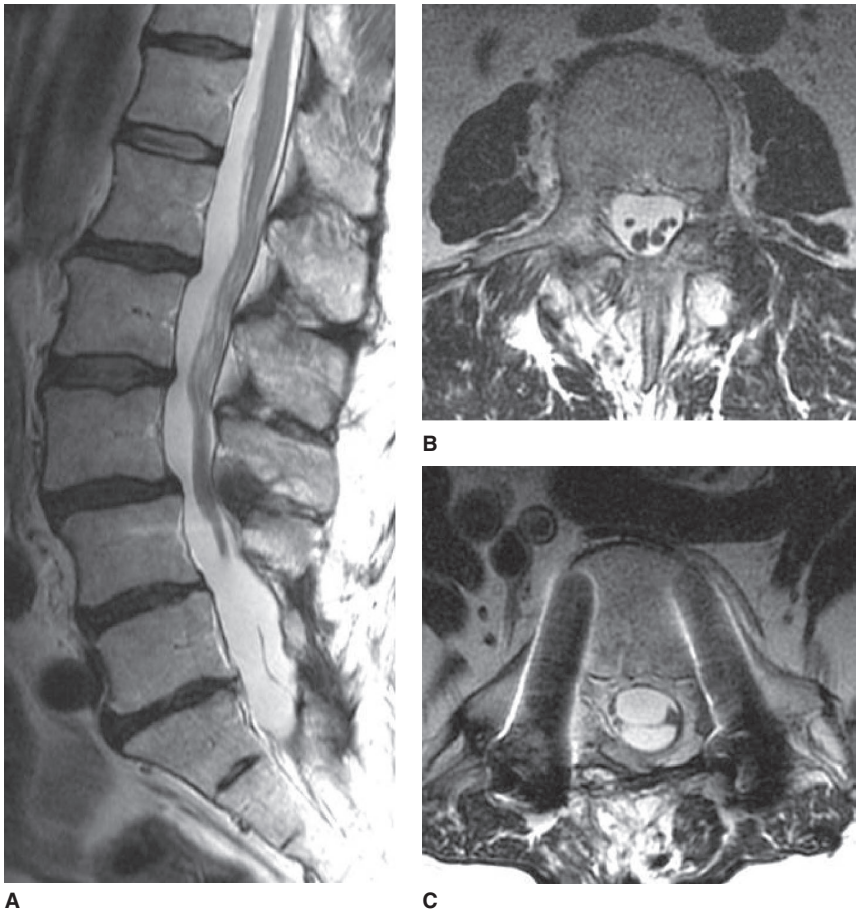

Figure 10-5. Lumbosacral MRI of a patient with radiation-induced arachnoiditis (underlying condition of lymphoma) causing severe back pain and leg weakness. *A*. Sagittal T2-weighted MRI showing clumping of the nerve roots of the cauda equina. *B*. Axial T2-weighted image at the L3 vertebral level showing clumping of the nerve roots. *C*. Axial T2-weighted image at the L5 vertebral level showing lateral displacement of nerve roots by acquired arachnoid cysts. There are bilateral metallic pedicle screws.

Multiple myelograms (largely a problem of the past), disc rupture, operative procedures, infections, and subarachnoid bleeding have been associated with the process. Some cases have followed spinal anesthesia and even epidural anesthesia by a period of months or years, but the mechanism is often not clear. The presumption is that the dura had been breached and often there were clinical signs of aseptic meningitis soon after the procedure. In the absence of such an acute reaction, the later diagnosis of arachnoiditis rests on less-certain grounds.

The MRI shows eccentrically thickened meninges in the spinal canal with arachnoid adhesions and collections of CSF that displace nerve roots (Fig. 10-5). Abnormalities may be even more striking on CT myelographic studies in which the contrast is loculated and fails to outline the roots. Treatment is generally unsatisfactory. Lysis of adhesions under an operating microscope and administration of intrathecal steroids have been of little value, although some experienced surgeons claim otherwise. Epidural injection of steroids is occasionally helpful.

Ankylosing Spondylitis

This disorder, referred to in the past as *rheumatoid spondylitis* and as *von Bechterew* or *Marie-Strümpell arthritis*, predominantly affects young adult men. Approximately 95 percent of patients carry the histocompatibility antigen HLA-B27 (which is present in only 7 percent of nonaffected persons of European extraction). Pain, usually centered in the low back, is the main early complaint. Often it radiates to the back of the thighs and groin. At first, the symptoms are vague (tired back, "catches" up and down the back, sore back), and the diagnosis may be overlooked for many years. Although the pain is recurrent, limitation of movement is constant and progressive and comes to dominate the clinical picture. Early in the course of disease, there is only morning stiffness or an increase in stiffness after periods of inactivity similar to lumbar osteoarthritis but unusual for the affected age group. In advanced stages, a cauda equina compression syndrome may complicate ankylosing spondylitis, the result apparently of an inflammatory reaction and proliferation of connective tissue (Matthews). Limitation of chest expansion, tenderness over the sternum, decreased motion and tendency to progressive flexion of the hips, and the characteristic immobility and flexion deformity of the spine ("poker spine") may be present early in the course of the disease.

The typical imaging hallmarks are destruction and subsequent obliteration of the sacroiliac joints, followed by

bony bridging of the vertebral bodies to produce the characteristic "bamboo spine." When this change becomes apparent, the pain usually subsides, but the patient by then has little motion of the back and neck. An unusual additional feature, almost unique to this condition, is an extreme dilatation of the lumbar thecal sac. The great risk in this disease is fracture dislocation of the spine from relatively minor trauma, particularly flexion–extension injuries.

Occasionally ankylosing spondylitis is complicated by destructive vertebral lesions. This complication should be suspected whenever the pain returns after a period of quiescence or becomes localized. The cause of these lesions is not known, but they may represent a response to nonunion of fractures, taking the form of an excessive production of fibrous inflammatory tissue. When it is severe, ankylosing spondylitis may involve both hips, greatly accentuating the back deformity and disability.

Neoplastic and Infectious Diseases of the Spine (See Also Chap. 42)

Metastatic carcinoma (breast, bronchus, prostate, thyroid, kidney, stomach, uterus), multiple myeloma, and lymphoma are the common malignant tumors that involve the spine. The primary lesion may be small and asymptomatic, and the first manifestation of the tumor may be pain in the back caused by metastatic deposits. The pain is constant and dull; it is often unrelieved by rest and is generally worse at night, interrupting sleep. Radicular pain may be added if the metastasis extends laterally. A fracture of a vertebral body in an otherwise healthy young or middle-aged person should alert the physician to the possibility of an underlying metastasis. At the time of onset of the back pain, there may be no radiographic changes on plain radiographs; when such changes do appear, they usually take the form of destructive lesions in one or several vertebral bodies with little or no involvement of the disc space, even in the face of a compression fracture. However, the changes are evident on CT and MRI or radioactive isotope scan that detects areas of osteoblastic activity caused by neoplastic or inflammatory disease.

Infection of the vertebral column, *osteomyelitis*, is usually caused by staphylococci and less often by coliforms and mycobacteria. The patient complains of subacute or chronic pain in the back, which is exacerbated by movement but not materially relieved by rest. Motion becomes limited, and there is percussion-induced tenderness over the spine in the involved segments and pain with jarring of the spine, as occurs when the heels strike the floor. Often these patients are afebrile and do not have a leukocytosis. The erythrocyte sedimentation rate and C-reactive protein are elevated as a rule. CT and MRI characteristically demonstrate the involvement of both the vertebral body and the adjacent intervertebral disc, and the finding of a breached disc space with the involvement of two adjacent vertebral bodies is one of the features that differentiates infectious from neoplastic diseases of the spine. Tuberculous spinal infection and the resultant kyphotic deformity (Pott disease) represent a special condition that is seen in developing countries (see Chaps. 31 and 42).

Emphasis is placed on *spinal epidural abscess*, which usually necessitates urgent surgical treatment. Failure to properly identify this lesion has led to cases of paraplegia or death from sepsis. Most often, this is caused by staphylococcal infection, which is carried in the bloodstream from a septic focus (e.g., furuncle) or is introduced into the epidural space from an osteomyelitic lesion. Another important avenue of infection is the intravenous self-administration of illicit drugs and use of contaminated needles. Rarely, the infection is introduced in the course of a lumbar puncture, epidural injection, or laminectomy for disc excision. In some instances, the source of an epidural abscess cannot be ascertained. The main symptoms are low-grade fever, leukocytosis, and persistent and severe localized pain that is intensified by percussion and pressure over the vertebral spines. Additionally, the pain may radiate in a radicular distribution. These symptoms mandate immediate investigation by MRI or CT myelography and surgical intervention, preferably before the signs of paraplegia, sphincter dysfunction, and sensory loss become manifest. Small abscesses and granulomas that are the residua of previous and partially treated abscesses can be sometimes treated successfully with antibiotics alone as discussed further on and in Chap. 42 on "Diseases of the Spinal Cord."

Intraspinal Hemorrhage (See Chap. 42)

Sudden, excruciating midline back pain (*le coup de poignard* or "the strike of the dagger")—often with rapidly evolving paraparesis, urinary retention, and numbness of the legs—may announce the occurrence of subarachnoid, subdural, or epidural bleeding. The most common causes of such an event are a coagulopathy (mainly from warfarin) and a spinal AVM, as discussed in Chap. 44. Spinal arterial aneurysms are much-less-common underlying lesions.

Coccydynia

This is the name applied to pain localized to the "tail piece," the three or four small vestigial bones at the lowermost part of the sacrum. The trauma of childbirth, a fall on the buttocks, avascular necrosis, a neurofibroma or glomus tumor, other rare tumors, anal disorders, and pilonidal cysts, can sometimes be established as the cause of pain in this region. Far more often, the source remains obscure. In the past, patients in this latter group were indiscriminately subjected to coccygectomy, but more recent studies have demonstrated that most cases respond favorably to injections of local anesthetic and methylprednisolone or to manipulation of the coccyx under anesthesia (Wray et al).

Obscure Low Back Pain and Psychiatric Disease

Chronic low back pain may be a medically unexplained symptom; this raises concern for an underlying psychological problem. It is good practice to assume that pain in the back in such patients may signify disease of the spine or adjacent structures, and this should always be carefully sought. However, even when some organic factors are found, the pain may be exaggerated, prolonged, or woven into a pattern of invalidism because of coexistent primary or secondary factors. This is especially true when there is the possibility of secondary gain (notably workers' compensation or settlement of personal injury claims). Patients seeking compensation for protracted low

back pain without obvious structural disease tend, after a time, to become suspicious, uncooperative, and hostile toward their physicians or anyone who might question the authenticity of their illness. One notes in them a tendency to describe their pain vaguely and a preference to discuss the degree of their disability and their mistreatment at the hands of the medical profession. The description of the pain may vary considerably from one examination to another. Often also, the region(s) in which pain is experienced and its radiation are nonphysiologic, and the condition fails to respond to rest and inactivity. These features and a negative examination of the back should lead one to suspect a psychologic factor. A few patients, usually frank malingerers, adopt bizarre gaits and attitudes, such as walking with the trunk flexed at almost a right angle (camptocormia), and are unable to straighten up although this sign can also be the result of dystonia. Or the patient may be unable to bend forward even a few degrees, despite the absence of muscle spasm, and may wince at the slightest pressure, even over the sacrum, which is seldom a site of tenderness.

Failed Back Syndrome

Among the most difficult patients to manage are those with chronic low back pain who have already had one or more lumbar laminectomies and sometimes a fusion without substantial relief. In one perhaps dated but large series of patients operated on for proven disc prolapse, 25 percent were left with troublesome symptoms, and 10 percent required further surgery (Weir and Jacobs). In such patients, our suggestion has been to repeat the MRI or CT myelography. In a fair number, it will be found that the disc has reruptured, or that there is unaddressed lateral recess stenosis, or that a disc or degenerative disease has appeared at the level just above, or less frequently, below the site of previous decompression. EMG and nerve conduction studies, searching for evidence of a radiculopathy, are also helpful. If there is evidence of a radiculopathy but no disc material, or only scar tissue is seen on MRI, one cannot know whether the pain relates to injury from the initial rupture or is the aftermath of surgery (Quiles et al; Long).

One would suppose that these patients with chronic pain could be subdivided into a group with continued radicular pain and another with referred pain from disease of the spine. However, once the pain becomes chronic, the separation is not easy. Pressure over the spine, buttock, or thigh may cause pain to be projected into the leg. Lidocaine blocks of nerve roots have yielded inconsistent results. Transcutaneous stimulators, posterior column stimulators, intrathecal injections of analgesics, and epidural steroid injections have seldom helped for long in our experience, but we have seen striking exceptions, especially with epidural pumps that administer analgesics. At present, the best that can be offered to the patient is weight reduction (in appropriate individuals), stretching and progressive exercises to strengthen abdominal and back muscles, as well as mild nonnarcotic analgesics and antidepressant drugs. A trial of epidural steroid injection, physiotherapy or a limited course of spinal chiropractic manipulation is reasonable.

PAIN IN THE NECK, SHOULDER, AND ARM

General Considerations

It is useful to distinguish three major categories of painful disease of the neck and arms—that originating in the *cervical spine*, in the *brachial plexus*, and in the *shoulder*. Although the distribution of pain from each of these sources may overlap, the patient can usually indicate its site of origin. Pain arising from the cervical part of the spine is felt in the neck or back of the head and is projected to the shoulder and upper arm; it is evoked or enhanced by certain movements or positions of the neck and is accompanied by limitation of motion of the neck and by tenderness to palpation over the cervical spine.

Pain of brachial plexus origin is experienced in the supraclavicular region or in the axilla and around the shoulder; it may be worsened by certain maneuvers and positions of the arm and neck (extreme rotation). A palpable abnormality above the clavicle may disclose the cause of the plexopathy (aneurysm of the subclavian artery, tumor, cervical rib). The combination of circulatory abnormalities and signs referable to the medial cord of the brachial plexus is characteristic of the *thoracic outlet syndrome*, described further on.

Pain localized to the shoulder region, worsened by motion, and associated with tenderness and limitation of movement, especially internal and external rotation and abduction, points to tendonitis, subacromial bursitis, or tear of the rotator cuff, which is made up of the tendons of the muscles surrounding the shoulder joint. The term *bursitis* is often used loosely to designate these disorders. Shoulder pain, like spine and plexus pain, may radiate vaguely into the arm and rarely into the hand, but sensorimotor and reflex changes—which always indicate disease of nerve roots, plexus, or nerves—are absent. Shoulder pain of this type is very common in middle and late adult life. It may arise spontaneously or after unusual or vigorous use of the arm. Local tenderness over the greater tuberosity of the humerus is characteristic. Plain radiographs of the shoulder may be normal or show a calcium deposit in the supraspinatus tendon or subacromial bursa. MRI is able to demonstrate more subtle abnormalities, such as muscle and tendon tears of the rotator cuff or a labral tear of the joint capsule. In most patients, the pain subsides gradually with immobilization and analgesics followed by a program of increasing shoulder mobilization. If it does not, the injection of small amounts of corticosteroids into the bursa, or the site of major pain indicated by passive shoulder movement in the case of rotator cuff injuries, is often temporarily effective and allows the patient to mobilize the shoulder. The problem of the "frozen shoulder" is addressed further on.

Osteoarthritis and osteophytic spur formation of the cervical spine may cause pain that radiates into the back of the head, shoulders, and arm on one or both sides. Coincident compression of nerve roots is manifest by paresthesia, sensory loss, weakness and atrophy, and tendon reflex changes in the arms and hands. Should bony ridges form in the spinal canal, as described in detail in Chap. 42,

the spinal cord may be compressed, with resulting spastic weakness, ataxia, and loss of vibratory and position sense in the legs (*cervical spondylosis*). The bony changes are evident on plain films but are better seen by CT and MRI. There may be difficulty in distinguishing cervical spondylosis with root and spinal cord compression from a disc (see further on) or from a primary neurologic disease (syringomyelia, amyotrophic lateral sclerosis, or tumor) with an unrelated cervical osteoarthritis. Here the MRI is of particular value in revealing compression of the spinal cord, but this study is prone to overinterpretation when a bony ridge barely comes into contact with the cord but does not deform it (see "Cervical Spondylosis with Myelopathy" in Chap. 42).

Spinal *rheumatoid arthritis* may be restricted to the cervical facet joints and the atlantoaxial articulation. The usual manifestations are pain, stiffness, and limitation of motion in the neck and pain in the back of the head. In contrast to ankylosing spondylitis, rheumatoid arthritis is rarely confined to the spine. Because of evident disease of other joints, the diagnosis is relatively easy to make, but significant involvement of the cervical spine may be overlooked. In the advanced stages, one or several of the vertebrae may become displaced anteriorly, or a synovitis of the atlantoaxial joint may damage the transverse ligament of the atlas, resulting in forward displacement of the atlas on the axis (atlantoaxial subluxation). In either instance, serious and even life-threatening compression of the spinal cord may occur gradually or suddenly. Cautiously performed lateral radiographs in flexion and extension are useful in visualizing atlantoaxial dislocation or subluxation of the lower segments. Occipital headache and neck pain related to degenerative changes in the upper cervical facets is discussed with other cranial pains in "'Third Occipital Nerve' Headache" (so-called third occipital nerve pain) in Chap. 9.

Traumatic and whiplash injury of the cervical spine Injury to ligaments and muscles as a result of forcible extension and flexion of the neck can create difficult clinical problems. The injury ranges from a minor sprain of muscles and ligaments to severe tearing of these structures, to avulsion of muscle and tendon from vertebral body, and even to vertebral and intervertebral disc damage. The latter lesions can be seen with MRI and, if severe, can result in root or spinal cord compression or, occasionally, in cartilaginous embolization of the spinal cord (see "Fibrocartilaginous Embolism" in Chap. 42). If there is preexisting cervical osteoarthritis, there may be considerable pain, and in extreme cases, cord compression.

However, the more ubiquitous and milder degrees of whiplash injury without the above described structural injuries are so often complicated by psychologic and compensation factors leading to prolonged disability that the syndrome becomes a vexing problem without clear medical definition and occupies a disproportionate amount of time on the part of physicians, compensation boards, and courts (LaRocca; also see Malleson for an interesting discussion of the sociology and psychology of this subject). We have no doubt that authentic traumatic neck injuries exist, even at times from minor trauma, but the high frequency of this putative injury is likely sustained by societal and legal structures.

Cervical Disc Herniation (See Table 10-1)

A common cause of neck, shoulder, and arm pain is disc herniation in the lower cervical region; the process is comparable to disc herniation in the lumbar region but gives rise, of course, to a different set of symptoms (Table 10-1). The problem appears most often without a clear and immediate cause, but it may develop after trauma, which may be major or minor (from sudden hyperextension of the neck, falls, diving accidents, and forceful manipulations as discussed by Kristoff and Odom). The roots most commonly involved are the seventh (in 70 percent of cases) and the sixth (in 20 percent of cases); fifth- and eighth-root compression makes up the remaining 10 percent (Yoss et al). The clinical diagnosis is established by a fairly discrete distribution of pain or paresthesias that corresponds to a single cervical root, reflex loss in the segment of the root, and by elicitation of exaggerated root pain with mechanical tests such as the *Spurling maneuver*, in which the examiner exerts downward pressure on the top of the head with the patient's head turned to the affected side and the neck slightly extended. The latter test is not very sensitive but is specific in radiculopathy that has been confirmed by EMG or imaging. It is infrequent that the entire syndrome of pain, motor, reflex, and sensory loss corresponding to a root is found. The region of pain is particularly variable in cervical radicular disease by comparison to lumbar root disease.

When the protruded disc lies between the sixth and seventh vertebrae, there is the involvement of the *seventh cervical root* as outlined in Table 10-1. The pain is then in the region of the shoulder blade, or spine of the scapula, and posterolateral upper arm; it may project to the elbow and dorsal forearm, index and middle fingers, or all the fingers. Occasionally discomfort is felt in the pectoral or axillary region. Tenderness is most pronounced over the medial aspect of the shoulder blade opposite the third to fourth thoracic spinous processes and in the supraclavicular area and triceps region. Paresthesia and sensory loss are most evident in the index and middle fingers. Weakness involves the extensors of the forearm and sometimes of the wrist; occasionally, the handgrip is weak as well; the triceps may be weak and the triceps reflex is usually diminished or absent; the biceps and supinator reflexes are preserved.

With a laterally situated disc herniation between the fifth and sixth cervical vertebrae, the symptoms and signs are referred to the *sixth cervical root*. The full syndrome is characterized by pain at the trapezius ridge and tip of the shoulder, with radiation into the anterior-upper part of the arm, radial forearm, often the thumb, and sometimes the index finger as well. There may also be paresthesia and sensory impairment in the same regions; tenderness in the area above the spine of the scapula and in the supraclavicular and biceps regions; weakness in flexion of the forearm (biceps) and in contraction of the deltoid when sustaining arm abduction; and diminished or absent biceps and supinator reflexes (the triceps reflex is retained or sometimes has the appearance of being slightly exaggerated because of flaccidity of the biceps).

The *fifth cervical root* syndrome, produced by disc herniation between the fourth and fifth vertebral bodies, is

characterized by pain in the shoulder and trapezius region and by supra and infraspinatus weakness, manifest by an inability to abduct the arm and rotate it externally with the shoulder adducted. There may be a slight degree of weakness of the biceps and a corresponding reduction in the reflex, but these are inconsistent findings. A small patch of diminished sensation commonly overlies the deltoid muscle.

Compression of the *eighth cervical root* (by a C7-T1 disc) may mimic ulnar nerve palsy. The pain is along the medial side of the forearm and the sensory loss is in the distribution of the medial cutaneous nerve of the forearm and of the ulnar nerve in the hand. The weakness largely involves the intrinsic muscles supplied by the ulnar nerve (see "Ulnar Nerve" in Chap. 43). The reflexes may be unaffected, but the triceps jerk is often slightly reduced.

These syndromes are usually incomplete in that only one or several of the typical findings are present. Particularly noteworthy is the occurrence, in laterally placed cervical disc rupture, of isolated weakness without pain, especially with discs at the fifth and sixth levels. A description of the distribution of pain in 250 cases of herniated cervical disc or spondylotic nerve root compression has been reported (Friis and coworkers in the text by Finnesen). Virtually every patient, irrespective of the particular root(s) involved, showed a limitation in the range of motion of the neck and aggravation of pain with movement (particularly hyperextension). Coughing, sneezing, and downward pressure on the head in the hyperextended position usually exacerbated the pain, and traction (even manual) tended to relieve it.

Unlike herniated lumbar discs, cervical ones, if large and centrally situated, result in compression of the spinal cord (Fig. 10-6). The centrally situated disc is often painless, and the cord syndrome may simulate multiple sclerosis or a degenerative neurologic disease. Bilateral hand numbness, paresthesia, or similar altered sensation is common. Failure to consider a protruded cervical disc in patients with obscure symptoms in the legs, including stiffness and falling, is a common error. A vague sensory

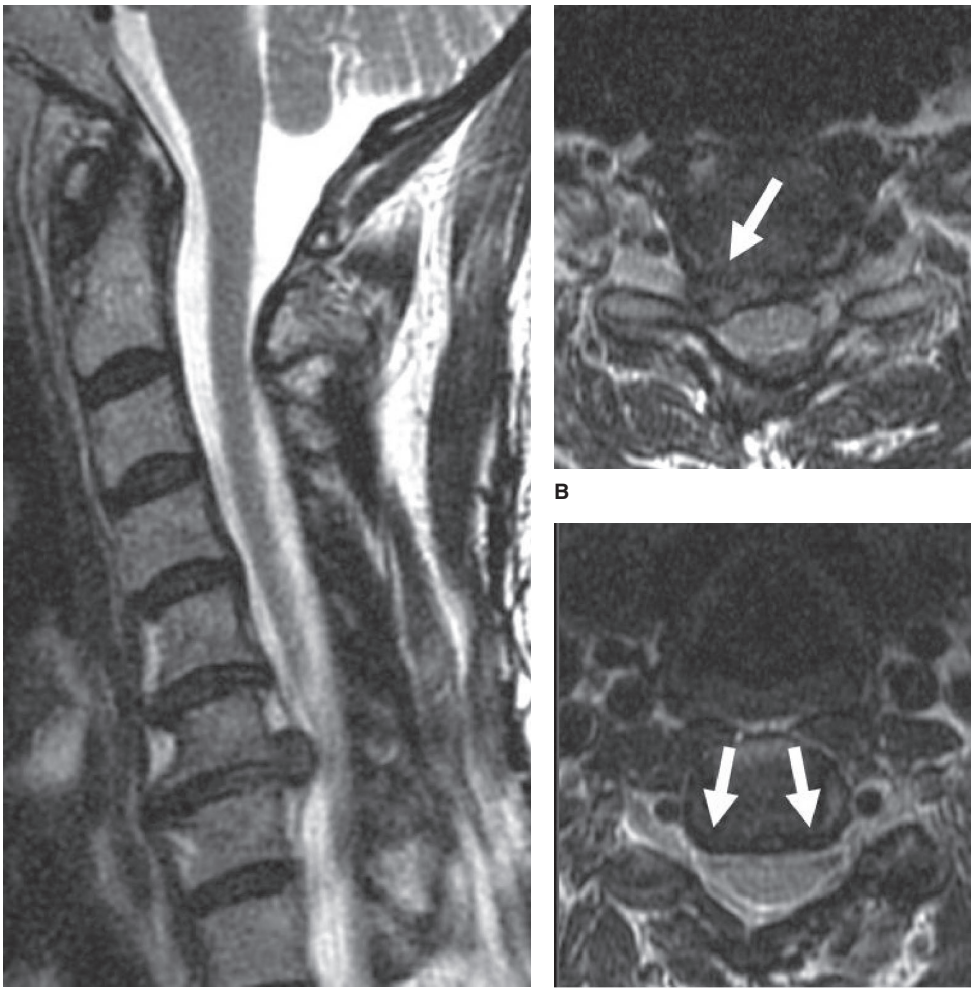

Figure 10-6. Cervical disc herniation as visualized with T2-weighted MRI. *A.* Parasagittal view of a large posterior disc extrusion at C6-C7. Smaller broad-based posterior disc bulges are seen at C4-C5 and C5-C6. *B.* Axial view of the large right posterolateral disc extrusion shown in (*A*) at C6-C7 (arrow) causing severe narrowing of the right neural foramen and compression of the exiting C7 nerve root. *C.* By way of contrast, an axial view of the broad-based posterior disc bulge at C4-C5 (arrows) causes only minimal narrowing of the spinal canal and no compression of the spinal cord.

change can often be detected on the thorax, the rostral margin of which is several dermatomes below the level of compression. The diagnosis and the level of disc protrusion can be confirmed by MRI or by CT myelography. Nerve conduction studies, F responses, and EMG are helpful in confirming the level of root compression and distinguishing pain of radicular origin from that originating in the brachial plexus or in individual nerves of the arm (see "Brachial Neuritis" in Chap. 43).

Management of Herniated Cervical Disc

Conservative measures should be instituted before turning to surgical removal of the disc unless there are signs of a rapidly or subacutely progressing myelopathy (i.e., leg and arm weakness, hyperreflexia in the legs, gait ataxia, sphincteric dysfunction) of a persistent and severe radiculopathy. In the case of cervical disc with radicular pain, a close-fitting foam collar is sometimes beneficial although there is controversy about the efficacy of this type of immobilization. The collar should be fitted so that minimal flexion and extension of the neck are allowed, but it must remain comfortable enough to encourage consistent use. The patient is advised to wear the collar at all times during the day, especially while riding in a car unless this becomes completely impractical. Although of uncertain value, traction with a halter around the occiput and chin may be of some benefit in reducing pain, albeit temporarily, in cervical disc-radiculopathy syndromes. Analgesic medication may be required for a few days.

In most instances, the radicular pain subsides over a few weeks or less, but severe or intractable cases may require surgery, especially if there is substantial weakness in the muscles corresponding to the affected root. Mild weakness alone is not recognized as an indication for surgery, and in those few cases where weakness alone has occurred, without pain, the same conservative measures outlined above should be considered.

When surgery is felt to be indicated, most often, the surgeon tackles this problem through an anterior approach (transdiscally), which leaves the posterior elements intact and allows for remaining stability of the spine if the procedure is at one level only but, if there is a concern for future instability or multiple levels have been operated on, a fusion of various types is added. There are scant data from clinical trials from which to judge the appropriateness and timing of surgery, in contrast to what has been learned from trials in lumbar disc disease.

Cervical Spondylosis (See Also Chap. 42)

This is a chronic degenerative disease of the mid-and lower cervical spine that narrows the spinal canal and intervertebral foramina, causing compressive injury of the spinal cord and roots (Theodore). The problem of central disc protrusion, discussed above, often contributes as one component of the narrowing of the canal. Because the main effects of cervical spondylosis are on the cord, this process is discussed in detail in Chap. 42, but cervical spondylosis is also a common cause of neck and arm pain, as described earlier. If minor signs of spinal cord and root involvement are present, a collar to limit movement of the head and neck may halt the progression and lead to improvement. Decompressive laminectomy or anterior excision of single spondylotic spurs and fusion are reserved for instances of the disease with advancing neurologic symptoms or intractable pain as discussed in Chap. 42. As with lumbar stenosis, success is not assured with surgery but can help prevent further progression of symptoms.

Thoracic Outlet Syndromes (Superior Thoracic Aperture Syndrome)

Several anatomic anomalies occur in the lateral cervical region. These may, under certain circumstances, compress the brachial plexus, the subclavian artery, and the subclavian vein, causing muscle weakness and wasting, pain, and vascular abnormalities in the hand and arm. The condition is undoubtedly diagnosed more often than is justified, and the term has been applied ambiguously to a number of conditions.

The most frequent of the abnormalities that cause neural compression, encompassed by the term *thoracic outlet syndrome*, is an anomalous incomplete cervical rib, with a sharp fascial band passing from its tip to the first rib; a taut fibrous band passing from an elongated and downcurving transverse process of C7 to the first rib; less often, a complete cervical rib, which articulates with the first rib; and anomalies of the position and insertion of the anterior and medial scalene muscles. Thus, the sites of potential neurovascular compression extend all the way from the intervertebral foramina and superior mediastinum to the axilla. Depending on the postulated abnormality and mechanism of symptom production, the terms *cervical rib*, *anterior scalene*, *costoclavicular*, and *neurovascular compression* have been applied. In addition, a *droopy shoulder syndrome* has been identified that purportedly stretches the brachial plexus and gives rise to similar symptoms; a majority of the patients have been young women with asthenic body habitus.

Variations in regional anatomy could explain these several postulated mechanisms, but to this day there is no full agreement about the validity of anterior scalene and costoclavicular syndromes. An anomalous cervical rib, which arises from the seventh cervical vertebra and extends laterally between the anterior and medial scalene muscles and then under the brachial plexus and subclavian artery to attach to the first rib, obviously disturbs the anatomic relationships of these structures and may compress them (Fig. 10-7). However, as an estimated 1 percent of the population has cervical ribs, usually on both sides, and only about 10 percent of these persons have neurologic or vascular symptoms (almost always one-sided), other factors must be operative.

The anterior and middle scalene muscles, which flex and rotate the neck, are both inserted into the first rib so that the subclavian artery and vein and the brachial plexus must pass between them. Hence abnormalities of insertion and hypertrophy of these muscles were once thought to be causes of the syndrome but sectioning them (scalenectomy) has so rarely altered the symptoms that this mechanism is no longer given credence.

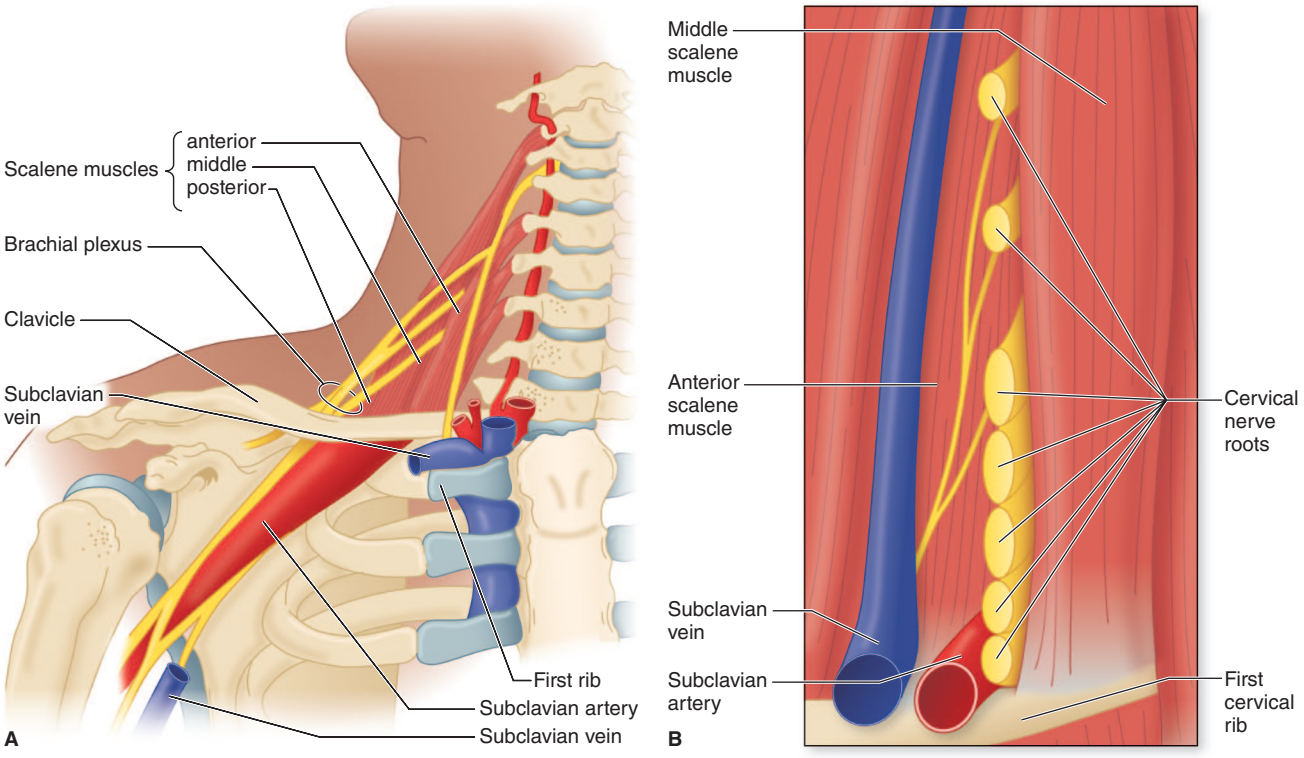

Figure 10-7. Course of the brachial plexus and subclavian artery between the anterior scalene and middle scalene muscles. Dilatation of the subclavian artery just distal to the anterior scalene muscle is illustrated. Immediately distal to the anterior and middle scalene muscles is another potential area of constriction between the clavicle and the first rib. With the extension of the neck and turning of the chin to the affected side (Adson maneuver), the tension on the anterior scalene muscle is increased and the subclavian artery compressed, resulting in a supraclavicular bruit and obliteration of the radial pulse.

Three neurovascular syndromes are associated with a rudimentary cervical rib (rarely with a complete cervical rib) and related abnormalities at the thoracic outlet: subclavian venous or arterial compression and a brachial plexopathy. In all three forms, shoulder and arm pain are prominent. The discomfort is of the aching type and is felt in the posterior hemithorax, pectoral region, and upper arm. These syndromes sometimes coexist, but more often, each occurs independently.

Compression or spontaneous thrombosis of the subclavian vein is a rare occurrence causing a dusky discoloration, venous distention, and edema of the arm. The vein may become thrombosed after prolonged exercise (Paget Schrötter syndrome) or in cases of a clotting diathesis in cancer patients.

Compression of the subclavian artery, which results in ischemia of the limb, may be complicated by digital gangrene and retrograde embolization, which is also a rare entity. A unilateral Raynaud phenomenon, brittle nails, and ulceration of the fingertips are important diagnostic findings. A supraclavicular bruit is suggestive but not in itself diagnostic of subclavian artery compression.

The conventional tests for vascular compression—obliteration of the pulse when the patient, seated and with the arm extended, takes and holds a full breath, tilts the head back, and turns it to the affected side (Adson test) or abducts and externally rotates the arm and braces the shoulders and turns the head to either side (Wright maneuver)—are not entirely reliable. Sometimes these maneuvers fail to obliterate the radial pulse in cases of proved compression; contrariwise, these tests may be positive in normal persons. Nevertheless, a positive test only on the symptomatic side (with reproduction of the patient's symptoms) is suggestive of the diagnosis of arterial compression and, by implication, some form of thoracic outlet syndrome. Plethysmographic recording of the radial pulse and ultrasound of the vessel add greatly to the accuracy of these positional tests.

A primarily neurologic problem may characterize the thoracic outlet syndrome. There is slight wasting and weakness of the hypothenar, interosseous, adductor pollicis, and deep flexor muscles of the fourth and fifth fingers (i.e., the muscles innervated by the lower trunk of the brachial plexus and ulnar nerve). Weakness of the flexor muscles of the forearm may be present in advanced cases. Tendon reflexes are usually preserved. In addition, most patients complain of an intermittent aching of the arm, particularly of the ulnar side, and about half of them also complain of numbness and tingling along the ulnar border of the forearm and hand. A loss of superficial sensation in these areas is variable. It may be possible to reproduce the sensory symptoms by firm pressure just above the clavicle or by traction on the arm. Vascular features are often absent or minimal in patients with the neurologic form of the syndrome.

In patients with neurologic signs, nerve conduction studies disclose reduced amplitude of the ulnar sensory potentials. There may be decreased amplitude of the median motor evoked potentials as well, a mild but uniform slowing of the median motor conduction velocity, and a prolongation of the F-wave latency. Concentric needle examination of affected hand muscles reveals large-amplitude motor units, suggesting collateral reinnervation. Somatosensory evoked potentials may be a useful adjunct to the conventional nerve conduction and EMG studies (Yiannikas and Walsh). Brachial artery MR angiography is usually reserved for patients with a suspected arterial occlusion, an aneurysm, or an obvious cervical rib. The place of venography in the diagnostic workup is uncertain, for a number of otherwise normal individuals can occlude the subclavian vein by fully abducting the arm.

In the authors' experience, unambiguous instances of thoracic outlet syndrome are not common and this has been corroborated by past reviews of the subject (Wilbourn). One should be skeptical of the diagnosis unless the clinical and EMG features enumerated above are present. Common mistakes are to confuse the thoracic outlet syndrome with carpal tunnel syndrome, ulnar neuropathy or entrapment at the elbow, or cervical radiculopathy caused by arthritis or disc disease. Brachial neuritis may have a similar presentation. Imaging studies and careful nerve conduction and EMG studies may be necessary to exclude these disorders.

Treatment of the Thoracic Outlet Syndrome

A conservative approach is advisable. If the main symptoms are pain and paresthesia, Leffert suggests the use of local heat, analgesics, muscle relaxants, and an assiduous program of special exercises to strengthen the shoulder muscles. A full range of neck motions is then practiced. On such a regimen, some patients experience a relief of symptoms after 2 to 3 weeks. Instruction by a qualified physical therapist is invaluable.

Only if the pain is severe and persistent and is clearly associated with the vascular or neurogenic features of the syndrome is surgery indicated. The usual approach is through the supraclavicular space, with cutting of fibrous bands and excision of the rudimentary rib. In cases of venous or minor arterial forms of the syndrome, some thoracic surgeons favor the excision of a segment of the first rib through the axilla. Pain is often dramatically relieved, but the sensorimotor defects improve only slightly. Sectioning of the scalenus muscle is not endorsed because, as already noted, the role of muscle in causing thoracic outlet syndrome has been questioned.

Other Painful Conditions Originating in the Neck, Brachial Plexus, and Shoulder

The brachial plexus is an important source of shoulder and arm pain. The main disorders are brachial neuritis and metastatic infiltration and radiation damage to the plexus. Chapter 44 discusses these disorders in detail. Metastases to the cervical region of the spine are less common than to other parts of the vertebral column. They are, however, frequently painful and may cause root compression. Posterior extension of the tumor from the vertebral bodies or compression fractures may lead to the rapid development of quadriplegia. The Pancoast tumor, usually a squamous cell carcinoma in the superior sulcus of the lung, may implicate the lower cervical and upper thoracic (T1 and T2) spinal nerves as they exit the spine. In these cases, a Horner syndrome, numbness of the inner side of the arm and hand, and weakness of all muscles of the hand and of the triceps muscle are combined with pain beneath the upper scapula and in the arm. The neurologic abnormalities may occur long before the tumor becomes visible radiographically.

Shoulder injuries (rotator cuff), subacromial or subdeltoid bursitis, periarthritis or capsulitis (frozen shoulder), tendonitis, and arthritis, as has been mentioned, may develop in patients who are otherwise well, but these conditions also occur as complications of hemiplegia. The pain tends to be severe and extends toward the neck and down the arm into the hand. The dorsum of the hand may tingle without other signs of nerve involvement. Immobility of an arm following myocardial infarction may be associated with pain in the shoulder and arm and with vasomotor changes and secondary arthropathy of the hand joints (shoulder–hand syndrome); after a time, osteoporosis and atrophy of cutaneous and subcutaneous structures occur (Sudeck atrophy or Sudeck-Leriche syndrome). Similar changes may occur in the foot and leg, or all articular structures on the side of a hemiplegia, or in association with the painful lesions described in the first part of this chapter. These complications can be ameliorated by proper exercises and relieved by cooling of the affected limb.

Lateral and medial epicondylitis (tennis elbow and golf elbow, respectively) are readily diagnosed by demonstrating tenderness over the affected parts and an aggravation of pain on certain movements of the elbow. We have observed entrapment of the ulnar nerve in cases of medial epicondylitis.

The pain of the carpal tunnel syndrome often extends into the forearm and sometimes into the anterior biceps region and may be mistaken for disease of the Vasomotor, sudomotor, and trophic changes in the skin, with atrophy of the soft tissues and decalcification of bone, may follow the prolonged immobilization and disuse of an arm (i.e., frozen shoulder syndrome) or leg for whatever reason. Similarly, involvement of the ulnar, radial, or median nerves may be mistaken for brachial plexus or root lesions. EMG and nerve conduction studies are helpful in these circumstances (this common disorder is discussed in Chap. 43).

Polymyalgia Rheumatica (See Also Chap. 9)

This syndrome is observed in middle-aged and elderly persons and is characterized by severe pain, aching, and stiffness in the proximal muscles of the limbs and a markedly elevated erythrocyte sedimentation rate. The shoulders are most affected, but half of these patients have hip or neck pain as well. Constitutional symptoms (loss of weight, fever, and anemia) and articular swelling are less consistent manifestations. A few patients have pitting edema of

the hands or feet (Salvarini and colleagues); others have knee or wrist arthritis or carpal tunnel syndrome. Arthroscopy and MRI suggest that the pain originates in a synovitis or, sometimes more accurately, a bursitis, and in an inflammation of periarticular structures. The fundamental cause is not known.

Activity of the disease correlates with elevation of the sedimentation rate, almost always above 40 mm/h and typically higher than 70 mm/h (and corresponding elevation of C-reactive protein); unlike the case in polymyositis, with which it is confused, creatine kinase levels are normal. In many patients, polymyalgia rheumatica is associated with giant cell (temporal or cranial) arteritis. The precise concordance of these two allied conditions is not known, but there is not a high frequency of overlap. The arteritis may affect one or both optic nerves; blindness is the main risk of the disease, as discussed in detail in Chap. 13.

Treatment This disorder is self-limiting, lasting 6 months to 2 years, and responds dramatically to corticosteroid therapy, although this may have to be continued in low dosage for several months or a year or longer. We begin treatment with 20 mg of prednisone if there is no evidence of temporal arteritis (which requires higher doses). The absence of improvement in a day or two should bring the diagnosis into question. The degree of hip and shoulder pain is the best guide to the duration of steroid therapy and the rate at which the drug is withdrawn, usually in very small increments every 2 weeks. The sedimentation rate or C-reactive protein can be used as a guide, but neither alone is adequate to alter the medication schedule.

SECTION 3

Disorders of the Special Senses

CHAPTER 11 **Disorders of Smell and Taste**
CHAPTER 12 **Disturbances of Vision**
CHAPTER 13 **Disorders of Ocular Movement and Pupillary Function**
CHAPTER 14 **Deafness, Dizziness, and Disorders of Equilibrium**

The four chapters in this section are concerned with the clinical aspects of the highly specialized functions of taste and smell, vision, hearing, and the sense of balance. These special senses and the cranial nerves that subserve them represent the most finely developed parts of the sensory nervous system. Dysfunctions of the eye and ear are, of course, the domain of the ophthalmologist and otorhinolaryngologist, but they also are of great interest to the neurologist. Some defects in the special sensory apparatus reflect the presence of systemic disease and others represent the initial or leading manifestation of neurologic disease. In keeping with the general scheme of this text, the disorders of the special senses and of ocular movement are discussed in a particular sequence: first, certain facts of anatomic and physiologic importance, followed by cardinal clinical manifestations of disease, and then the syndromes of which these manifestations are a part.

11

Disorders of Smell and Taste

The sensations of smell (olfaction) and taste (gustation) are suitably considered together. Physiologically, these modalities share the singular attribute of responding primarily to chemical stimuli; that is, the end organs that mediate olfaction and gustation are chemoreceptors. Also, taste and smell are interdependent clinically, as the appreciation of the flavor of food and drink depends to a large extent on its aroma, and an abnormality of one of these senses is frequently misinterpreted as an abnormality of the other. In comparison to sight and hearing, taste and smell play a less critical role in the life of the individual. However, chemical stimuli in communication between humans are probably very important for some functions that have not been fully explored. Pheromones (*pherein*, "to carry"; *hormon*, "exciting"), that is, odorants exuded from the body, as well as perfumes, play a part in social and sexual attraction; noxious body odors may repel. In certain vertebrates the olfactory system is remarkably well developed, rivaling the sensitivity of the visual system. Though humans were thought to be capable of discriminating as many as 10,000 different odorants (Reed), more recent experimental studies have shown that this may be a vast underestimation (Bushdid and colleagues).

Disorders of taste and smell can be persistently unpleasant, but only rarely is the loss of either of these modalities a serious handicap. Nevertheless, as all foods and inhalants pass through the mouth and nose, these two senses serve to detect noxious odors (e.g., smoke) and to avoid tainted food and potential poisons. The loss of these senses could then have serious consequences. Also, because a loss of taste and smell may signify a number of intracranial, neurodegenerative, and systemic disorders, they assume additional clinical importance.

OLFACTORY SENSE

Anatomic and Physiologic Considerations

Nerve fibers subserving the sense of smell have their cells of origin in the mucous membrane of the upper and posterior parts of the nasal cavity (superior turbinates and nasal septum). The entire olfactory mucosa covers an area of about 2.5 cm^2 and contains three cell types: the olfactory receptor cells, which number between 6 and 10 million in each nasal cavity; sustentacular or supporting cells, which maintain the electrolyte (particularly potassium) levels in the extracellular milieu; and basal cells, which are stem cells and the source of both the olfactory and sustentacular cells during regeneration. The olfactory cells are actually bipolar neurons. Each of these cells has a peripheral process (the olfactory rod) from which project 10 to 30 fine hairs, or cilia. These hair-like processes, which lack motility, are the sites of olfactory receptors.

The central processes of these cells, or *olfactory fila*, are very fine (0.2 mm in diameter) unmyelinated fibers that converge to form small fascicles enwrapped by Schwann cells that pass through openings in the cribriform plate of the ethmoid bone into the olfactory bulb (Fig. 11-1). Collectively, the central processes of the olfactory receptor cells constitute the *first cranial (olfactory) nerve*. Notably, this is the only site in the body where neurons are in direct contact with the external environment. The epithelial surface is covered by a layer of mucus, which is secreted by tubuloalveolar cells (Bowman glands) and within which there are immunoglobulins A and M, lactoferrin, and lysoenzyme as well as odorant-binding proteins. These molecules are thought to prevent the intracranial entry of pathogens via the olfactory pathway (Kimmelman).

In the olfactory bulb, the receptor-cell axons synapse with granule cells and mitral cells (so-called because they are triangular, like a bishop's miter), the dendrites of which form brush-like terminals or olfactory glomeruli (see Fig. 11-1). Smaller tufted cells in the olfactory bulb also contribute dendrites to the glomerulus. Approximately 15,000 olfactory cell axons converge on a single glomerulus. This high degree of convergence is thought to account for an integration of afferent information. The mitral and tufted cells are excitatory; the granule cells—along with centrifugal fibers from the olfactory nuclei, locus ceruleus, and piriform cortex—inhibit mitral cell activity. Presumably, interaction between these excitatory and inhibitory neurons provides the basis for the special physiologic aspects of olfaction.

The axons of the mitral and tufted cells form the olfactory tract, which courses along the olfactory groove of the cribriform plate to the cerebrum. Within the olfactory tract and posterior to the olfactory bulbs are groups of cells that constitute the anterior olfactory nucleus (see Fig. 11-1). Dendrites of these cells synapse with fibers

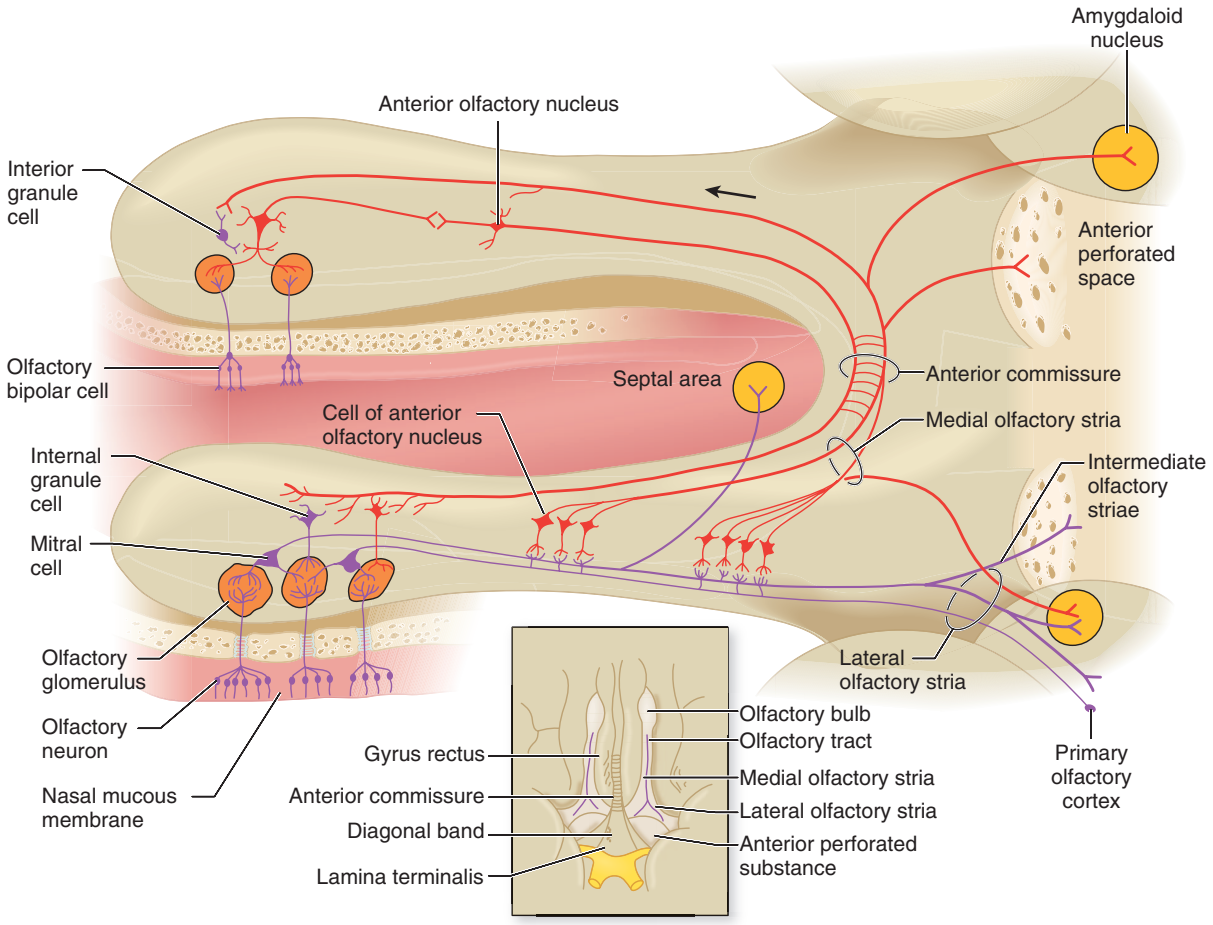

Figure 11-1. Diagram illustrating the relationships between the olfactory receptors in the nasal mucosa and neurons in the olfactory bulb and tract. Cells of the anterior olfactory nucleus are found in scattered groups caudal to the olfactory bulb. Cells of the anterior olfactory nucleus make immediate connections with the olfactory tract. They project centrally via the medial olfactory stria and to contralateral olfactory structures via the anterior commissure. *Inset:* diagram of the olfactory structures on the inferior surface of the brain.

of the olfactory tract, while their axons project to the olfactory nucleus and bulb of the opposite side; these neurons are thought to function as a reinforcing mechanism for olfactory impulses.

Posteriorly, the olfactory tract divides into medial and lateral olfactory striae. The medial stria contains fibers from the anterior olfactory nucleus; these pass to the opposite side via the anterior commissure. Fibers in the lateral stria originate in the olfactory bulb, give off collaterals to the anterior perforated substance, and terminate in the nuclei of the amygdaloid complex and the prepiriform area (also referred to as the lateral olfactory gyrus). The latter represents the *primary olfactory cortex*, which in humans occupies a restricted area on the anterior aspect of the parahippocampal gyrus and uncus (area 34 of Brodmann; see Figs. 21-1 and 21-2). Thus, olfactory impulses reach the cerebral cortex without a relay through the thalamus; in this respect also, olfaction is unique among sensory systems. From the prepiriform cortex, fibers project to the neighboring entorhinal cortex (area 28 of Brodmann) and the medial dorsal nucleus of the thalamus; the amygdaloid nuclei connect with the hypothalamus and septal nuclei. The role of these latter structures in olfaction is not well understood, but presumably they subserve reflexes related to eating and sexual function. As with all sensory systems, feedback regulation occurs at every point in the afferent olfactory pathway.

In quiet breathing, little of the air entering the nostril reaches the olfactory mucosa; sniffing (ortonasal olfaction) carries the air into the olfactory crypt, which contains the olfactory receptors. Air can also reach the olfactory receptors via inhalation through the mouth (retronasal olfaction). To be perceived as an odor, an inhaled substance must be volatile—that is, spread in the air as very small particles—and soluble in water. Molecules provoking the same odor seem to be related by their shape more than by their chemical quality. When a jet of scented vapor is directed to the sensory epithelium, as by sniffing, a slow negative potential shift called the *electroolfactogram* (EOG) can be recorded from an electrode placed on the mucosa.

The conductance changes that underlie this receptor potential are induced by molecules of odorous material dissolved in the mucus overlying the receptor.

The transduction of odorant stimuli to electrical signals is mediated in part by a guanosine triphosphate (GTP)-dependent adenylyl cyclase ("G protein"). Like other cyclic adenosine monophosphate (AMP) pathways, this one utilizes the same intracellular *second messenger*, which opens a voltage-gated calcium channel in the receptor. There follow conformational changes in transmembrane receptor proteins and a series of intracellular biochemical events that generate axon potentials.

Intensity of olfactory sensation is determined by the frequency of firing of afferent neurons. The quality of the odor is thought to be provided by "cross-fiber" activation and integration, as described earlier, because the individual receptor cells are responsive to a wide variety of odorants and exhibit different types of responses to stimulants—excitatory, inhibitory, and on–off responses have been obtained. The olfactory potential can be eliminated by destroying the olfactory receptor surface or the olfactory filaments. The loss of EOG occurs 8 to 16 days after severance of the nerve; the receptor cells disappear, but the sustentacular (Sertoli) cells are not altered. As a result of division of the basal cells of the olfactory epithelium, the olfactory receptor cells are constantly dying and being replaced by new ones. In this respect, the chemoreceptors, both for smell and for taste, constitute one of the few examples of neuronal regeneration in humans.

The trigeminal system also participates in chemesthesis through undifferentiated receptors in the nasal mucosa. These receptors have little discriminatory ability but a great sensitivity to irritant stimuli. The trigeminal afferents also release neuropeptides that result in hypersecretion of mucus, local edema, and sneezing. Finally, stimulation of the olfactory pathway at cortical sites of the temporal lobe may also induce olfactory experiences.

The olfactory system adapts quickly to a sensory stimulus, and for sensation to be sustained, there must be repeated stimulation. The olfactory sense differs from other senses in yet another way. It is common experience that an aroma can restore long-forgotten memories of complex experiences. That olfactory and emotional stimuli are strongly linked is not surprising in view of their common roots in the limbic system. Yet, paradoxically, the ability to recall an odor is negligible in comparison with the ability to recall sounds and sights. As Vladimir Nabokov has remarked, "Memory can restore to life everything except smells." It is also interesting that dreams do not embody olfactory experiences.

The remarkable evolutionary role of olfactory receptors can be appreciated by the fact that about 3 percent of the human genome exists to express unique odorant receptors (over 400 distinct functional genes). The wide diversity of these transmembrane proteins permits subtle differentiation of thousands of different odorant molecules (Young and Trask), and the genetic basis for which Linda Buck and Richard Axel were awarded a Nobel Prize in 2004.

This specificity for molecules is encoded neuroanatomically. Different odorant molecules activate specific olfactory receptors. Each olfactory neuron expresses only one allele of one receptor gene. Moreover, each olfactory glomerulus receives inputs from neurons expressing only one type of odorant receptor. In this way, each of the glomeruli is attuned to a distinct type of odorant stimulus. Presumably, this encoding is preserved in the olfactory cortex.

Something is to be learned from a second, distinct olfactory system in many animals (the vomeronasal olfactory system, or organ of Jacobson), in which the repertoire of olfactory receptors is much more limited than in their main olfactory system. This functionally and anatomically distinct olfactory tissue is attuned to pheromones and thereby importantly influences menstrual, reproductive, ingestive, and defensive behavior (Wysocki and Meredith). The vomeronasal receptors employ different signaling mechanisms than other olfactory receptors and project to the hypothalamus and amygdala via a distinct accessory olfactory bulb.

Clinical Manifestations of Olfactory Lesions

Disturbances of olfaction may be subdivided into four groups, as follows:

1. *Quantitative abnormalities:* loss or reduction of the sense of smell (anosmia, hyposmia) or, rarely, increased olfactory acuity (hyperosmia)
2. *Qualitative abnormalities:* distortions or illusions of smell (dysosmia or parosmia)
3. *Olfactory hallucinations and delusions* caused by temporal lobe disorders or psychiatric disease
4. *Higher-order loss* of olfactory discrimination (olfactory agnosia)

Anosmia, or Loss of the Sense of Smell (Table 11-1)

This is the most frequent clinical abnormality of olfaction and, if unilateral, usually is not recognized by the patient. Unilateral anosmia can sometimes be demonstrated in a patient with a functional neurologic disorder on the same

Table 11-1

MAIN CAUSES OF ANOSMIA

Nasal
- Smoking
- Chronic rhinitis (allergic, atrophic, cocaine, infectious—herpes, influenza, COVID)
- Overuse of nasal vasoconstrictors

Olfactory epithelium
- Head injury with tearing of olfactory filaments
- Cranial surgery
- Subarachnoid hemorrhage, meningitis
- Toxic (organic solvents, certain antibiotics—aminoglycosides, tetracyclines, corticosteroids, methotrexate, opiates, L-dopa)
- Metabolic (thiamine deficiency, adrenal and thyroid deficiency, cirrhosis, renal failure, menses)
- Wegener granulomatosis
- Compressive and infiltrative lesions (craniopharyngioma, meningioma, aneurysm, meningoencephalocele)

Central
- Degenerative diseases (Parkinson, Alzheimer, Huntington)
- Temporal lobe epilepsy

Malingering and hysteria

side as anesthesia, blindness, or deafness. Bilateral anosmia, on the other hand, is a common complaint, and the patient is usually convinced that the sense of taste has been lost as well (*ageusia*). This calls attention to the fact that taste depends largely on the volatile particles in foods and beverages, which reach the olfactory receptors through the nasopharynx, and that the perception of flavor is a combination of smell, taste, and tactile sensation. This can be proved by demonstrating that patients with anosmia but without a complaint of ageusia are able to distinguish the elementary taste sensations on the tongue (sweet, sour, bitter, and salty). The olfactory defect can be verified readily enough by presenting a series of nonirritating olfactory stimuli (vanilla, peanut butter, coffee, tobacco) and asking the patient to sniff once and identify them. If the odors can be detected and described, even if they cannot be named, it may be assumed that the olfactory nerves are relatively intact (humans can distinguish many more odors than they can identify by name). If they cannot be detected, there is an olfactory defect. Ammonia and similar pungent substances are unsuitable stimuli because they do not test the sense of smell but have a primary irritating effect on the mucosal-free nerve endings of the trigeminal nerves.

The value of testing smell in one nostril at a time has been questioned by studies of olfactory groove meningiomas (Welge-Luessen and colleagues). Contrary to expectations, this test was not found to be sensitive to the presence of a unilateral lesion, ostensibly because of mixing of air in the nasopharynx as well as crossing of medial olfactory stria fibers as described earlier. Nonetheless, other experience suggests that rapidly sniffing through one nostril does briefly allow segregation of each side of the nasal cavities and can detect unilateral lesions.

A more elaborate scratch-and-sniff test (University of Pennsylvania Smell Identification Test) has been developed and standardized (Doty and colleagues, 1984). In this test the patient attempts to identify 40 microencapsulated odorants, and olfactory performance is compared with that of age and sex-matched normal individuals. Unique features of this test are a means for detecting malingering and amenability to self-administration. Air-dilution olfactory detection is an even more refined way of determining thresholds of sensation and of demonstrating normal olfactory perception in the absence of odor identification. The use of olfactory evoked potentials is being investigated in some electrophysiology laboratories, but their reliability is uncertain. These last two refined techniques are essentially research tools and are not used in neurologic practice.

The loss of smell usually falls into one of three categories: *nasal* (in which odorants do not reach the olfactory receptors), *olfactory neuroepithelial* (caused by destruction of receptors or their axon filaments), and *central* (olfactory pathway lesions).

Viewed from another perspective, in an analysis of 4,000 cases of anosmia from specialized clinics, the three most common diagnoses were viral infection of the upper respiratory tracts (the largest group), nasal or paranasal sinus disease, and head injury (Hendriks).

Regarding the nasal diseases responsible for bilateral hyposmia or anosmia, the most frequent are those in which hypertrophy and hyperemia of the nasal mucosa prevent olfactory stimuli from reaching the receptor cells. Heavy smoking is the most frequent cause of this type of hyposmia in practice. Chronic atrophic rhinitis; sinusitis of allergic, vasomotor, or infective types; nasal polyposis; and overuse of topical vasoconstrictors are other common causes. Biopsies of the olfactory mucosa in cases of allergic rhinitis have shown that the sensory epithelial cells are still present, but their cilia are deformed and shortened and are buried under other mucosal cells. Influenza, herpes simplex, and other viral infections may be followed by hyposmia or anosmia caused by destruction of receptor cells; if the basal cells are also destroyed, this may be permanent. These cells may also be affected as a result of atrophic rhinitis and local radiation therapy or by a rare type of tumor (*esthesioneuroblastoma*) that originates in the olfactory epithelium. One of the common clinical symptoms of some of the early variants of SARS-CoV-2 (COVID-19) viral infection was a period of anosmia lasting approximately 7 days (longer in some indviduals); the relatively short duration perhaps arguing against viral invasion and killing of olfactory receptor neurons, though the mechanism of this symptom is incompletely understood (Koralnik and Tyler).

There is also a group of uncommon diseases in which the primary receptor neurons are congenitally absent or hypoplastic and lack cilia. One of these is the *Kallmann syndrome* of congenital anosmia and hypogonadotropic hypogonadism. A similar disorder occurs in Turner syndrome and in albinism.

Anosmia that follows head injury is most often a result of tearing of the delicate filaments of the receptor cells as they pass through the cribriform plate, especially if the injury is severe enough to cause fracture. The damage may be unilateral or bilateral. With closed head injury, complete anosmia is relatively infrequent (6 percent of 584 cases; see Sumner), but lesser degrees are common in our experience. Some recovery of olfaction occurs in about one-third of cases over a period of several days to months. Beyond 6 to 12 months, recovery is negligible. Cranial surgery, subarachnoid hemorrhage, and chronic meningeal inflammation may have similar effects.

In some of the cases of traumatic anosmia, there is also a loss of taste (ageusia). Ferrier, who first described traumatic ageusia in 1876, noted that there was always anosmia as well—an observation that has been subsequently corroborated (Sumner). Often, the ageusia also clears within a few weeks. A bilateral traumatic lesion near the frontal operculum and paralimbic region, where olfactory and gustatory receptive zones are in close proximity, would best explain this concurrence, but this has not been proven. As stated earlier, the interruption of olfactory filaments alone would explain a reduction in the ability to perceive the subtleties of specific flavors but does not explain ageusia.

Olfactory acuity varies throughout the menstrual cycle, possibly through an imputed vomeronasal system in humans, and may be altered during pregnancy as well. Nutritional and metabolic disorders such as thiamine deficiency (Wernicke disease), vitamin A deficiency, adrenal and perhaps thyroid insufficiency, cirrhosis, and chronic

renal failure may give rise to anosmia, all as a result of sensorineural dysfunction. A large number of toxic agents—the more common ones being organic solvents (benzene), metals including platinum-containing chemotherapies, dusts, cocaine, corticosteroids, methotrexate, aminoglycoside antibiotics, tetracyclines, opiates, and L-dopa—can damage the olfactory epithelium (Doty and colleagues, 1984). Alcoholics with Korsakoff psychosis also have a defect in odor discrimination (Mair and colleagues). In this disorder, anosmia is presumably caused by degeneration of neurons in the higher-order olfactory systems involving the medial thalamic nuclei.

Anosmia has been found in some patients with temporal lobe epilepsy and particularly in such patients who had been subjected to anterior temporal lobectomy. In these conditions, impairment in discriminating the quality of odors and in matching odors with test objects seen or felt have been described (Andy and coworkers).

As with other sensory modalities, olfaction (and taste) is diminished with aging (*presbyosmia*). The receptor cell population is depleted, and if the loss is regional, neuroepithelium is slowly replaced with respiratory epithelium (which is normally present in the nasal cavity and serves to filter, humidify, and warm incoming air). Neurons of the olfactory bulb may also be reduced as part of the aging process.

Bilateral anosmia has been a manifestation of *malingering*, now that it has been recognized as a compensable disability. The fact that true anosmics will complain inordinately of a loss of taste (but show normal taste sensation) may help to separate them from malingerers. If it were to be perfected, testing of olfactory evoked potentials would be of use here.

The nasal epithelium or the olfactory nerves themselves may be affected in Wegener granulomatosis and by craniopharyngioma, respectively. A meningioma of the olfactory groove may implicate the olfactory bulb and tract and may extend posteriorly to involve the optic nerve, sometimes with optic atrophy; if combined with papilledema in the fellow eye, these abnormalities are known as the *Foster Kennedy syndrome* (see Chap. 12). A large aneurysm of the anterior cerebral or anterior communicating artery may produce a similar constellation. With tumors confined to one side, the anosmia may be strictly unilateral, in which case it will not be reported by the patient but will be found on examination. The limitations of testing each side of the nose separately have been mentioned earlier. These defects in the sense of smell are attributable to lesions of either the receptor cells and their axons or the olfactory bulbs, and current test methods do not distinguish between lesions in these two localities. In some cases of increased intracranial pressure, olfactory sense has been impaired without evidence of lesions in the olfactory bulbs.

The term *specific anosmia* has been applied to an unusual olfactory phenomenon in which a person with normal olfactory acuity for most substances encounters a particular compound or class of compounds that is odorless to him, although obvious to others. In a sense, this is a condition of "smell blindness," analogous to color blindness. The basis of this disorder is unclear although there is evidence that specific anosmia for musky and uriniferous odors is inherited as an autosomal recessive trait.

Whether a true *hyperosmia* exists is a matter of conjecture, but it is so frequently reported by migraineurs that the problem seems worthy of attention. Anxious, highly introspective individuals may complain of being unduly sensitive to odors, but for the most part there is no proof of an actual change in their threshold of perception of odors. Interestingly, enhanced sensitivity to the odorant isovaleric acid has been linked to single nucleotide polymorphism (SNP) variants of the olfactory receptor gene *OR11H7P*, and more associations of this kind may be elucidated (Menashe and colleagues).

Olfaction in neurodegenerative disease Early neuronal degeneration in the olfactory region of the hippocampus in cases of Alzheimer, Lewy body, and Parkinson disease has been observed (Hyman and colleagues). Moreover, a large proportion of patients with other degenerative diseases of the brain have anosmia or hyposmia. A number of theories have been proposed to explain the initial loss of smell, the most relevant of which is based on the finding that the earliest neuropathologic changes of many neurodegenerative processes begin in olfactory structures and then appear serially in neighboring structures, only later reaching the parts of the brain that produce the characteristic neurologic features of these diseases. The implication from these findings, originating with Braak and Braak, has been that Lewy bodies in particular are caused by a pathogen that enters through the peripheral olfactory system and proceeds centrally through the medial temporal lobe (see Chap. 38 for further details). Prions have been suggested as a candidate agent because of their ability to alter protein folding and to transfer this property in a sequentially topographic manner. The studies relating to olfaction in Parkinson disease have been reviewed (Doty and colleagues, Braak and colleagues, Hawkes and colleagues, Quinn and colleagues, and Benarroch). It should be emphasized to patients, however, that the reverse is not the case; that is, the majority of individuals with hyposmia do not have a generalized neurodegenerative disease.

Dysosmia or Parosmia

These terms refer to distortions of odor perception where an odor is present. Parosmia may occur with local nasopharyngeal conditions such as infection of the nasal sinuses and upper respiratory infections. In some instances, the abnormal tissue itself may be the source of unpleasant odors; in others, where partial injuries of the olfactory bulbs have occurred, parosmia is in the nature of an olfactory illusion. Parosmia may also be a troublesome symptom in persons with depressive and psychotic illnesses, who may report that every article of food has an extremely unpleasant odor (cacosmia). Sensations of disagreeable taste are often associated (cacogeusia). Nothing is known on the basis of this state; there is usually no loss of discriminative sensation.

The treatment of parosmia is difficult. The use of neuroleptic or antiepileptic drugs has yielded unpredictable results. Claims for the efficacy of zinc and vitamins have not been verified (and there is a risk that zinc administration may interfere with the absorption of copper). Some reports

indicate that repeated anesthetization of the nasal mucosa reduces or abolishes the parosmic disturbance. In many cases, the disorder subsides spontaneously. Minor degrees of parosmia are not necessarily abnormal, for unpleasant odors have a way of lingering for several hours and of being reawakened by other olfactory stimuli, as every pathologist knows.

Olfactory Hallucinations

The report of an odor without stimulus, olfactory hallucination, is always of central origin. The patient perceives an odor that no one else can detect (phantosmia). Most often this a manifestation of temporal lobe seizures ("uncinate fits"), in which circumstances the olfactory hallucinations are brief and accompanied or followed by an alteration of consciousness and other manifestations of epilepsy (see Chap. 15 on epilepsy).

If the patient is convinced of the presence of what is in fact a hallucination and also gives it personal origin, the symptom assumes the status of a delusion (a fixed false belief). The combination of olfactory hallucinations and delusions of this type signifies a psychiatric illness (Zilstorff). There is often a complaint of a large array of odors, most of them noxious and seemingly emanating from the patient (intrinsic hallucinations); in others, they are attributed to an external source (extrinsic hallucinations). Both types vary in intensity and are remarkable with respect to their persistence. They may be combined with gustatory hallucinations. In a series of 137 patients with olfactory hallucinations, most were associated with endogenous depression or schizophrenia (Pryse-Phillips). In schizophrenia, the olfactory stimulus is usually interpreted as arising externally, and as being induced by someone for the purpose of upsetting the patient. In depression, the perception is of the stimulus being intrinsic. The patient may go to great lengths to rid himself of the perceived odor, the usual ones being excessive washing and use of deodorants; the condition may lead to social withdrawal. There is reason to believe that the amygdaloid group of nuclei is the source of the hallucinations, as stereotactic lesions here have reportedly ameliorated both the olfactory hallucinations and the psychiatric disorder (Chitanondh).

Olfactory hallucinations and delusions may occur in conjunction with Alzheimer dementia, but one should also consider the possibility of a late-life depression.

Loss of Olfactory Discrimination (Olfactory Agnosia)

Finally, one must consider a disorder in which the primary perceptual aspects of olfaction (detection of odors, adaptation to odors, and recognition of different intensities of the same odor) are intact, but the capacity to distinguish between odors and their recognition by quality is impaired or lost. In the writings on this subject, this deficit is usually referred to as a disorder of olfactory discrimination. In dealing with other sense modalities, however, the inability to identify and name a perceived sensation would be called an *agnosia*. To recognize this deficit requires special testing, such as matching to sample, the identification and naming of a variety of scents, and determining whether two odors are identical or different.

Such an alteration of olfactory function has been shown to characterize patients with the alcoholic form of Korsakoff psychosis; this impairment is not attributable to reduced olfactory acuity or to failure of learning and memory (Mair and colleagues). The olfactory disorder in the alcoholic Korsakoff patient is most likely caused by lesions in the medial dorsal nucleus of the thalamus; several observations in animals indicate that this nucleus and its connections with the orbitofrontal cortex give rise to deficits in odor discrimination (Mair and colleagues; Slotnick and Kaneko). A similar impairment of olfactory capacities was reported in a patient who had undergone extensive bilateral medial temporal lobe resections (Eichenbaum and colleagues). In patients with stereotactic or surgical amygdalotomies, a similar reduction in odor discrimination was noted (Andy and colleagues). Thus, it appears that both portions of the higher olfactory pathways (medial temporal lobes and medial dorsal nuclei) are necessary for the discrimination and identification of odors.

GUSTATORY SENSE

Anatomic and Physiologic Considerations

The sensory receptors for taste (taste buds) are distributed over the surface of the tongue and, in smaller numbers, over the soft palate, pharynx, larynx, and esophagus. Mainly they are located in the epithelium along the lateral surfaces of the circumvallate and foliate papillae and to a lesser extent on the surface of the fungiform papillae. The taste buds are round or oval structures, each composed of up to 200 vertically oriented receptor cells arranged like the staves of a barrel. The superficial portion of the bud is marked by a small opening, the taste pore or pit, which opens onto the mucosal surface. The tips of the sensory cells project through the pore as a number of filiform microvilli ("taste hairs"). Fine, unmyelinated sensory fibers penetrate the base of the taste bud and synapse directly with the sensory taste cells, which have no axons.

The taste receptors are activated by chemical substances in solution and transmit their activity along the sensory nerves to the brainstem. Four primary and readily tested taste sensations were long known: salty, sweet, bitter, and sour; and a fifth, *umami,* signifying a savory taste—the taste of glutamate, aspartate, and certain ribonucleotides—has been added. The full range of taste sensations is much broader, consisting of combinations of these five elementary gustatory sensations. Older notions of a "tongue map," which implied the existence of specific areas subserving one or another taste, are incorrect. Any one taste receptor is capable of responding to a number of sapid substances, but each is preferentially sensitive to one substance. In other words, the receptors are only relatively specific. The sensitivity of these receptors is remarkable: as little as 0.05 mg/dL of quinine sulfate will arouse a bitter taste when applied to the base of the tongue.

A G-protein transduction system (gustducin), similar to the one for olfaction, has been found to be operative in signaling taste sensations in the tongue receptors. A discussion of this system can be found in the commentary by Brand.

The receptor cells of the taste buds have a brief life cycle (about 10 days), being replaced constantly by mitotic division of adjacent basal epithelial cells. The number of taste buds, not large to begin with (approximately 10,000), is gradually reduced with age; also, changes occur in the taste cell membranes, with impaired function of ion channels and receptors (Mistretta). Gustatory (and olfactory) acuity diminishes with age. Taste thresholds for salt, sweeteners, and amino acids are 2 to 2.5 times higher in the elderly than in the young (Schiffman, 1991). The reduction in the acuity of taste and smell with aging may lead to a distortion of food habits (e.g., excessive use of salt and other condiments) and contribute to the anorexia and weight loss of elderly persons.

Animals made deficient in sodium, calcium, certain vitamins, proteins, etc., will automatically select the correct foods, on the basis of their taste, to compensate for their deficiency (Richter). Interesting genetic polymorphisms in the receptor for sweet substances in rats have been found to underlie differences in the proclivity to ingest sweet substances, and a similar system has been proposed in humans (Chaudhari and Kinnamon).

Neural Innervation of the Tongue

Sensory impulses for taste arise from several sites in the oropharynx and are transmitted to the medulla via cranial nerves V, VII, IX, and X. The main pathway arises on the *anterior two-thirds of the tongue*; these taste fibers first run in the lingual nerve (a major branch of the mandibular segment of the trigeminal [V] cranial nerve). After coursing within the lingual nerve for a short distance, the taste fibers diverge to enter the chorda tympani (a branch of the facial [VII] nerve); thence they pass through the pars intermedia and geniculate ganglion of the seventh nerve to the rostral part of the *nucleus of the tractus solitarius* in the posterolateral medulla, where all taste afferents converge (see the following text and Fig. 44-3).

From the *posterior one-third of the tongue*, soft palate, and palatal arches, the sensory taste fibers are conveyed via the glossopharyngeal (IX) nerve and ganglion nodosum to the nucleus of the tractus solitarius. Taste fibers from the extreme dorsal part of the tongue and the few that arise from taste buds on the pharynx and larynx run in the vagus (X) nerve. The *gustatory nucleus* is situated in the rostral and lateral parts of the nucleus tractus solitarius, which receives the special afferent (taste) fibers from the facial and glossopharyngeal nerves. Probably both sides of the tongue are represented in this nucleus.

Fibers from the palatal taste buds pass through the pterygopalatine ganglion and adjacent to greater superficial petrosal nerve fibers, joining the facial nerve at the level of the geniculate ganglion, and proceed to the nucleus of the tractus solitarius (see Fig. 44-3). Possibly, some taste fibers from the tongue may also reach the brainstem via the mandibular division of the trigeminal nerve. The presence of this alternative pathway probably accounts for reported instances of unilateral taste loss that have followed section of the root of the trigeminal nerve and instances in which no loss of taste has occurred with section of the chorda tympani.

The second sensory neuron for taste has been difficult to identify. Neurons from the gustatory segment of the nucleus solitarius project to adjacent nuclei (e.g., dorsal motor nucleus of the vagus, ambiguus, salivatorius superior and inferior, trigeminal, and facial nerves), which serve viscerovisceral and viscerosomatic reflex functions, but those concerned with the conscious recognition of taste are currently considered to form an ascending pathway to a pontine parabrachial nucleus. From the latter, two ascending pathways have been traced (in animals). One is the solitariothalamic lemniscus to the ventroposteromedial nucleus of the thalamus. A second passes to the ventral parts of the forebrain, to parts of the hypothalamus (which probably influences autonomic function), and to other basal forebrain limbic areas in or near the uncus of the temporal lobe. Other ascending fibers lie near the medial lemniscus and are both crossed and uncrossed. Experiments in animals indicate that taste impulses from the thalamus project to the tongue–face area of the primary somatosensory cortex. This is probably the end station of gustatory projections in humans as well, insofar as gustatory hallucinations have been produced by electrical stimulation of the parietal and/or rolandic opercula (Hausser-Hauw and Bancaud) and the anterior insula (Penfield and Faulk).

Clinical Manifestations of Disorders of Taste

Testing of Taste Sensation

Unilateral gustatory impairment can be identified by withdrawing the tongue with a gauze sponge and using a moistened applicator to place a few crystals of salt, sugar, lemon (sour), and quinine (bitter) on discrete parts of the tongue; the tongue is then wiped clean and the subject is asked to report what was sensed. One use of such testing is to corroborate the existence of Bell palsy by comparing taste sensation on each side of the anterior tongue (see Chap. 44). A stimulus that has been used as a surrogate for sour sensation is a low-voltage direct current, the electrodes of which can be accurately placed on the tongue surface. If the taste loss is bilateral, mouthwashes with a dilute solution of sucrose, sodium chloride, citric acid, and quinine may be used. After swishing, the test fluid is spit out and the mouth rinsed with water. The patient indicates whether a taste was detected and then is asked to try to identify it. Special types of apparatus (electrogustometers) have been devised for the measurement of taste intensity and for determining the detection and recognition thresholds of taste and olfactory stimuli (see Krarup; Henkin and colleagues, 1963), but these are beyond the needs of the usual clinical examination.

Ageusia, or Loss of the Sense of Taste (Table 11-2)

Apart from the loss of taste sensation that accompanies normal aging, smoking is probably the most common cause of impairment of taste sensation. Extreme drying of the tongue from any cause may lead to temporary loss or reduction of the sense of taste (*ageusia* or *hypogeusia*), as saliva is essential for normal taste function. Saliva acts as a solvent for chemical substances in food and for conveying them to taste receptors. Dryness of the mouth (xerostomia) from inadequate saliva, as occurs in Sjögren syndrome;

Table 11-2

MAIN CAUSES OF AGEUSIA

Bell palsy
Diabetes mellitus
Malnutrition (zinc deficiency) and hypovitaminosis (A, B_2, B_{12})
Sjögren syndrome
Infections (gingivitis, oral thrush, influenza, HIV) Lead or copper toxicity
Exposure to organic solvents, certain antibiotics, methotrexate, L-dopa, and zinc depleters/chelators
Radiation exposure
Degenerative disease (Parkinson)

hyperviscosity of saliva, as in cystic fibrosis; irradiation of head and neck; and pan-dysautonomia all interfere with taste. Also, in familial dysautonomia (Riley-Day syndrome), the number of circumvallate and fungiform papillae is reduced, accounting for a diminished ability to taste sweet and salty foods. If unilateral, ageusia is seldom the source of complaint. Taste is frequently lost over the anterior two-thirds of one side of the tongue in cases of mundane Bell palsy, as indicated previously and in Chap. 44.

A permanent decrease in the acuity of taste and smell (hypogeusia and hyposmia), sometimes associated with perversions of these sensory functions (dysgeusia and dysosmia), may follow influenza-like illnesses. These abnormalities have been associated with pathologic changes in the taste buds as well as in the nasal mucous membranes. In a group of 143 patients who presented with hypogeusia and hyposmia, 87 were of this postinfluenza type; the remainder developed their symptoms in association with scleroderma, acute hepatitis, viral encephalitis, myxedema, adrenal insufficiency, malignancy, deficiency of vitamins B and A, and the administration of a wide variety of drugs (Henkin and colleagues, 1975). Also, more than 250 drugs have been implicated in the alteration of taste sensation, making it necessary to consider virtually all drugs as a cause of taste loss (Schiffman, 1981). Lipid-lowering drugs, antihistamines, antimicrobials, antineoplastics, bronchodilators, antidepressants, and antiepileptics are the main offenders, but little is known about the mechanisms by which drugs induce these effects. More obvious is altered taste because of nasally and orally administered inhalant drugs, including the "triptans" for migraine and a variety of antiallergy and antiasthmatic medications.

Distortions of taste and loss of taste are sources of complaint in patients with certain local malignant tumors. Oropharyngeal tumors may, of course, abolish taste by invading the chorda tympani and lingual nerves or the skull base foramina through which these nerves pass. Malnutrition because of neoplasm or radiation therapy may also cause ageusia. Some patients with certain cancers remark on a reduced perception for bitter foods, and some who have been radiated for breast cancer or sublingual or oropharyngeal tumors find sour foods intolerable. The loss of taste from radiation of the oropharynx is usually recovered within a few weeks or months; the reduced turnover of taste buds caused by radiation therapy usually recovers.

An interesting syndrome of *idiopathic hypogeusia*—in which decreased taste acuity is associated with dysgeusia, hyposmia, and dysosmia—has been described (Henkin, Schechter, and colleagues). Food has an unpleasant taste and aroma, to the point of being revolting (cacogeusia and cacosmia); the persistence of these symptoms may lead to a loss of weight, anxiety, and depression.

Unilateral lesions of the medulla oblongata have not been reported to cause ageusia, perhaps either because the nucleus of the tractus solitarius is outside the zone of infarction or because there is representation from both sides of the tongue in each nucleus. In rare cases, unilateral thalamic and parietal lobe lesions have both been associated with contralateral impairment of taste sensation.

As indicated previously, a gustatory aura occasionally marks the beginning of a seizure originating in the frontoparietal (supra-sylvian) cortex or in the uncal region. Gustatory hallucinations are much less frequent than olfactory ones. Nevertheless, gustatory sensations were reported in 30 of 718 cases of intractable epilepsy (Hausser-Hauw and Bancaud). During surgery, these investigators produced an aura of disagreeable taste by electrical stimulation of the parietal and frontal opercula, and also by stimulation of the hippocampus and amygdala (uncinate seizures). In their view, the low-threshold seizure focus for taste in the temporal lobe is secondary to functional disorganization of the opercular gustatory cortex by the seizure. Gustatory hallucinations were more frequent with right hemisphere lesions, and in half of the cases the gustatory aura was followed by a convulsion.

Zinc supplements are contained in over-the-counter and complementary medical products aimed at improving smell and appetite and for the treatment of incipient colds. We have had no opportunity to confirm the often-cited benefits of zinc on any of these conditions, and the supporting evidence is sparse; however, the continued administration of zinc in high doses has been associated with the development of copper deficiency and a myeloneuropathy (see Chaps. 38 and 42).

Burning mouth syndrome Another poorly defined disorder is the burning mouth syndrome, which occurs mainly in postmenopausal women and is characterized by persistent, severe intraoral pain (particularly of the tongue). We have seen what we believe to be fragmentary forms of the syndrome in which pain and burning are isolated to the alveolar ridge or gingival mucosa. The oral mucosa appears normal and some patients may report a diminution of taste sensation. A small number of such patients prove to have diabetes, Sjögren syndrome, or vitamins B_2 or B_{12} deficiency (causing glossitis), but in most no systemic illness or local abnormality can be found. Many such patients that we have encountered appeared to have a depressive illness, but they responded only inconsistently to the administration of antidepressants. A few patients have this oral complaint as a component of a small fiber neuropathy or ganglionopathy (see Chap. 43). Clonazepam may be useful, and capsaicin has been tried with uncertain results. This disorder and others in which burning is a prominent feature is commented on in Chap. 7.

Disturbances of Vision

The importance of the visual system is reflected by the magnitude of its representation in the central nervous system. A large part of the cerebrum is committed to vision, including the perception of the form and color of objects, the perception of spatial relationships and motion, and the control of movements under visual guidance. The optic nerve, which is a tract of the central nervous system, contains more than a million fibers (compared to 50,000 in the auditory nerve). The visual system also has special significance in that study of this system has greatly advanced our knowledge of the organization of all sensory neuronal systems as well as the relationships between perception and conscious awareness. Indeed, we know more about neural underpinnings of vision than we do about any other sensory function. Furthermore, the eyes, because of their diverse composition of epithelial, vascular, neural, and pigmentary tissues, are virtually a medical microcosm, susceptible to many diseases, and their tissues are available for inspection through a transparent medium.

Impairment of visual function expressed as defects in acuity and alterations of visual fields constitute the most important symptom of eye disease. A number of terms are commonly used to describe the visual loss. *Amaurosis* is a general term that refers to partial or complete loss of sight. *Amblyopia* refers to any monocular deficit in vision in the presence of normal ocular structures. A major cause of amblyopia is the suppression by the brain of vision from one eye caused by either strabismus, anisometropia (a significant difference in refractive error), or media opacities during early childhood. *Nyctalopia* is a term for poor twilight or night vision and is associated with extreme myopia, cataracts, vitamin A deficiency, retinitis pigmentosa, and, often, color blindness. There are also a number of positive visual symptoms that are named based on their characteristics, including *phosphenes*, migrainous *scintillations*, visual *illusions*, and *hallucinations*. Irritation, redness, photophobia, pain, diplopia and strabismus, changes in pupillary size, and drooping or closure of the eyelids are other major ocular symptoms and signs.

APPROACH TO THE PROBLEM OF VISUAL LOSS

In the investigation of a disturbance of vision, one carefully inquires what the patient means when he describes the perceived change, for the disturbance in question may vary from near- or farsightedness to partial syncope, hemianopia, dizziness, or diplopia. Measurement of visual acuity is an essential part of the ocular examination. Inspection of the refractive media and the optic fundi, the testing of pupillary reflexes, color vision, and the plotting of visual fields complete this part of the examination. Examination of the eye movements is also essential, as discussed in Chap. 13.

The *Snellen chart*, which contains letters, numbers, or pictures arranged in rows of decreasing size, is used in the measurement of distance visual acuity (Fig. 12-1*A*). Each eye is tested separately at a distance of 20 ft. Spectacles should be worn if they are required for distance. The letter at the top of the chart subtends 5 min of an arc at a distance of 200 ft (or roughly 60 m). The patient attempts to identify rows of letters that can normally be read at lesser distances. Acuity is then reported as a nonmathematical fraction that represents the distance at which the patient has read the chart and the distance at which a person with normal vision would be able to read a letter of the same size. Thus, at a distance of 20 ft if the patient can read only the top letter on the chart, which would normally be visible at 200 ft, the acuity is expressed as 20/200 (if the distance is measured in meters, it is 6/60). If the patient's eyesight is normal, the visual acuity will equal 20/20, or 6/6, corresponding to the eighth line on most charts. Many persons, especially during youth, can read at 20 ft the line that can "normally" be read at 15 ft from the chart, and thus have acuity of 20/15.

For bedside testing, a "near card" held 14 in from the eyes can be used, and the results expressed in a distance equivalent as if a distance chart had been used (Fig. 12-1*B*). Here, the Jaeger system is used (J1 is "normal" vision, corresponding to the line 20/20 on a Snellen chart, J7 to 20/50, J13 to 20/100, and J16 to 20/200). In young children or individuals who are unable to read, acuity can be estimated by having the patient match symbols on an eye chart to choices

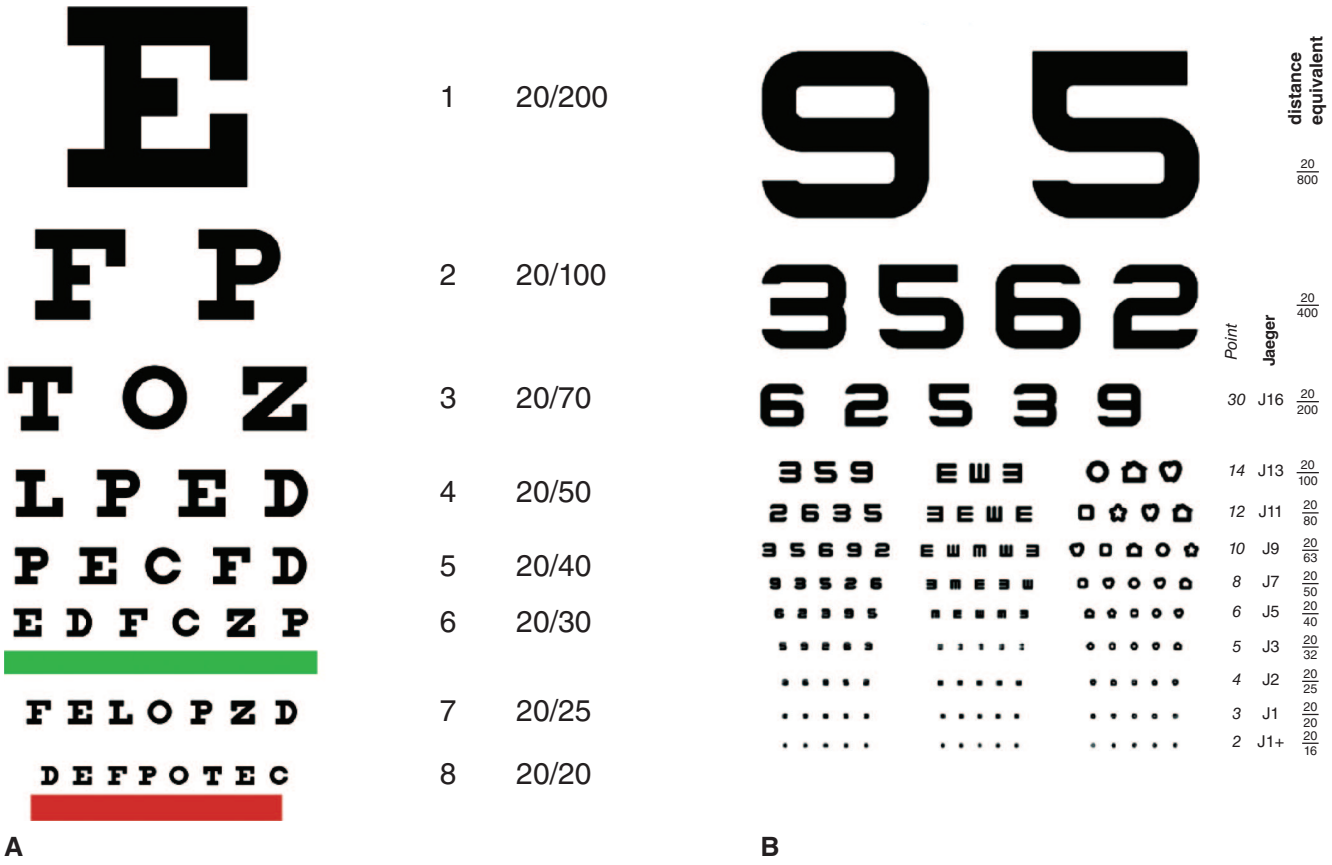

Figure 12-1. *A.* Conventional Snellen chart and *B.* Jaeger card for the estimation of visual acuity. The Snellen chart is placed 20 ft from the subject. The Jaeger card is used at 16 in from the subject's eyes and approximates Snellen acuity if convergence and accommodation are normal.

on a card. The Teller acuity cards estimate visual acuity by evaluating a child's automatic preference (and hence ability) to view cards with increasingly fine stripes without the need for them to make any other explicit response.

When visual acuity is reduced, it is helpful to use a pinhole to judge whether an uncorrected refractive error or other ocular disturbances are the cause. The pinhole permits a narrow shaft of light to fall on the fovea (the area of greatest visual acuity), eliminating the need for light to be correctly focused by the anterior segments of the eye. If the acuity improves to near normal with a pinhole, one can conclude that the reduced vision relates to a refractive error caused by a defect in the optical media (lens, cornea, aqueous, vitreous) of the eye rather than a neurological cause.

Light entering the eye is focused by the cornea and then the biconvex lens onto the outer layer of the retina. The cornea, fluid of the anterior chamber, lens, vitreous, and inner retinal layers must be transparent to produce a clear, focused image. The clarity of these media can be assessed with direct ophthalmoscopy, although slit lamp biomicroscopy offers more detailed, stereoscopic views. A complete examination requires that the pupil be dilated to at least 6 mm in diameter, accomplished by instilling phenylephrine (a sympathomimetic) and/or tropicamide (an anticholinergic) in each eye (after the visual acuity has been measured, the pupillary response is recorded, and the intraocular pressure is estimated). Rarely, an attack of angle-closure glaucoma (manifesting with diminished vision, ocular redness, and pain, and sometimes nausea and vomiting) may be precipitated by pharmacologic pupillary dilatation; this requires the administration of pilocarpine to the eye and the immediate attention of an ophthalmologist.

By looking through a high-plus lens of the direct ophthalmoscope from a distance of 6 to 12 in, the examiner can visualize opacities in the refractive media; by adjusting the lenses from a high-plus to a zero or minus setting, it is possible to "depth-focus" from the cornea to the retina. The illuminated pupil appears as a red circular structure (red reflex), the color being provided by blood in the capillaries of the choroid layer. The main limit of direct ophthalmoscopy is its inability to visualize lesions in the retina that lie anterior to the equator of the globe; these are seen only by the indirect method, which requires a headband, binocular lenses, light source, and hand-held condensing lenses, and is typically in the purview of ophthalmologists. Improvements in imaging technology have led to the availability of fundus cameras that can acquire excellent photographs without requiring pupillary dilation. These devices have proven to be clinically valuable in settings such as emergency departments, allowing the images to be reviewed remotely by those with appropriate expertise (Bruce). In addition, artificial intelligence algorithms to automatically

detect specific fundus abnormalities are being developed and validated (Milea).

Lesions of the macula, retina, or optic nerve cause a scotoma (an island of impaired vision surrounded by normal vision) rather than a defect that extends to the periphery of one visual field ("field deficit"). Scotomas can be named according to their position (central, cecocentral) and their shape (ring, arcuate). A scotoma that is situated in the macular part of the visual field often causes profound loss of visual acuity, with the patient relying on eccentric fixation to use parafoveal portions of the retina, where the maximal acuity drops precipitously.

Testing for Abnormalities of the Visual Fields

Figure 12-2 illustrates the visual field defects caused by lesions of the retina, optic nerve and tract, lateral geniculate body, geniculocalcarine pathway, and striate cortex of the

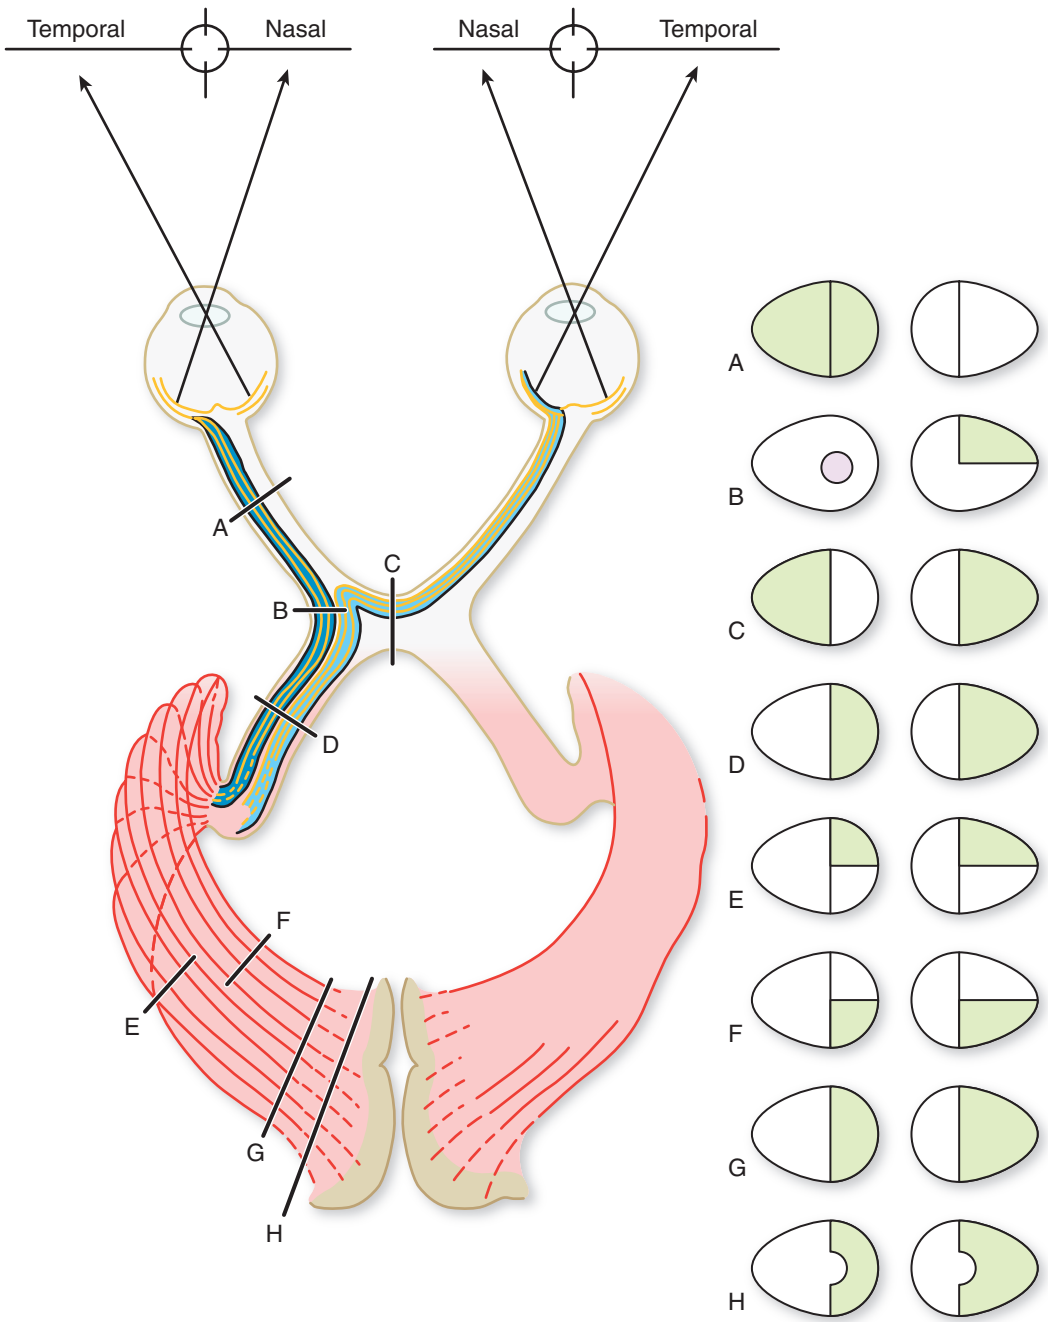

Figure 12-2. Diagram showing the effects on the fields of vision produced by lesions at various points along the optic pathway. *A*. Complete blindness in left eye from an optic nerve lesion. *B*. A left "junctional scotoma" with vision loss in the left eye coupled with a superotemporal defect in the right eye. *C*. Chiasmatic lesion causing bitemporal hemianopia. *D*. Right homonymous hemianopia from optic tract lesion. *E* and *F*. Right superior and inferior quadrant hemianopia from interruption of visual radiations. *G*. Right homonymous hemianopia caused by lesion of occipital striate cortex. *H*. Hemianopia with macular sparing, typically from posterior cerebral artery infarction.

occipital lobe. In the alert, cooperative patient, the visual fields can be plotted coarsely but fairly accurately with confrontation testing. With one of the patient's eyes covered and the other fixed on the corresponding eye of the examiner (patient's right with examiner's left), a target—such as a moving finger, a cotton pledget, or a white disc mounted on a stick—is brought from the periphery toward the center of the visual field. With the target at an equal distance between the eye of the examiner and that of the patient, the fields of the patient and examiner are then compared. Similarly, the patient's blind spot can be aligned with the examiner's, and its size determined by moving a small target outward from the blind spot until it is seen. Finger counting and comparison of color intensity of a red object or the clarity of the examiner's hand from quadrant to quadrant are simple confrontation tests that will disclose most field defects. Movement of the visual target provides the coarsest stimulus to the retina so that a perception of its motion may be preserved while a stationary target of the same size may not be seen. Similarly, a scotoma may be defined by asking the patient to report changes in color or brightness of a red test object as it is moved toward or away from the point of fixation. A central scotoma may be identified by having the patient fix with one eye on the examiner's nose, on which the examiner places the index finger of one hand or a white-headed pin and has the patient compare it for brightness, clarity, and color with a finger or pin held in the periphery. A central scotoma is suggested when the patient reports that the target in the periphery is the clearer of the two. In young children or uncooperative patients, the integrity of the fields may be roughly estimated by observing whether the patient is attracted to objects in the peripheral field or blinks in response to sudden threatening gestures in half of the visual field. Visual field defects are always described from the patient's view (nasal, temporal, superior, inferior) rather than of the retinal defect or the examiner's perspective.

We continue to teach that these confrontation techniques are reasonably sensitive for routine clinical examinations if performed carefully, but we are mindful of the high false-negative rate when compared with static automated perimetry, depending on the pretest probability and suspicion of deficits in the population of patients being examined (Pandit). Although automated perimetry techniques encompass only the central 24 to 30 degrees of visual field, this method is usually adequate to detect the most clinically important changes.

The method of testing by double simultaneous stimulation may elicit defects in visuospatial attention that are undetected by conventional perimetry. Movement of one finger in all parts of each temporal field may disclose no abnormality, but if movement is simultaneous in analogous parts of both temporal fields, the patient with hemispatial neglect from a parietal lobe lesion, especially on the right, may perceive only the one in the normal right hemifield.

One type of abnormality disclosed by visual field examination is concentric constriction. This may be a result of severe papilledema, in which case it is usually accompanied by an enlargement of the blind spot. A progressive constriction of the visual fields, at first unilateral and later bilateral, associated with pallor of the optic discs (optic atrophy), should suggest a chronic meningeal process involving the optic nerves (syphilis, cryptococcosis, sarcoidosis, lymphoma). Long-standing, untreated glaucoma and retinitis pigmentosa are other causes of concentric constriction. Marked constriction of the visual fields that remains constant regardless of the distance at which the visual field is tested is termed "tubular constriction"; it defies geometric principles and is a sign of functional visual loss. With organic disease, the constricted visual field enlarges as the distance between the patient and the testing screen increases.

NONNEUROLOGIC CAUSES OF REDUCED VISION

It is hardly possible within the confines of this chapter to describe all the ophthalmologic causes of visual loss. Those with the most important medical or neurologic implications are briefly commented upon. Although changes in the refractive media do not involve neural tissue primarily, certain ones assume importance because they are associated with neurologic disease.

In the *cornea*, the most common abnormality that reduces vision is scarring caused by trauma and infection. Ulceration and subsequent fibrosis may occur following recurrent herpes simplex, herpes zoster, and trachomatous infections of the cornea, or with certain muco-cutaneous-ocular syndromes (Stevens-Johnson, Reiter). Hypercalcemia secondary to sarcoidosis, hyperparathyroidism, and vitamin D intoxication or milk-alkali syndrome may give rise to precipitates of calcium phosphate and carbonate beneath the corneal epithelium, primarily in a plane corresponding to the interpalpebral fissure—so-called band keratopathy. Other causes of corneal opacity include chronic uveitis, interstitial keratitis, corneal edema, lattice corneal dystrophy (amyloid deposition), and long-standing glaucoma. Polysaccharides are deposited in the corneas in some of the mucopolysaccharidoses (see Chap. 36, and copper is deposited in the Descemet membrane in hepatolenticular degeneration (Kayser Fleischer rings). Crystal deposits may be observed in multiple myeloma and cryoglobulinemia. The corneas are also diffusely clouded in certain lysosomal storage diseases (see Chap. 36). Arcus senilis occurring at an early age (because of hyperlipidemia), sometimes combined with yellow lipid deposits in the eyelids and periorbital skin (xanthelasma), serves as a marker of atheromatous vascular disease.

The exact pathophysiology of open-angle glaucoma remains imperfectly understood, but one component seems to be elevated intraocular pressure from impaired outflow of aqueous fluid. This type of glaucoma comprises 90 percent of cases. Approximately 5 percent of cases are referred to as angle-closure glaucoma, in which the angle between the iris and the peripheral cornea is narrow and can be blocked when the pupil is dilated; these cases can be treated prophylactically by a surgical iridotomy. In the

remaining cases, the condition is a result of some disease process that blocks outflow channels—inflammatory debris of uveitis, red blood cells from hemorrhage in the anterior chamber (hyphema), new formation of vessels and connective tissue on the surface of the iris (rubeosis iridis), or ocular ischemia.

The visual loss is gradual in open-angle glaucoma and the eye looks normal, unlike the red, painful eye of acute angle-closure glaucoma. Intraocular pressures that are persistently above 20 mm Hg may contribute to the damage occurring to the optic nerve over time, typically manifesting first as an arcuate defect in the upper or lower nasal field, which, if untreated, may proceed to blindness. The classic finding in glaucoma is the *Bjerrum field defect,* consisting of an arcuate scotoma extending from the blind spot and sweeping around the macula to end in a horizontal line at the nasal equator. Other characteristic glaucomatous field patterns are winged extensions from the blind spot (Seidel scotoma) and a narrowing of the superior nasal quadrant that may progress to a horizontal edge, corresponding to the horizontal raphe of the retina (nasal step). The damage occurs at the optic nerve head, the optic disc appearing excavated, typically without pallor of the neuroretinal rim, thus distinguishing it from other optic neuropathies. Elongation of the optic cup in the vertical axis is typical. It is now appreciated that elevated intraocular pressure is only a concurrent finding and a risk factor for glaucoma, and similar optic nerve damage with "cupping" may occur in patients with near normal pressure, described as having "normal tension glaucoma." This shift in the understanding of the pathophysiology of glaucoma represents a major revision of the previous view that pressure was the elemental cause.

In the *lens*, cataract formation is a common abnormality characterized by clouding that usually develops slowly. The so-called senile cataract occurs with aging because lens proteins denature and degrade over time. The cataract associated with diabetes mellitus is the result of sustained high levels of blood glucose, which changes in the lens to sorbitol that causes a high osmotic gradient leading to swelling and disruption of the lens fibers. Galactosemia is a much rarer cause, but the mechanism of cataract formation is similar, that is, the accumulation of dulcitol in the lens. In hypoparathyroidism, lowering of the concentration of calcium in the aqueous humor is in some way responsible for the opacification of superficial lens fibers. Prolonged high doses of corticosteroids, as well as radiation therapy, induce lenticular opacities in some patients. Down syndrome and oculocerebrorenal syndrome (see Chap. 37), spinocerebellar ataxia with oligophrenia (see Chap. 38), and certain dermatologic syndromes (atopic dermatitis, congenital ichthyosis, incontinentia pigmenti) are also accompanied by lenticular opacities. Myotonic dystrophy (see Chap. 45) and, rarely, Wilson disease (see Chap. 36) are associated with special types of cataracts. Subluxation of the lens, the result of weakening of its zonular ligaments, occurs in syphilis, Marfan syndrome (upward displacement), and homocystinuria (downward displacement).

In the *vitreous humor*, hemorrhage may occur from the rupture of a ciliary or retinal vessel. On ophthalmoscopic examination, the hemorrhage appears as a diffuse haziness of part or all of the vitreous or takes the form of a sharply defined clot if it lies between the retina and the vitreous (termed preretinal or subhyaloid hemorrhage). The common cause is rupture of newly formed vessels of proliferative retinopathy in patients with diabetes mellitus, but there are many others including orbital or cranial trauma, rupture of an intracranial aneurysm or arteriovenous malformation with sudden high intracranial pressure (Terson syndrome), Valsalva maneuvers, retinal vein occlusion, sickle cell disease, age-related macular degeneration (ARMD), and retinal tears, in which the hemorrhage breaks through the internal limiting membrane of the retina. The most common vitreous opacities are benign "floaters" caused by the condensation of vitreous collagen fibers, which appear as darting gray flecks or threads with changes in the position of the eyes; they may be annoying or even alarming until the person stops looking for them.

A sudden burst of flashing lights associated with an increase in floaters may mark the onset of retinal detachment. Patients complaining of bright flashes and spots in vision should be examined with indirect ophthalmoscopy to rule out tears, holes, or detachments of the vitreous or retina. Another common occurrence with advancing age is shrinkage of the vitreous humor and retraction from the retina, causing persistent streaks of light, usually in the periphery of the visual field. These phosphenes, also known as *Moore lightning streaks*, had been thought to be quite benign, but they may at times indicate incipient retinal or vitreous tears or detachment, and their first appearance requires prompt evaluation by an ophthalmologist. They are most prominent on the movement of the globe, on closure of the eyelids, at the moment of accommodation, with saccadic eye movements, and with sudden exposure to dark. The vitreous may also be infiltrated by lymphoma also occurring in the brain; biopsy by planar vitrectomy may be used to establish the diagnosis in some instances.

The term *uveitis* refers to an infective or noninfective inflammatory disease that affects any of the uveal structures (iris, ciliary body, and choroid). The inflammation may be in the anterior part of the eye or in the posterior part, behind the iris, and extending to the retina and choroid. Infective causes of posterior uveitis (choroidal) are toxoplasmal and cytomegalic inclusion disease, occurring mainly in patients with AIDS and other forms of reduced immune function. Noninfective autoimmune types are also common in adults. Anterior uveitis is sometimes linked to ankylosing spondylitis and the human leukocyte antigen (HLA) B-27 marker, sarcoidosis, and recurrent meningitis (Vogt-Koyanagi-Harada disease); the posterior forms are associated with sarcoidosis, Behçet disease, and lymphoma.

NEUROLOGIC CAUSES OF REDUCED VISION

Knowledge of certain anatomic and physiologic facts is required for an interpretation of the neurologic lesions that affect vision. Light entering the eye traverses the inner layers of the retina to reach its outer (posterior) layer,

which contains two classes of photoreceptor cells: the flask-shaped cones and the slender rods. The photoreceptors rest on a single layer of pigmented epithelial cells, which form the outermost surface of the retina. The rods and cones and pigmentary epithelium receive their blood supply primarily from the capillaries of the choroid. The rods function in the perception of visual stimuli in subdued light (twilight or scotopic vision), and the cones are responsible for color discrimination and the perception of stimuli in bright light (photopic vision). Most of the cones are concentrated in the macular region, particularly in its central part, the *fovea*, and are responsible for the highest level of visual acuity. Traquair described the rapid fall-off of acuity as the distance from the fovea increases as "an island of vision in a sea of blindness." Specialized pigment molecules in the rods and cones absorb light energy and transform it into electrical signals, which are transmitted to the bipolar cells of the retina and then to the neurons, or ganglion cells, in the innermost retinal layer (Fig. 12-3). In the fovea, ganglion cells and other inner retinal structures are displaced so that photoreceptors can be very highly concentrated to maximize central spatial acuity. The axons of the retinal ganglion cells follow an arcuate course across the inner surface of the retina. Being unmyelinated, they are not visible, although an experienced examiner, using a bright light and deep green filter, can visualize them through direct ophthalmoscopy. The axons of ganglion cells are collected in the optic discs and then travel posteriorly to form the *optic nerves*, *optic chiasm*, and *optic tracts*, finally synapsing in the lateral geniculate nuclei, the superior colliculi, the midbrain pretectum, and the suprachiasmatic nucleus of the hypothalamus (Figs. 12-2 and 12-3). The fibers derived from macular cells form a discrete group (the papillomacular bundle) that arrive at the temporal side of the disc and then assume a more central position within the nerve. These fibers are of a smaller caliber than the peripheral optic nerve fibers and appear to be especially sensitive to toxic and metabolic injury. Damage to the papillomacular bundle produces the "cecocentral" scotoma (extending from fixation to the blind spot).

The absence of photoreceptors on the optic disc accounts for the normal monocular physiologic blind spot present in the temporal visual field. The normal optic disc varies in color, being paler in infants and in blond individuals. The ganglion cell axons normally acquire their myelin sheaths after penetration of the lamina cribrosa, but they sometimes do so in their intraretinal course adjacent to the disc; the rare finding of myelinated retinal nerve fibers appear as white patches with fine-feathered edges and are a normal variant, not to be confused with optic disc edema or retinal ischemia.

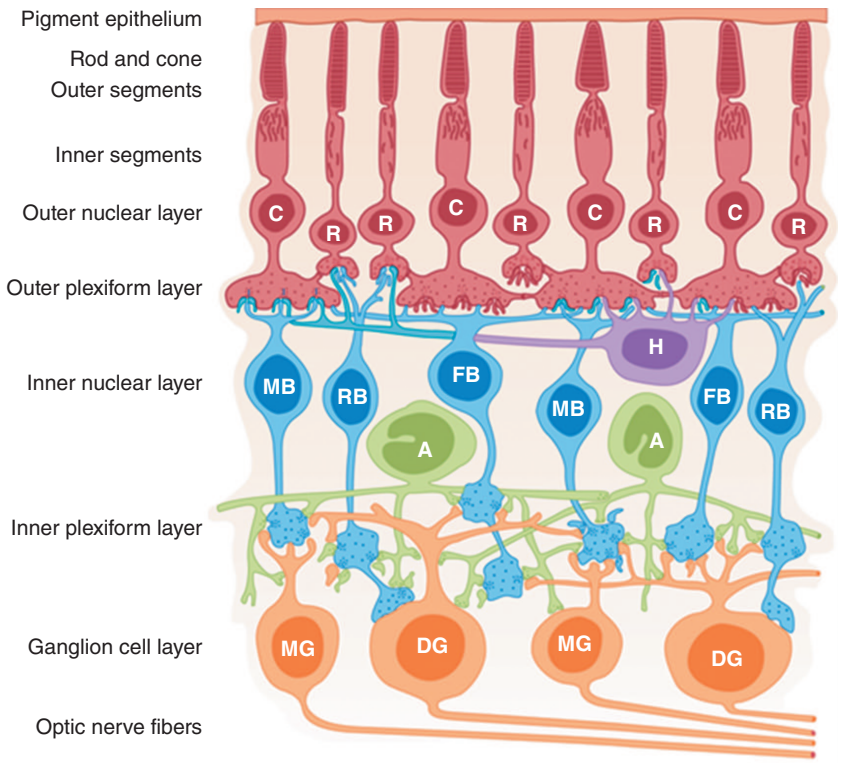

Figure 12-3. Diagram of the cellular elements of the retina. Light entering the eye anteriorly passes through the full thickness of the retina to reach the rods and cones (first system of retinal neurons). Impulses arising in these cells are transmitted by the bipolar cells (second system of retinal neurons) to the ganglion cell layer. The third system of visual neurons consists of the ganglion cells and their axons, which run uninterruptedly through the optic nerve, chiasm, and optic tracts, synapsing with cells in the lateral geniculate body. (Reproduced with permission from Dowling JE, Boycott BB. Organization of the primate retina: electron microscopy. *Proc R Soc Lond B Biol Sci*. 1966;166(1002):80-111.)

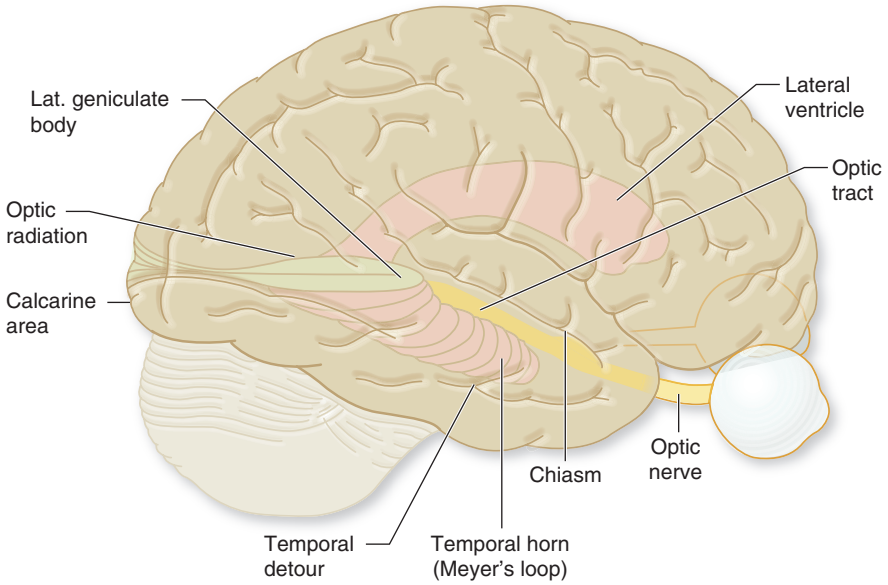

Figure 12-4. The geniculocalcarine projection, showing the detour of lower fibers around the temporal horn.

A lesion in one optic nerve does not produce anisocoria. Unless an eye is completely blind, when light is shined into the affected eye, both pupils still demonstrate constriction. Similarly, when light is shined into the normal eye, both pupils constrict as well. One piece of evidence indicating the presence of an optic neuropathy can be obtained by performing the swinging flashlight test, which assesses the constriction of both pupils as light is alternately shined into one eye then the other at approximately one second intervals. Normally the initial reaction of the pupils should be to constrict each time the light is shined into an eye (although some movements of the iris that cause the pupil diameter to fluctuate can be normal, termed *hippus*). However, if both pupils consistently dilate (or constrict less intensely) each time the light is shined into one eye, the finding is termed a *relative afferent pupillary defect* (the Marcus Gunn pupil), suggesting dysfunction in the afferent limb of the pupillary reflex on that side. In most cases, a relative afferent pupillary defect indicates an optic neuropathy, but it can also occur with retinal diseases and other ocular disturbances predominantly affecting one eye. In some instances, this finding can be the only objective abnormality corroborating the presence of an optic neuropathy.

To be able to detect a relative afferent pupillary defect reliably, it is best to examine the pupils in a darkened room and use a well-focused beam of bright light (i.e., the light on a direct ophthalmoscope or on most modern smartphones, though convenient, is not well suited to this purpose). The examiner must gain experience aiming the flashlight so that light is directed into each eye equally when it is swung to and fro. A relative afferent pupillary defect may not be present in situations where the patient has previously had an optic neuropathy on the contralateral side.

In the optic chiasm, the fibers derived from the nasal half of each retina decussate and continue in the optic tract with the uncrossed temporal fibers of the other eye (Figs. 12-2 and 12-4). Thus, interruption of the left optic tract causes a right homonymous (left nasal and right temporal) field defect (see Fig. 12-2*D*). In partial tract lesions, the visual defects in the two eyes may not be congruent, as the tract fibers are not evenly admixed. Lesions at the junction of the optic nerve and chiasm, generally compressive in nature, may cause a small contralateral superotemporal quadrantic defect in addition to the expected central scotoma in the ipsilateral eye ("junctional scotoma," Fig. 12-2*B*). This deficit had been thought for many decades to result from compression of Wilbrand knee, a bundle of fibers that turn back into the contralateral optic nerve before crossing in the chiasm, but it has since been demonstrated by Horton that the existence of the bundle is mostly an artifact of severe atrophy of one optic nerve. The optic chiasm lies just above the pituitary gland and anterior to the third ventricle; hence, the crossing fibers may be compressed from below by a pituitary tumor, a meningioma of the tuberculum sellae, or an aneurysm, and from above by a dilated third ventricle or craniopharyngioma. The resulting field defect is bitemporal ("bitemporal hemianopia"; Fig. 12-2*C*). In albinism, there is an abnormality of chiasmatic decussation, in which a majority of the fibers cross to the other side because of a defect in melanin signaling that normally contributes to patterning of the chiasm.

From the retina, there is a point-to-point projection to the lateral geniculate nucleus and from there, to the calcarine cortex of the occipital lobe. For purposes of description of the visual fields, each retina and macula are divided into a temporal and nasal half by a vertical line passing through the fovea. A horizontal line represented roughly by the junction of the superior and inferior retinal vascular

arcades also passes through the fovea and divides each half of the retina and macula into upper and lower quadrants. The retinal image of an object in the visual field is inverted and reversed from right to left, like the image on the film of a camera. Thus the left visual field of each eye is represented in the opposite half of each retina, with the upper part of the field represented in the lower part of the retina (Figs. 12-2 and 12-4).

Approximately 80 percent of the fibers of the optic tract terminate in the lateral geniculate nucleus of the thalamus and synapse with the six laminae of its neurons. Three of these laminae (1, 4, 6) receive crossed (nasal) fibers from the contralateral eye, and three (2, 3, 5) receive uncrossed (temporal) fibers from the ipsilateral eye. Selective occlusion of either component of the dual blood supply to the lateral geniculate, consisting of the anterior and posterior choroidal arteries, is infrequent but when it does occur, produces a characteristic defects that correspond to the retinotopic organization of vision within the LGN. Occlusion of the anterior choroidal artery affects the lateral and medial portions of the LGN, producing a contralateral quadruple sectoranopia, meaning homonymous sectoral defects in the upper and lower quadrants of both eyes. Occlusion of the posterior (lateral) choroidal artery affects the central portion (hilum) of the LGN, producing a contralateral homonymous horizontal sectoranopia.

The geniculate cells project via the optic radiations to the visual (striate) cortex of the occipital lobe, also called area 17 (Brodmann classification) or V1 (Figs. 12-4 and 12-5). In their course through the temporal lobes, the fibers from the lower and upper quadrants of each retina diverge. The lower ones arch around the anterior pole of the temporal horn of the lateral ventricle before turning posteriorly (forming Meyer loop), and their disruption causes a contralateral superior quadrant field deficit. The upper ones follow a more direct path through the white matter of the uppermost part of the temporal lobe (Fig. 12-4) and probably of the adjacent interior parietal lobe; their disruption causes a contralateral inferior field deficit. Both groups of fibers merge posteriorly at the internal sagittal stratum (Fig. 12-2*E* and *F*).

The primary visual cortex has a retinotopic arrangement that corresponds to the contralateral homonymous visual field (Fig. 12-5). At the occipital pole, approximately 50 percent of the primary visual cortex represents the central 10 degrees of the contralateral visual field. The anterior portions of the primary visual cortex represent more peripheral portions of the contralateral field. The most anterior portion of the primary visual cortex represents the most lateral portion of the contralateral field, which is referred to as the monocular crescent because it is represented by visual inputs from only one eye, as opposed to

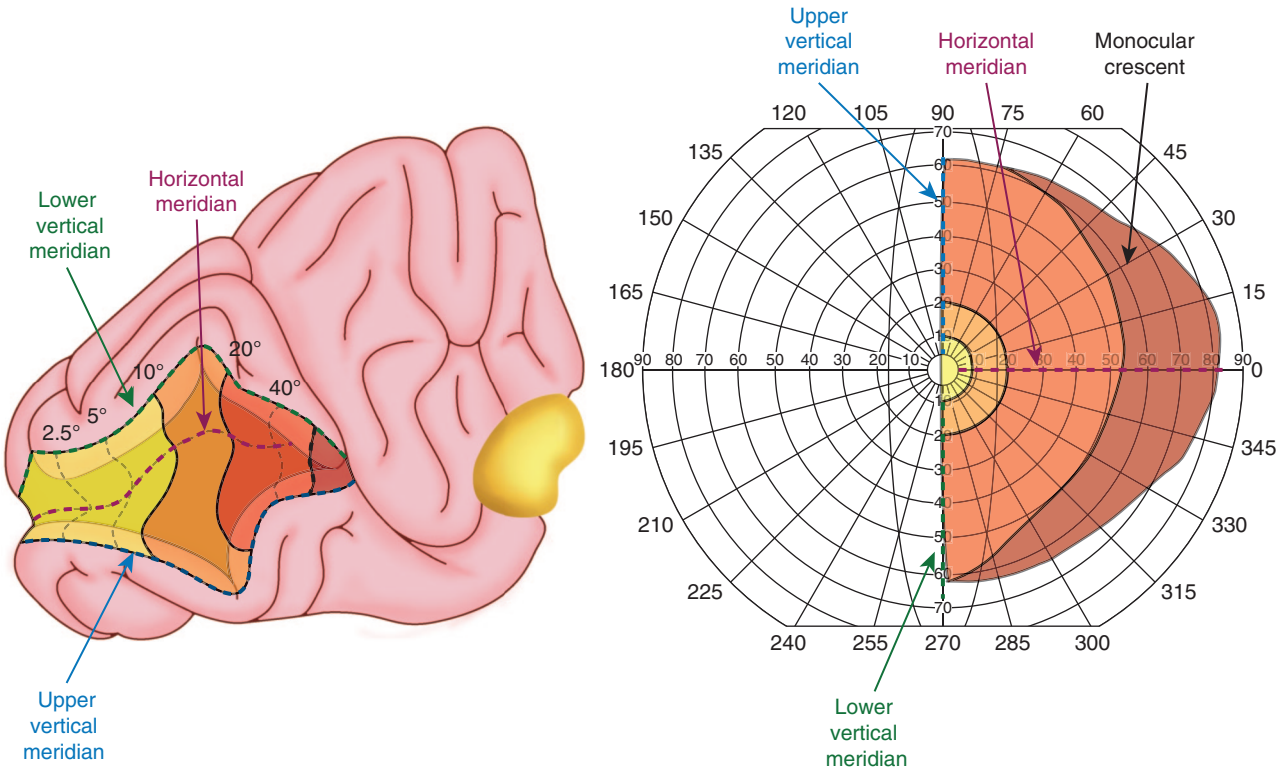

Figure 12-5. Diagrammatic depiction of the retinotopic organization of the primary visual cortex. The occipital pole represents the central 10 degrees of vision in the contralateral visual field. More peripheral areas of the visual field and then represented more anteriorly in the primary visual cortex, ending with representation of the so-called monocular crescent of vision in the most peripheral visual field that is seen by just one eye rather than two. Primary visual cortex is organized such that the upper gyrus represents the lower part of the visual field and the lower gyrus represents the upper part.

the central areas of the field, which have binocular representation. The upper bank of the primary visual cortex represents the contralateral lower visual field, and the lower bank of the primary visual cortex represents the contralateral upper visual field.

The receptive neurons in primary visual cortex are arranged in columns, some of which are activated by edges and forms and others by moving stimuli or by color. The neurons for each eye are grouped together and have concentric, center-surround receptive fields. The seminal studies of Hubel and Wiesel, for which they were awarded the Nobel Prize, have elucidated much of this visual cortical anatomy and physiology. The neurons of area 17 project to the numerous downstream visual areas of the occipitotemporal and occipitoparietal cortex of the same and opposite cerebral hemispheres and also to other multisensory cortices. These complex extrastriate connections are still being elucidated.

Portions of the visual systems are specialized for the perception of motion, color, stereopsis, contour, and depth perception. As Ungerleider and Mishkin proposed, the flow of secondary visual processing can be conceptually divided into a dorsal ("where") stream, which carries predominantly spatial information to the parietal lobe and a ventral ("what") stream, which carries shape and color information to the temporal lobe.

The normal development of the connections described previously requires that the visual system be activated through several critical periods of development. The early deprivation of vision in one eye causes a failure of development of the geniculate and cortical receptive fields of that eye. Moreover, in this circumstance, the cortical receptive fields of the seeing eye become abnormally large and usurps the monocular dominance columns of the blind eye (Hubel and Wiesel). In children with a congenital cataract, if the opacity is removed after a critical period of development, the eye will remain amblyopic. A severe strabismus in early life will have the same effect (*amblyopia ex anopsia*).

The vascular supply of the eye is through the ophthalmic branch of the internal carotid artery that supplies the retina, posterior (uveal) coats of the eye, and optic nerve head. This artery gives origin to the posterior ciliary arteries, which form a rich circumferential plexus of vessels (arterial circle of Zinn-Haller) located deep to the lamina cribrosa. The lamina cribrosa is a sieve-like scleral (dural) structure through which the axons of the central and nasal parts of the disc run. This arterial circle fed by posterior ciliary arteries supplies the optic disc and adjacent part of the distal optic nerve, the choroid, and the ciliary body.

The other major branch of the ophthalmic artery is the *central retinal artery*. It pierces the retrobulbar optic nerve and then emerges int the eye from the optic disc, where it divides into four branches that supply the inner retinal layers; it is these vessels and their branches that are visible by ophthalmoscopy. A short distance from the disc, these vessels lose their internal elastic lamina, and the media (muscularis) becomes thin; they are properly classed as arterioles. The inner layers of the retina, including the ganglion and bipolar cells, receive their blood supply from these arterioles and their capillaries, whereas the deeper photoreceptor elements and the fovea are nourished by the underlying choroidal vascular bed by diffusion through the retinal pigmented cells and the semipermeable Bruch membrane upon which they rest. In up to one-third of individuals, a small cilioretinal artery may arise from either the choroidal circulation or from the circle of Zinn-Haller and supply the macula. In the case of a central retinal artery occlusion, the presence of this cilioretinal artery leads to the preservation of central acuity.

Abnormalities of the Retina

As indicated previously, the thin (100 to 350 mm) retinal sheet and the optic nerve head are exteriorized parts of the central nervous system and the only part of the nervous system that can be inspected directly. In cases of visual loss, it is important during funduscopic examination to carefully inspect the macular zone (which is located 3 to 4 mm lateral to the optic disc and provides central visual acuity). There are variations in the appearance of the normal macula and optic disc, but with experience one can identify the normal variations of the retinal pigment epithelium or a few drusen that commonly occur. It is possible to visualize the unmyelinated nerve-fiber layer of the retina by using bright-green (red-free) illumination, and detecting loss of the discrete bundles of axons as they converge to the disc can be helpful to identify demyelinating, toxic, or hereditary lesions of the optic nerve.

In evaluating the retinal vessels, one must remember that these are arterioles and not arteries. Since the walls of retinal arterioles are transparent, what is observed with the ophthalmoscope is a column of blood within them. The central light streak of normal arterioles is thought to represent the reflection of light as it strikes the interface of the column of blood and the concave vascular wall. In *arteriolosclerosis* (usually coexistent with hypertension), the lumen of the vessels is segmentally narrowed because of fibrous tissue replacement of the media and thickening of the basement membrane. Other signs of hypertension and arteriolosclerosis are straightening of the arterioles and venous compression by thickened arterioles within the adventitial envelope shared by both vessels at the site of crossing ("A-V nicking"). Progressive arteriolar disease, to the point of occlusion of the lumen, results in a narrow, white ("silver-wire") vessel with no visible blood column. This change is associated most often with severe, long-standing hypertension but may follow other types of occlusion of the central retinal artery or its branches (see descriptions and retinal illustrations further on). Sheathing of the venules, possibly representing focal leakage of cells from the vessels, had been reported in inflammatory conditions including optic neuritis. Arterial and venule sheathing are also seen in leukemia, sarcoid, Behçet disease, and other forms of vasculitis.

In *malignant hypertension,* there are, in addition to swelling of the optic nerve head and the retinal arteriolar changes noted previously, a number of extravascular lesions: so-called soft exudates or cotton-wool patches, sharply marginated and glistening "hard" exudates, and

Figure 12-6. Hypertensive retinopathy, showing optic disc edema, cotton wool spots, hard exudates, and intraretinal hemorrhages.

Figure 12-7. Preretinal (subhyaloid) hemorrhage extending through the macular of the left eye, precipitated by strong Valsalva maneuver.

retinal hemorrhages (Fig. 12-6). In many patients who show these retinal changes, analogous lesions are found in the brain (reversible vasoconstriction and infarcts), forming the basis of hypertensive encephalopathy.

Microaneurysms of retinal vessels appear as small, discrete red dots that most frequently occur in the midperipheral retina. They are most often a sign of diabetes mellitus, sometimes appearing before the usual clinical manifestations of that disease. The use of the red-free (green) light on the ophthalmoscope helps to pick out microaneurysms from the background. Microscopically, the aneurysms take the form of small (20–90 mm) saccular outpouchings from the walls of capillaries, venules, or arterioles. The vessels of origin of the aneurysms are invariably abnormal, being either acellular branches of occluded vessels or themselves occluded by fat or fibrin.

The ophthalmoscopic appearance of *retinal hemorrhage* is determined by the exact layer in which it occurs. Hemorrhages within the inner retina are linear or flame-shaped ("splinter" hemorrhages) because of their confinement by the horizontally coursing nerve fibers in that layer. These hemorrhages usually overlie and obscure the retinal vessels. Round or oval ("dot-and-blot") hemorrhages lie behind the vessels in the outer plexiform layer of the retina (synaptic layer between bipolar cells and nuclei of rods and cones—Fig. 12-3); in this layer, blood accumulates in the form of a cylinder between vertically oriented nerve fibers and appears round or oval when viewed end-on with the ophthalmoscope. Sudden severe elevation of intracranial pressure, from causes such as acute subarachnoid hemorrhage, can lead to *Terson syndrome*, which is the accumulation of a sharply outlined lake of blood between the internal limiting membrane of the retina and the vitreous or hyaloid membrane (the condensed gel at the periphery of the vitreous body); this is known as subhyaloid or preretinal hemorrhage (Fig. 12-7). Superficial or deep retinal hemorrhages with a central or eccentric pale (Roth) spot are most closely associated with infective endocarditis but also occur with leukemia. The pale spot within these hemorrhages represents the accumulation of white blood cells, fibrin, histiocytes, or amorphous material between the vessel and the hemorrhage.

Cotton-wool patches, or *soft exudates*, refer to areas of inner retina, which are normally transparent, that have become semi-opacified owing to ischemia from occlusion of precapillary arterioles. These patches, even large ones, rarely cause serious disturbances of vision unless they involve the macula. They are composed of clusters of ovoid structures called *cytoid bodies*, representing the terminal swellings of interrupted axons. *Hard exudates* appear as punctate white or yellow bodies; they lie in the outer plexiform layer, behind the retinal vessels, like the punctate hemorrhages. If present in the macular region, they are arranged in lines radiating toward the fovea (*macular star*). Hard exudates consist of lipid and other serum precipitants that accumulate as a result of abnormal vascular permeability. They are observed most often in cases of diabetes mellitus and chronic hypertension, as well as massive optic disc swelling from severe intracranial hypertension or some inflammatory optic neuropathies.

Retinal drusen (colloid bodies) appear ophthalmoscopically as pale yellow spots that may be a benign finding but occur with greater frequency in ARMD. The source of retinal drusen is uncertain, but they may result from chronic inflammation generated by degeneration of the retinal pigment epithelium. *Hyaline bodies,* located on or near the optic disc, are also referred to as drusen but must be distinguished from those occurring peripherally. In contrast to peripheral retinal drusen, drusen of the optic

discs are probably mineralized residues of dead axons. In some cases, they can be visualized on noncontrast CT. Their main significance for neurologists is that drusen that are buried under the disc ("buried drusen") often produce elevation of the disc that can be mistaken for papilledema (see further on). Orbital ultrasound can be used to identify buried drusen in these cases in order to avoid other testing that would be performed for true papilledema.

Various vascular tumors and malformations may arise in the retina and be appreciated with ophthalmoscopic examination. The periphery of the retina may harbor a hemangioblastoma, which may appear during adolescence, before the more characteristic cerebellar lesion. A large retinal artery may be seen leading to it and there may be a large draining vein. Occasionally, retinal examination discloses the presence of a vascular malformation that may coexist with a malformation of the optic nerve and basilar portions of the brain.

Ischemic Lesions of the Retina

Transient monocular blindness Transient ischemic attacks of visual loss involving all or part of the field of vision of one eye are referred to as *amaurosis fugax* or *transient monocular blindness* (TMB). They are common manifestations of atherosclerotic carotid stenosis but have other causes. An altitudinal horizontal border, or "shade," is often, but not invariably, described. The shade may rise or fall at the onset or cessation of the spell and occasionally remains throughout the episode. Fortuitous inspection of the retina during an attack may show segments of arteries that are filled with white material that migrate distally over many minutes. There can be stagnation of arterial and venous blood flow, which returns within seconds or minutes as vision is restored (Fisher). One interpretation of these observations is that an embolus to the central retinal artery and has broken up and moved distally. Fisher thus brought into question a prevalent theory of the time that TMB was due to vasospasm of the retinal arteries.

Episodes of TMB may precede infarction of a cerebral hemisphere, or they may abate without adverse consequences. In one series of 80 patients followed for 4 years, in an era prior to modern treatment of atherosclerosis, 16 percent developed permanent unilateral blindness, a completed hemispheric stroke, or both (Marshall and Meadows). Chapter 33 discusses this subject further.

Occlusion of the internal carotid artery usually causes no disturbance of vision, provided that there are adequate anastomotic branches from the external carotid artery or other sources to the ophthalmic artery. Occasionally, occlusion of the proximal internal carotid artery is marked by an episode of TMB on the same side, just as a hemispheric transient ischemic attack may indicate recent acute carotid occlusion. Chronic carotid occlusion with inadequate collateralization is associated with ocular ischemic syndrome, which may predominantly affect the anterior or posterior segment or both (Young and Appen). In this case, insufficient circulation to the anterior segment of the globe is manifest by scleral vascular congestion, cloudiness of the cornea, anterior chamber flare, and low intraocular pressure (hypotony), or sometimes high intraocular pressure if neovascularization of the iris (rubeosis iridis) occurs and compromises the outflow of aqueous humor. Ischemia of the posterior segment of the eye is manifest by circulatory changes in the optic nerve or by venous stasis. Light-induced amaurosis, in which periods of blindness are precipitated by exposure to bright light, is a characteristic symptom. Other signs of carotid disease may be present, for example, a local bruit over the carotid bifurcation.

Central or branch retinal artery occlusion Most often, ischemia of the retina can be traced to occlusion of the central retinal artery or its branches by thrombi or emboli—*central or branch retinal artery occlusion* (CRAO or BRAO). Central retinal artery occlusion presents with sudden painless blindness of the affected eye. The retina then becomes whitened and the arterioles are narrowed, with segmentation of columns of blood. A "cherry-red spot" appears in the fovea, where the retina is thinnest and the intact underlying choroidal circulation is visible (Fig. 12-8).

With occlusions of branches of the central retinal artery by emboli, one may be able to see the occluding material at a vascular bifurcation. Most frequently observed are Hollenhorst plaques—glistening, white-yellow atheromatous particles (Fig. 12-9) that may be seen in 40 of 70 cases of retinal embolism (Arruga and Sanders). These plaques can also be an asymptomatic manifestation of carotid or aortic atherosclerosis without producing retinal ischemia and visual loss. Intraluminal particles may alternatively have the appearance of white calcium from aortic or mitral valves. Red or white fibrin-platelet emboli may emanate from the heart, its valves, or other sources. Central and branch retinal artery occlusions also occur as a consequence of hypercoagulable states, including antiphospholipid antibody syndrome. Giant cell arteritis is another important cause; patients who are in their fifties or older should be screened for this condition.

When possible, acute central retinal artery occlusion a number of methods may be urgently tried in the hope that the embolus or thrombus will be propelled into more

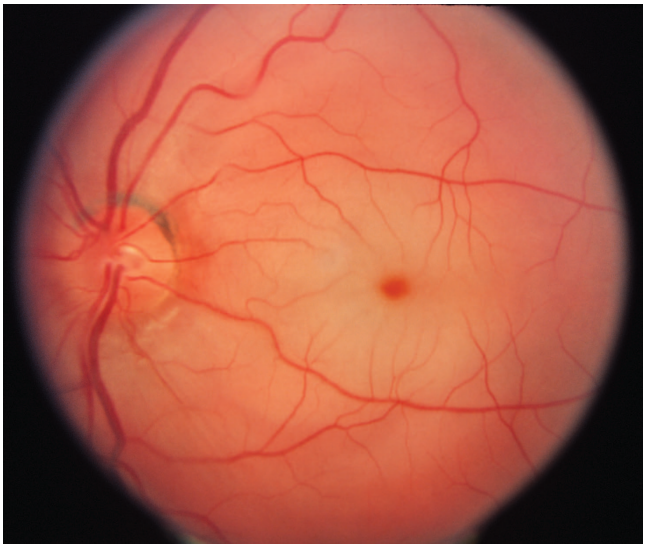

Figure 12-8. Appearance of the fundus in central retinal artery occlusion. The retina has a creamy gray appearance and there is a "cherry-red spot" at the fovea due to choroidal circulation. The caliber of arterioles is attenuated.

Figure 12-9. Glistening "Hollenhorst plaque" occlusion of an inferior retinal artery branch (*arrow*). These occlusions represent atheromatous particles or, less often, platelet-fibrin emboli. Some are asymptomatic and others are associated with segmental visual loss or are seen after central retinal artery occlusion.

Figure 12-10. Occlusion of the central retinal vein with suffusion of the veins, swelling of the disc, and florid retinal hemorrhages.

distal vessels. These treatments are generally aimed at lowering intraocular pressure (intravenous acetazolamide, topical glaucoma medications, inhalation of carbon dioxide, paracentesis of the anterior chamber, ocular massage) to try to improve perfusion pressure in the compromised vessels. These measures generally offer limited efficacy. Administration of intravenous tissue plasminogen activator (IV-tPA) is of uncertain efficacy and has been difficult to study adequately in sufficient numbers. A multicenter trial of selective intraarterial thrombolysis was halted early because of concerns about safety (Eagle Study cited under Schumacher and colleagues).

Retinal venous occlusion Because the central retinal artery and vein share a common adventitial sheath, atheromatous plaques in the artery can provoke thrombosis of the retinal vein. This affected veins become engorged and tortuous, and multiple diffuse "dot-and-blot" and linear retinal hemorrhages ensue (Fig. 12-10). Retinal vein thrombosis is observed most frequently with diabetes mellitus, hypertension, and leukemia; less frequently with sickle cell disease, systemic lupus erythematosus, antiphospholipid syndrome, and other disorders of hypercoagulability; and rarely with multiple myeloma and Waldenstrom macroglobulinemia in relation to hyperviscosity. Sometimes, no associated systemic disease can be identified, in which case the possibility of an orbital mass (e.g., optic nerve glioma) should be considered. In retinal vein thrombosis, visual loss is variable, depending on the extent to which it produces ischemic changes of the retina. When then vein occlusion includes ischemic changes in the retina in the form of cotton wool spots and areas of retinal whitening, visual loss can be substantial. In other cases, the vein occlusion is not accompanied by these ischemic changes in the retina, and the vision may be well preserved despite the dramatic appearance of retinal venous stasis and hemorrhages. In cases where macular edema ensues, recovery may be enhanced by laser photocoagulation.

Benign retinal vasospasm and migraine Recurrent episodes of TMB occur occasionally, presumably owing to benign vasospasm of the central retinal artery. This diagnosis is made on clinical grounds, typically after negative diagnostic evaluation for other causes. It is very rare to examine a patient during one of the episodes. This entity is more common in patients prone to migraine. The episodes may cease with the introduction of a calcium channel blocker (Winterkorn and colleagues).

Other Diseases of the Retina

Aside from vascular lesions, tears and detachments of the retina may impair vision acutely. The most common form of detachment is a separation of the pigment epithelium layer from the sensory retina with fluid accumulation through a tear or hole in the retina. Retinal detachment often presents with sudden flashes and floaters in one eye. Urgent surgical intervention is often needed, and the visual prognosis depends on whether the macula is involved. Some predisposing conditions for retinal detachment include high myopia, proliferative retinopathy secondary to diabetes or other vascular disease, and retinopathy of prematurity.

Serous retinopathy is a cause of monocular visual disturbance in which the perimacular zone is elevated by edema. Metamorphopsia (distortion of vision) in one eye is a common presentation, but acuity is not much impaired. The optic disc remains normal. The leakage of vascular fluid into the subretinal space causes a loss of visualization of the detail of the choroid and is readily demonstrated by fluorescein angiography or by optical coherence tomography (OCT). The condition can occur spontaneously, with a predilection for young or middle-aged males, and it can

occur in association with the use of corticosteroids. It tends to resolve over several months and can be treated by laser to seal the sites of leakage.

Chorioretinitis is often the result of an infectious process. Cat Scratch disease, caused by *Bartonella henselae,* is characterized by an optic neuritis together with the formation of a macular star, although the star is not a universal feature.

Patients with HIV-AIDS can develop retinal lesions of various types. Infarcts of the nerve-fiber layer (cotton-wool patches), hemorrhages, and perivascular sheathing are the usual findings. Toxoplasmosis is the most common infective lesion, followed in frequency by cytomegalovirus (CMV), but histoplasmosis, *Pneumocystis carinii*, herpes zoster, syphilis, and tuberculosis are also well documented. CMV may cause a particularly severe necrotizing retinitis and permanent impairment of vision. Both the retina and choroid may be involved by these diseases, in which case the fundus appearance is characteristic, showing "punched-out" lesions that expose the whitish sclera, and deposits of black pigment. The choroid may also be the site of viral and noninfective inflammatory reactions, often in association with painful recurrent iridocyclitis and lacrimal inflammation.

Degenerations of the retina are important causes of chronic progressive visual loss. The retinal degenerations assume several forms and can be isolated or associated with progressive conditions of the brain or other organs. The most frequent degeneration in youth and middle age is *retinitis pigmentosa*, a hereditary disease of the outer photoreceptor layer and subjacent pigment epithelium. The retina is thin, and there are fine deposits of black pigment in the shape of bone corpuscles, more in the periphery; later, the optic discs become atrophic (described as "waxy pallor"). The disorder is marked by constriction of the visual fields with relative sparing of central vision ("gun-barrel" vision), metamorphopsia (distorted vision), delayed recovery from glare, and nyctalopia (reduced twilight vision). The causes of retinitis pigmentosa and related retinal degenerations are diverse, linked to deficits in more than 75 different genes. In one form of isolated retinitis pigmentosa, which follows an autosomal dominant pattern of inheritance, the gene for rhodopsin (a combination of vitamin A and the rod-cell protein opsin) produces a defective opsin, resulting in a diminution of rhodopsin, diminished response to light, and eventual degeneration of the rod cells (Dryja et al). Retinitis pigmentosa is associated with the Laurence-Moon-Biedl syndrome, with certain mitochondrial diseases (Kearns-Sayre syndrome, Chap. 37), and with a number of degenerative and metabolic diseases (e.g., Refsum disease) of the nervous system. Another early life hereditary retinal degeneration, characterized by massive central retinal lesions, is the autosomal recessive Stargardt form of juvenile tapetoretinal degeneration. Like some forms of retinitis pigmentosa, Stargardt disease may be accompanied by progressive spastic paraparesis or ataxia. *Nonpigmentary retinal degeneration* is a feature of some rare syndromes including neuronal ceroid lipofuscinosis, Bassen-Kornzweig disease, Batten-Mayou disease, and others (see Chap. 36).

Toxic effects of medications are an important cause of retinal damage. Hydroxychloroquine toxicity has been estimated to occur in 7.5 percent of individuals taking the medication for greater than 5 years, with increasing frequency with longer periods of use (Yusuf). The mechanism by which it causes retinal injury is uncertain but may relate to the impairment of recycling of the retinol chromophore molecule used in photoreceptor signaling. Patients develop parafoveal distortions and impaired color vision, ultimately developing a characteristic "bull's-eye retinopathy" lesion, which may be best observed early on with imaging modalities such as OCT or fluorescein angiography. Phenothiazine derivatives, less often used in practice than they had been, may conjugate with the melanin of the pigment layer, resulting in degeneration of the outer layers of the retina. Among drugs used to treat neurologic disease, the antiepileptic drug *vigabatrin* is notable for causing retinal degeneration and a concentric restriction of the visual fields in almost half of the exposed patients. Elevated levels of gamma-aminobutyric acid (GABA) in the retina are presumably the cause of toxicity. High-dose tamoxifen has caused toxicity in the retina, characterized by the deposition of refractile opacities and, in more severe cases, by macular edema.

A paraneoplastic *cancer-associated retinopathy* (CAR) has been described in patients with small-cell lung cancer and other tumors (see Chap. 30). The typical presentation is of positive visual phenomenon and rapid bilateral visual loss. Some patients have been found to harbor antibodies against the recoverin protein, which modulates rhodopsin kinase (Grunwald et al; Kornguth et al; Jacobson et al). Melanoma-associated retinopathy (MAR) that produces night blindness and affects primarily rods has also been described. These paraneoplastic processes are further described in Chap. 30.

Certain lysosomal diseases of infancy and early childhood are characterized by an abnormal accumulation of undegraded proteins, polysaccharides, and lipids in cerebral neurons, as well as in the macula and other parts of the retina (hence the terms *storage diseases* and *cerebromacular degenerations*). Corneal clouding, cherry-red spot and graying of the retina, and later optic atrophy are the observed ocular abnormalities. Tay Sachs, Fabry, and Gaucher diseases are prime examples, which are further discussed in Chap. 36.

In some of these retinal diseases, minimal changes in the pigment epithelium or other layers of the retina may not be readily detected by ophthalmoscopy. A test to expose such subtle retinal changes is to estimate the time required for recovery of visual acuity following light stimulation (macular photostress test) (Glaser). The test is conducted by shining a strong light through the pupil of an affected eye for 10 s and measuring the time necessary for the acuity to return to the pretest level (normally 50 s or less). With macular lesions, recovery time is prolonged, but with lesions of the optic nerve, it is not affected. As described earlier, delayed recovery of vision with the photostress test may also be observed in the eye on the side of a carotid occlusion, which in essence, causes an ischemic retinopathy. Because retinal diseases reduce or abolish the electrical activity generated by the outer layers of the retina, a very useful test in their diagnosis is an electroretinogram (ERG). Fluorescein retinography provides highly detailed vascular anatomy. OCT uses reflected light to construct a high-resolution cross-sectional image of the retinal layers;

it is able to demonstrate with remarkable resolution retinal edema, tears, macular holes, and the thinning of the retinal nerve-fiber and ganglion cell layers that follow optic neuropathy.

Age-related macular degeneration This is a frequent cause of visual loss in the elderly. As ARMD begins to disturb vision, the straight lines on the Amsler grid are observed by the patient to be distorted. Over time, central vision gradually diminishes, impairing reading, but these patients can navigate because of retained peripheral vision. Examination discloses a central scotoma with pigmentary changes in the region around the macula. The two most common types of macular degeneration are an atrophic "dry" type, which is a true pigmentary degeneration associated with retinal drusen, of unknown cause but with a genetic component, and an exudative "wet" type, which is the result of choroidal neovascularization that results in secondary macular damage (DeJong). The wet form is amenable to laser treatment and injection into the orbit of ranibizumab or similar antiangiogenic monoclonal antibodies against vascular endothelial growth factor. The progression of the dry form may be slightly reduced by the use of antioxidants and zinc.

Diabetic retinopathy Although not strictly speaking a problem taken up by neurologists, this is such an important cause of reduced vision and blindness that the basic facts should be known to all physicians (Antonetti). The earliest changes are of microaneurysms and tiny intraretinal hemorrhages; these are present in almost all diabetics who have had type 1 disease for more than 20 years. Cotton-wool spots and small hemorrhages appear as the retina becomes ischemic. Subsequently, there is a more threatening proliferative retinopathy that consists of the formation of new blood vessels and consequent leakage of proteins and blood. The new vessels can grow into the vitreous, and hemorrhages from them may cause traction on the retina, which results in detachment. Visual loss may also be the result of macular edema. Reabsorption of the edema leads to the deposition of lipid "hard exudates." Locally elevated levels of vascular endothelial growth factor have been shown to be involved in the pathophysiology of diabetic retinal neovascularization, and intravitreal injections of antivascular endothelial growth factor (anti-VEGF) antibody can improve neovascular leakage, at least in the short term. Panretinal photocoagulation is a procedure that is performed to produce multiple lesions in peripheral areas of the retina using a laser. The purpose of this treatment is to destroy portions of the retina, without causing clinically significant visual loss, in order to reduce the mismatch between the retina's metabolic demands and its inadequate vascular supply. The long-term effect of this treatment is that it reduces abnormal neovascularization that stems from elevated VEGF production in the eye. Panretinal photocoagulation was controversial when it was developed in the 1970s, but it has proven to be highly effective in the treatment of nonproliferative diabetic retinopathy to mitigate the further progressive loss of vision, reducing the risk of severe visual loss from 16.3 to 6.4 percent over two years (Diabetic Retinopathy Study Research Group). The proliferative form of diabetic retinopathy ultimately occurs in half of type 1 diabetics and 10 percent of those who have had type 2 disease for 15 to 20 years. The maintenance of glucose control reduces the frequency and severity of retinopathy but does not prevent it.

Papilledema and Raised Intracranial Pressure

Of the various abnormalities of the optic disc, *papilledema* has the greatest neurologic implication, for it signifies the presence of increased intracranial pressure. The term papilledema has come to mean disc swelling due to raised intracranial pressure, although there are other causes of a similar funduscopic appearance. An ophthalmoscopic appearance identical to that of papilledema can be produced, for example, by infarction of the optic nerve head (as with anterior ischemic optic neuropathy) and other conditions affecting the intraorbital portion of the optic nerve (especially inflammatory or infiltrative conditions); these causes without elevated intracranial pressure are best referred to as *optic disc swelling* rather than papilledema. Certain clinical and funduscopic findings, listed in Table 12-1 and described in the following text, assist in distinguishing between these processes.

In its mildest form, papilledema appears as a slight elevation of the disc and blurring of the disc margins, especially of the superior and inferior aspects, and a mild fullness of the veins in the disc. Subtle disc elevation is also indicated by a loss of definition of the vessels overlying the disc as they approach the disc margin from the periphery; this appearance is produced by edema in the adjacent retina. Because many normal individuals, especially those with hypermetropia, have ill-defined disc margins, the early stage of papilledema may be difficult to detect (Fig. 12-11). Pulsations of the retinal veins, best seen where the veins turn to enter the disc, will have disappeared by the time intracranial pressure is raised, but this finding is not specific, as venous pulsations are not present in a proportion of normal individuals in the seated position. On the other hand, the presence of spontaneous venous pulsations has been said to be a reliable indicator of

Table 12-1

CAUSES OF EPISODIC VISUAL LOSS

Adolescence and young adulthood
Migraine

Temporal arteritis (generally over age 55)
Glaucoma
Papilledema

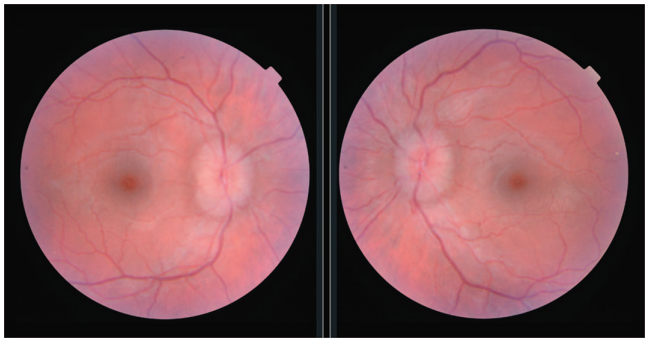

Figure 12-11. Circumferential papilledema with hyperemia of the disc and blurring of the disc margins.

an intracranial pressure below 20 cm H_2O and thus argues against true papilledema from elevated intracranial pressure (Levin). Fluorescein angiography, red-free fundus photos (which highlight the retinal nerve fibers), and ocular coherence tomography are helpful in detecting early edema of the optic discs.

More severe degrees of papilledema appear as further elevation or "mushrooming" of the entire disc and surrounding retina. There is obscuration of vessels at the disc margins and, in some instances, peripapillary hemorrhages (Fig. 12-12). Advanced papilledema is almost always bilateral, although it may asymmetric. In contrast, purely unilateral edema of the optic disc suggests an optic nerve sheath meningioma or other tumor involving the optic nerve, although it will sometimes be observed an early stage of increased intracranial pressure. As papill-edema becomes chronic, the elevation of the disc margin becomes less prominent and the optic nerve head develops pallor, representing a dropout of nerve fibers (atrophy) (Fig. 12-13). Varying degrees of secondary optic atrophy occurs in the wake of papilledema that has persisted for more than several days or weeks, ultimately leaving the disc pale and gliotic.

Acute papilledema, while it may enlarge the blind spot slightly, usually does not have a great affect on visual

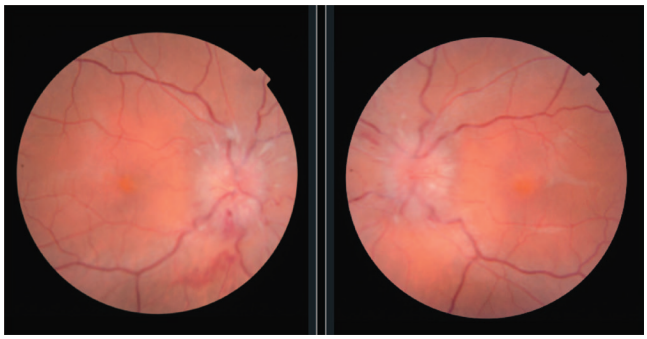

Figure 12-12. Severe acute papilledema. The main characteristics are marked swelling and enlargement of the disc, vascular engorgement, obscuration of small vessels at the disc margin as a result of nerve-fiber edema, and white "cotton-wool spots" that represent superficial infarcts of the nerve-fiber layer.

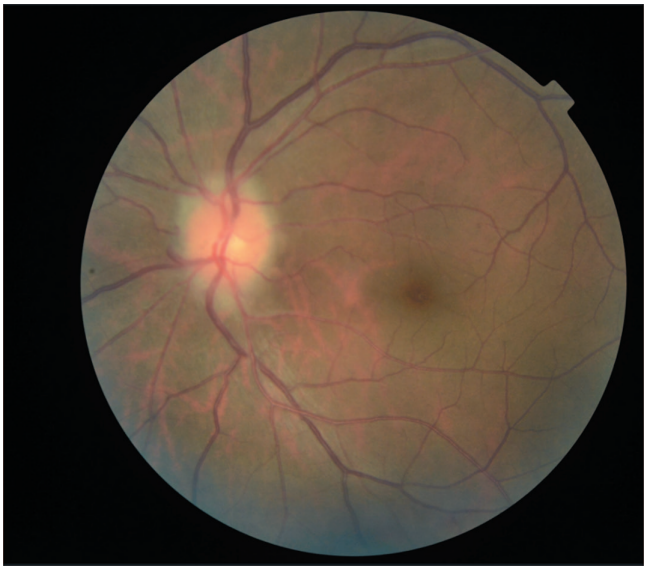

Figure 12-13. Chronic papilledema with beginning optic atrophy, in which the disc stands out like a champagne cork. The hemorrhages and exudates have been absorbed, leaving a glistening residue around the disc.

acuity (except transiently during spontaneous waves of increased intracranial pressure). Therefore, acute optic disc swelling in a patient with severely reduced vision should not be attributed to papilledema; instead, intraorbital optic neuritis (papillitis) or infarction of the nerve head (ischemic optic neuropathy) are more likely explanations. Repeated testing of visual acuity is often inadequate to assess a patient's course; serial evaluation of the visual fields by automated perimetry or tangent screen testing is sensitive to changes in field constriction that raise concern for ensuing optic atrophy. In rare cases of pseudotumor cerebri, visual loss may be unexpectedly abrupt, appearing in a day or less. This seems to happen most often in patients with constitutionally small optic nerves, no optic cup of the nerve head, and, presumably, a small aperture of the lamina cribrosa. Such fulminant visual loss in pseudotumor cerebri may respond to urgent optic nerve fenestration, as discussed in "Pseudotumor Cerebri" in Chap. 30.

The occurrence of papilledema on one side and optic atrophy on the other is referred to as the Foster Kennedy syndrome; it is typically caused by a frontal lobe tumor or an olfactory meningioma on the side of the atrophic disc that is sufficiently large to cause elevated intracranial pressure. In its complete form, which is seen only rarely, there is also anosmia on the side of the optic atrophy. Another cause of the same funduscopic appearance has been called the "pseudo-Foster Kennedy syndrome," which occurs when optic disc swelling in one eye occurs years after an optic neuropathy with disc pallor in the fellow eye, for example from sequential episodes of nonarteritic anterior ischemic optic neuropathy (NAION) (discussed further on) in one eye and then the other.

The essential element in the pathogenesis of papilledema is an increase in pressure in the sheaths

surrounding the optic nerves, which communicate directly with the subarachnoid space of the brain. This was demonstrated convincingly by Hayreh (1964), who produced bilateral chronic papilledema in monkeys by inflating balloons in the subarachnoid space and then opening the sheath of one optic nerve; the papilledema promptly subsided on the operated side but not on the opposite side. The appearance of the swollen disc has been specifically ascribed to a blockage of axoplasmic flow in the optic nerve fibers (Minckler et al; Tso and Hayreh). It was found that compression of the optic nerve by elevated cerebrospinal fluid (CSF) pressure resulted in swelling of axons behind the optic nerve head and leakage of their contents into the extracellular spaces of the disc. The block in axoplasmic flow alone, however, probably does not account for the marked congestion of vessels and hemorrhages that accompany papilledema and an additional component of vascular congestion is likely.

The mechanism of papilledema that, on rare occasions, accompanies spinal tumors, particularly oligodendrogliomas, and Guillain-Barré syndrome is not entirely clear. Usually, the CSF protein is more than 1,000 mg/100 mL, but this cannot be the entire or only explanation, as instances occur in which the protein concentration is only slightly elevated (also, the concentration of protein in the ventricular and cerebral subarachnoid spaces is considerably lower than in the lumbar sac, where it is usually sampled; see Chap. 29). In other diseases that at times give rise to papilledema—for example, a chronic lung disease with hypercapnia, cancer with meningeal infiltration, or dural arteriovenous malformation—the mechanism is most often a generalized increase of intracranial pressure. Other causes of papilledema are cyanotic congenital heart disease and other forms of polycythemia, hypocalcemia though an obscure mechanism, and POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes, with elevated circulating VEGF; see Chap. 43).

Diseases of the Optic Nerves

The optic nerves constitute the axonal projections of the retinal ganglion cells to the lateral geniculate bodies and other sites. Their proximal portion, the optic nerve head, can be visually inspected and changes in the optic disc. Swelling of the optic disc may reflect the presence of raised intracranial pressure as already described; optic neuritis ("papillitis"); infarction of the optic nerve head; congenital defects of the optic nerves (optic pits and colobomas); hypoplasia and atrophy of the optic nerves; and glaucoma (see Chester, and Biousse and Newman). In general, optic neuropathies are distinguished from other causes of visual loss by a predominance of loss of color vision and by the presence of a relative afferent pupillary defect. Table 12-2 lists the main causes of optic neuropathy, which are discussed in the following portions of this chapter.

Optic Neuritis (See Chap. 35)

This inflammatory process causes unilateral acute impairment of vision that may appear in one or both eyes, either simultaneously or successively. It develops in a number of clinical settings but has a special relationship to multiple sclerosis. The most common situation is one in which an adolescent or young adult woman has a rapid diminution of vision in one eye as though a veil had covered the eye, progressing within hours or days. Pain on movement of the globe is a common, relating to inflammation of the optic nerve sheath that is sensitive to mechanical forces; some cases of optic neuritis can be painless, but in general, the absence of pain should prompt consideration of other causes of visual loss (Table 12-1). The swinging flashlight test usually confirms a relative afferent pupillary defect on the affected side unless the fellow eye has previously been affected.

The optic disc and retina appear normal in the majority of cases, in which the inflammatory lesion is situated posteriorly in the optic nerve (retrobulbar optic neuritis). However, if the inflammation is near the nerve head, swelling of the disc (papillitis) is observed (Fig. 12-14). The disc

Table 12-2

CAUSES OF OPTIC DISC SWELLING

OPHTHALMIC ABNORMALITY	UNDERLYING CAUSE	VISUAL LOSS	ASSOCIATED SYMPTOMS
Papilledema	Increased intracranial pressure	None or transient blurring; constriction of visual fields and enlargement of blind spot; findings almost always binocular	Headache; signs of intracranial mass
Anterior ischemic optic neuropathy	Infarction of disc and intraorbital optic nerve due to atherosclerosis or temporal arteritis	Acute visual loss, monocular (usually); may be an altitudinal defect	Painless with nonarteritic ischemic optic neuropathy; Headache with temporal arteritis
Optic neuritis ("papillitis")	Inflammatory changes in disc and intraorbital part of optic nerve—usually due to MS, sometimes to ADEM	Rapidly progressive visual loss; usually monocular	Tender globe, pain on ocular defect movement
Hyaline bodies[b] (drusen)	Congenital, familial	Usually none but may be slowly progressive Enlargement of blind spot or arcuate inferior nasal defect	Usually none; rarely transient visual obscurations

Abbreviations: ADEM: acute disseminated encephalomyelitis; MS: mutiple sclerosis.

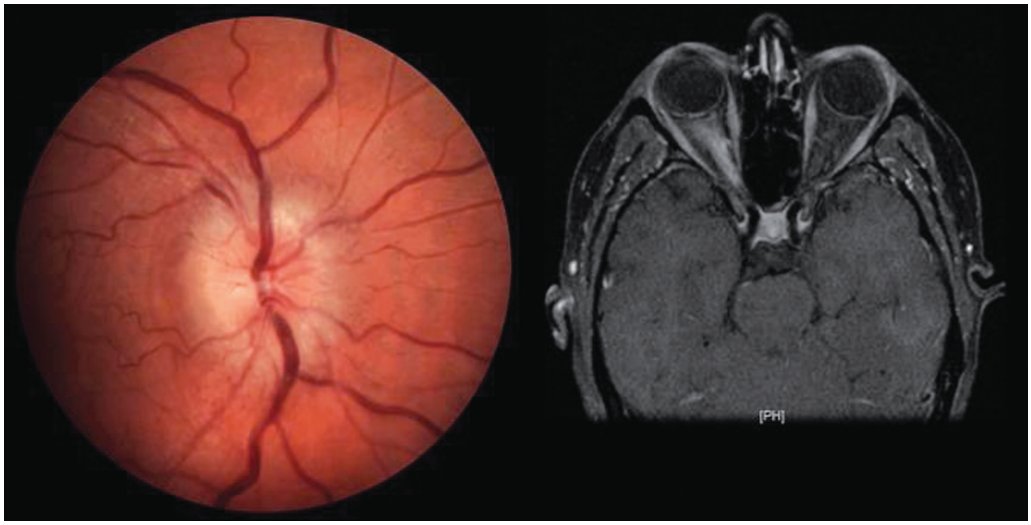

Figure 12-14. Acute optic neuritis. *Left*, The disc is swollen from an inflammatory process near the nerve head (papillitis). *Right*, MRI of the orbits with fat-saturation shows pathologic contrast enhancement of the right optic nerve.

margins are then seen to be elevated, blurred, and, rarely, surrounded by hemorrhages. In extreme cases, edema may suffuse from the disc to cause a rippling in the adjacent retina.

The natural history of idiopathic optic neuritis is typically one of spontaneous recovery after several weeks to months; vision returns to near normal in more than two-thirds of cases. Recovery of vision may be hastened by the intravenous administration of high doses of corticosteroids (see "Treatment of Optic Neuritis" in Chap. 35). Diminution of brightness, dyschromatopsia, or a scotoma may remain; rarely, the patient is left with severe permanent visual deficits. Often, after an episode of optic neuritis, patients report transient increases in blurring with exertion or with exposure to heat (Uhthoff phenomenon).

Despite the return of visual acuity in the majority of patients with optic neuritis, a degree of optic atrophy almost always results. The disc then appears pale, particularly in its temporal sector (temporal pallor), and the pallor extends beyond the margins of the disc into the peripapillary retinal nerve fibers. Pattern-shift visual evoked potential testing shows persistent delay on the side of the affected eye; as a result, this test is a highly sensitive indicator of previous, even asymptomatic, episodes of optic neuritis.

As time progresses, more than half of adults with idiopathic optic neuritis will develop other symptoms and signs of multiple sclerosis within 5 years, and even more do so when they are observed for longer periods. Conversely, in approximately 15 percent of patients with multiple sclerosis, the history discloses that retrobulbar neuritis was the first symptom. A proportion of patients with acute optic neuritis are found at the time of an acute attack to have characteristic subclinical radiographic features of multiple sclerosis on MRI of the cerebrum and spine. The treatment of optic neuritis is taken up with multiple sclerosis in Chap. 35.

Optic neuritis is also a main component of neuromyelitis optica (Devic disease; see Chap. 35), now recognized as being caused in most cases by antibodies to aquaporin 4 (anti-AQP4) or to myelin oligodendrocyte glycoprotein (anti-MOG); the vision loss is often more severe and the prognosis for recovery is poorer than for optic neuritis in multiple sclerosis. Clinical features suggestive of neuromyelitis optica, rather than optic neuritis associated with multiple sclerosis, include severe visual loss (hand motion vision or worse), bilateral visual loss, enhancement of greater than 50 percent of the optic nerve on MRI, and associated clinical deficits suggestive of myelitis, hiccoughs, or vomiting (from the area postrema syndrome), or disorders of arousal from diencephalic involvement (see Chap. 35). Retrospective studies suggest that prompt treatment with plasma exchange may improve outcomes in cases of acute severe visual loss in which neuromyelitis optica is considered to be the cause. Often these acute management decisions need to be made before the results of antibody testing can be obtained.

Postinfectious demyelinating disease is a possible cause in some cases that do not later show signs of multiple sclerosis. Optic neuritis in children is more often bilateral and frequently relates to a preceding viral infection ("neuroretinitis," see the following text). Their prognosis is better than that of adults. Some cases of optic neuritis have been convincingly attributed to paranasal sinus disease, but this association only occurs rarely, as discussed further on. As described above, *neuroretinitis* is a rare parainfectious process seen mostly in children and young adults, sometimes in association with exposure to the *Bartonella henselae* bacteria, the cause of cat scratch fever. Papillitis is accompanied by macular edema and exudates situated radially in the Henle layer, producing a "macular star" appearance.

Ischemic Optic Neuropathy

Ischemic optic neuropathy often produces a severe visual loss. With *anterior* ischemic optic neuropathy, the optic disc is involved and optic disc edema is visualized in the acute phase. In contrast, with *posterior* ischemic optic neuropathy, there are no changes in the optic disc until disc pallor develops in the chronic stages. Ischemic optic neuropathy

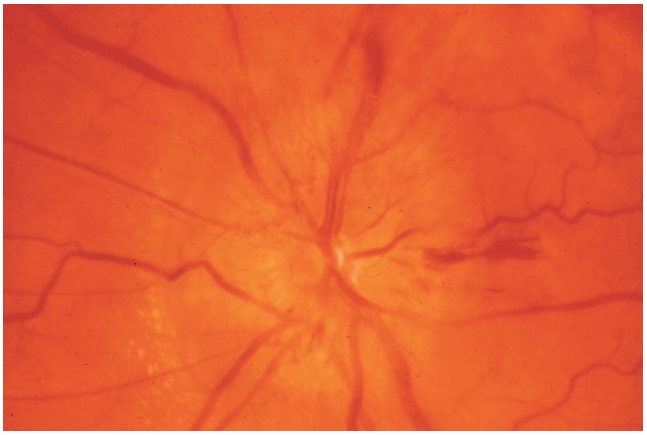

Figure 12-15. Nonarteritic anterior ischemic optic neuropathy (NAION) related to hypertension and diabetes. There is diffuse disc swelling from infarction that extends into the retina. The veins are engorged. Exudates can be seen to the left of the disc and a "flame" hemorrhage extends from the right disc margin.

can be either arteritic (discussed in the following text) or nonarteritic. With NAION, the onset is typically abrupt and painless, but on occasion, the visual loss is progressive for several days. Affected individuals tend to be 50 years of age or older. Usually, there are no premonitory symptoms or episodes of transient visual loss. The field defect is often altitudinal. If the area of central fixation is involved, then acuity can be severely compromised. Swelling of the optic disc may be sectoral, with certain portions of the disc circumference visibly spared. Associated small, flame-shaped hemorrhages are also typical (Fig. 12-15). The retina and retinal vessels are not affected, as they are in cases of embolic occlusion of the central retinal artery. Despite these distinctive clinical features, ischemic optic neuropathy can sometimes be difficult to differentiate from optic neuritis (Rizzo and Lessell). MRI of the orbit often discloses optic nerve T2 hyperintensity with both optic neuritis and ischemic optic neuropathy, enhancement is characteristic of the former but does not commonly occur with the latter.

The pathogenesis of NAION relates to insufficiency of the posterior ciliary artery and peripapillary choroidal arterial circulation (Hayreh). Most cases occur on a background of hypertensive vascular disease and diabetes. A crowded optic nerve with a small optic cup is an anatomic risk factor for the condition. Episodes of nocturnal hypotension are thought to precipitate a cycle of ischemia with swelling of the optic disc that further compromises perfusion leading to more ischemia. Patients are often counseled to avoid medications that could cause the blood pressure to decline overnight.

A possible relationship has been observed between ischemic optic neuropathy and the use of nitric oxide inhibitors, such as sildenafil, for erectile dysfunction. The visual loss has occurred within 24 h of taking the drug and is usually unilateral. Affected patients have had risk factors for vascular disease including hypertension, diabetes, or hyperlipidemia, but there have been exceptions (Pomeranz). NAION may also occasionally complicate intraocular surgery including cataract extraction.

The prognosis for visual recovery from NAION is generally poorer than for other forms of optic neuropathy. As the disc edema subsides, optic atrophy becomes evident. The lifetime risk for involvement of the second eye is estimated to be approximately 25 percent (Newman). Avoidance of nocturnal hypotension, and treatment of obstructive sleep apnea, if it is present, are some measures that may reduce this risk, but prophylactic treatment with antiplatelet drugs or other medications has not proven to be effective.

Massive blood loss or intraoperative hypotension, particularly in association with the use of cardiac surgery with a bypass pump, may also produce visual loss owing to ischemic infarction of the retina and optic nerve. Prolonged laminectomy operations, performed with the patient in the prone position, are another situation that can be complicated by severe unilateral or bilateral ischemic optic neuropathy. Many of these cases represent posterior optic neuropathy, where the optic disc appears normal acutely, without evident swelling (Lee).

Temporal, or *giant cell, arteritis* is another important cause of ischemic optic neuropathy (see also Chap. 9 on the related headache and Chap. 33 for a discussion of cerebrovascular disease in association with giant cell arteritis). Fleeting premonitory symptoms of visual loss (amaurosis fugax) may precede infarction of the nerve. Infarction caused by cranial arteritis may affect both optic nerves or retina in close succession and also, less often, impair ocular motor function. Patients may report symptoms of polymyalgia rheumatic including myalgias, unintentional weight loss, or fevers. Jaw claudication, in which the muscles of mastication easily fatigue and ache with chewing, is among the most specific symptoms for giant cell arteritis when it is correctly distinguished from other causes of jaw discomfort or pain. Giant cell arteritis is more common with increasing age, particularly in the 8th or 9th decade, and is rare below the age of 50. Elevated inflammatory markers serve to corroborate the clinical suspicion; it is quite rare, though possible, for both the ESR and C-reactive protein to be in the normal range. Temporal artery biopsy, taken with a segment of 1cm or more to increase the yield, shows mural inflammation, often (but not always) with multinucleated giant cells and granulomas, as well as lumen narrowing and destruction of elastic lamina. When the history or examination suggests that vision is threatened and there is reasonable clinical certainty of a diagnosis of giant cell arteritis, prompt treatment with high doses of corticosteroids should be initiated before additional diagnostic testing is completed. Untreated, there can be a substantial risk of further ischemia leading to irreversible bilateral visual loss.

Toxic and Nutritional Optic Neuropathies (Table 12-3)

Progressive, symmetric impairment of vision in both eyes with central or centrocecal scotomas can be caused by nutritional deficiency. This occurrence is observed most often in chronically alcoholic or malnourished patients. Impairment of visual acuity evolves over several days to weeks, and examination discloses bilateral, roughly symmetrical central or centrocecal scotomas, with the peripheral fields being intact. With appropriate treatment

Table 12-3

CAUSES OF UNILATERAL AND BILATERAL OPTIC NEUROPATHY

I. Demyelinative (optic neuritis)
- Multiple sclerosis
- Postinfectious and viral neuroretinitis

II. Ischemic
- Arteriosclerotic (usually in-situ occlusion; occasionally carotid artery disease)
- Granulomatous (giant cell) arteritis
- Syphilitic arteritis

III. Parainfectious
- Cavernous sinus thrombosis
- Paranasal sinus infection

IV. Toxins and drugs
- Methanol
- Ethambutol
- Chloroquine
- Streptomycin
- Chlorpropamide
- Chloramphenicol
- Tiagabine
- Linezolid
- Infliximab
- Sildenafil
- Ergot compounds

V. Deficiency states
- Vitamin B_{12}
- Thiamine or possibly several B vitamins ("tobacco-alcohol" amblyopia)
- Epidemic nutritional types (Cuban, Jamaican)

VI. Heredofamilial and developmental
- Dominant juvenile optic atrophy
- Leber optic atrophy
- Developmental failure of disc or papillomacular bundle
- Progressive hyaline body encroachment

VII. Compressive and infiltrative
- Meningioma of sphenoid wing or olfactory groove
- Metastasis to optic nerve or chiasm
- Glioma of optic nerve (neurofibromatosis type I)
- Optic atrophy following long-standing papilledema
- Pituitary tumor and apoplexy
- Thyroid ophthalmopathy
- Sarcoidosis
- Giant aneurysms
- Lymphoma
- Wegener granulomatosis

VIII. Radiation-induced optic neuropathy

(nutritious diet and B vitamins) instituted soon after the onset of visual loss, recovery is possible. If treatment is delayed, patients are left with varying degrees of a permanent defect in central vision and pallor of the temporal portions of the optic discs. This disorder has been referred to as "tobacco-alcohol amblyopia," the implication being that it is caused by the toxic effects of tobacco or alcohol or both. In fact, the problem is more likely one of nutritional deficiency and is more properly designated as *nutritional optic neuropathy* (see Chap. 41). The same disorder may be seen under conditions of severe dietary deprivation (see Chap. 41) and in patients with vitamin B_{12} deficiency.

Clusters of similar cases are described periodically in regions with high rates of poor nutrition. A notable example occurred in Cuba in the early 1990s with an epidemic of optic neuropathy associated with sensory polyneuropathy. A nutritional etiology, possibly compounded by tobacco use, was the likely cause of these outbreaks (Sadun and The Cuba Neuropathy Field Investigation Team report). A putative role of exposure to cyanide, either from smoking or consumption of cassava, has been a feature of some of these epidemics.

Subacute development of toxic optic neuropathy can occur with prescribed therapeutic agents, notably ethambutol, linezolid, isoniazid, streptomycin, chloramphenicol, methotrexate, and chlorpropamide (Grant). Ethambutol toxicity is not uncommon in regions with high rates of treatment for tuberculosis; appropriate weight-based dosing of the medication is critical to mitigate the risks of its toxic effects and irreversible visual loss. Impairment of vision because of *methanol intoxication* has a different clinical profile, being abrupt in onset and accompanied by symptoms of acidosis. Treatment is directed mainly to the correction of the acidosis and possibly the administration of fomepizole. A similar presentation may occur with ethylene glycol ingestion. Infliximab and other TNF-alpha blocking medications can occasionally precipitate optic neuritis and other demyelinating syndromes of the central or peripheral nervous system. The main drugs reported to have a toxic effect on the optic nerves are listed in Table 12-3.

Hereditary Abnormalities of the Optic Nerve

Several optic neuropathies have a genetic cause. Leber hereditary optic neuropathy, a maternally inherited mitochondrial disorder, is an infrequent but important cause of blindness that usually presents in young adults. It may simulate the more common inflammatory optic neuropathies that also cause a relatively abrupt onset of visual loss, although it is painless. It presents either simultaneously in both eyes or else sequentially within a period of weeks to months. The visual field defect typically takes the form of a severe cecocentral scotoma. In general, the prognosis for visual recovery is poor, but some cases show a degree of spontaneous recovery (see "Hereditary Optic Atrophy of Leber" in Chap. 36). Idebenone has shown marginal benefits in these patients, and gene therapy delivered through intravitreal injection has been developed and is currently in human trials.

The presentation of dominantly inherited optic atrophy, known as Kjer optic neuropathy, is usually less dramatic; it presents with insidious, bilateral vision loss. The abnormality might be detected, for example, during a vision screening test in the early years of school. Vision is typically modestly reduced, but the optic discs can show significant temporal pallor with an excavated appearance. The condition shows a mendelian autosomal dominant pattern of inheritance because it is caused by a nuclear genetic mutation, although the dysfunctional protein causes a mitochondrial metabolic defect. A growing number of pathogenic mutations have been identified, most involving the *OPA1* gene. Some patients have dominant optic atrophy "plus," in which the syndrome includes other abnormalities such as hearing loss or peripheral neuropathy.

Developmental Abnormalities of the Optic Nerve

Congenital defects of the optic disc can arise from defective closure of the optic fissure during embryogenesis.

These defects, known either as an optic pit or as a larger optic coloboma, may cause clinically significant visual loss, particularly when the fibers of the papillomacular bundle are affected. Usually, the abnormality is unilateral and not associated with developmental abnormalities of the brain, but hereditary forms with more complex syndromic deficits are known (Brown and Tasman).

Optic nerve hypoplasia refers to nerves with an abnormally small diameter. Funduscopic examination may reveal the "double ring" sign, referring to a small optic disc within the larger opening of the scleral canal. Optic nerve hypoplasia can be part of the septo-optic dysplasia, known as de Morsier syndrome, which includes other midline patterning deficits such as absence of the septum pellucidum and hypothalamic-pituitary abnormalities, as well as cortical heterotopias.

Other Optic Neuropathies

Optic nerve and chiasmal compression and infiltration by meningiomas, pituitary adenomas, craniopharyngiomas, and metastatic tumors may cause loss of vision and optic atrophy (see Chap. 30). Pituitary tumors characteristically cause bitemporal hemianopia because they compress the chiasm and disrupt crossing fibers from the nasal retina of each eye, but very large adenomas can cause vision loss that also extends through the nasal hemifield of one or both eyes. Pituitary apoplexy, referring to acute involutional hemorrhage into a pituitary adenoma, presents with an acute headache that may be accompanied by visual loss from compression of the optic nerves and chiasm, as well as ocular motility deficits (discussed further in Chap. 30).

Optic nerve glioma occurs either sporadically or in patients with type I von Recklinghausen neurofibromatosis. Usually, it develops in children, often before the fourth year, causing a mass within the orbit and progressive loss of vision. Approaches to treatment remain controversial. In general, if vision is retained, patients may be observed carefully, but if vision declines, radiation and chemotherapy are often recommended. If the eye is blind, the recommended therapy is surgical removal to prevent extension into the optic chiasm and hypothalamus. The risk of progression tends to be low after the 2nd decade of life. Malignant forms including glioblastoma of the optic pathway can occur in adults.

Radiation necrosis of the optic nerves and chiasm typically presents months to years after an individual has received radiation for a skull base lesion, occurring at an average of 18 months after exposure. Enhancement of the nerve on MRI is typical. It is more common following radiation doses in excess of 50 Gy (5,000 rad) (Jiang et al). Attempted treatment strategies have included corticosteroids, hyperbaric oxygen, and the VEGF-inhibitor bevacizumab, but all show limited results (discussed further in Chap. 30).

Infiltration of an optic nerve may occur with inflammatory conditions, especially sarcoidosis. Uveitis and other evidence of systemic involvement may be clues to the diagnosis. Systemic lupus erythematosus is a less common cause of optic neuropathy. Granulomatosis with polyangiitis (formerly Wegener granulomatosis) causes optic neuropathy, often with a destructive orbital mass lesion. Infiltrative optic neuropathy can also be a prominent feature of leukemia and lymphoma.

Lesions of the Chiasm, Optic Tract, and Geniculocalcarine Pathway

Hemianopia describes visual loss in one-half of the visual field for each eye. *Bitemporal hemianopia* is heteronymous because the field deficit is on opposite sides of the vertical meridian for each eye. Bitemporal hemianopia is caused by a lesion that disrupts the decussating fibers of the optic chiasm and is caused most often by the suprasellar extension of a tumor of the pituitary gland (Fig. 12-2*C*). It may also be the result of a craniopharyngioma, Rathke cleft cyst, a saccular aneurysm or dolichoectatic artery of the anterior circle of Willis, and a meningioma of the tuberculum sellae; less often, it may be a result of sarcoidosis, metastatic carcinoma, ectopic pinealoma or dysgerminoma, Hand-Schüller-Christian disease, or hydrocephalus with dilatation and downward herniation of the anterior part of the third ventricle (Corbett).

Variations in the pattern of visual loss from chiasmal lesions are frequent, in part accounted for by the location of the chiasm in an individual patient. A "postfixed" chiasm is located more posteriorly, and a compressive lesion arising from the pituitary sella is more likely to present with deficits relating to optic neuropathy. In contrast, a "prefixed" chiasm is located more anteriorly so that a compressive lesion from the pituitary sella is more likely to compress the optic tract rather than the optic chiasm. As noted previously, the visual field pattern created by a lesion of the optic nerve as it joins the chiasm typically includes a scotomatous defect on the affected side coupled with a contralateral superior quadrantanopia (a combination referred to as a "junctional field defect").

Homonymous hemianopia (loss of vision in corresponding halves of the visual fields) signifies a lesion of the visual pathway behind the chiasm. When a homonymous hemianopia is *complete*, it is difficult to discern the localization within the retrochiasmal visual pathways on the basis of the field loss alone. On the other hand, *incomplete* homonymous hemianopia has more localizing value. If the field defects in the two eyes are identical (*congruous*), the lesion is likely to be posterior in the calcarine cortex and subcortical white matter of the occipital lobe (although perfect congruity of field defects is infrequent, even with occipital lesions). In contrast, if the incomplete homonymous deficit has a different pattern in each eye (with one eye showing greater field loss than the other, but both on the same side of the vertical meridian), the pattern is *incongruous*, and the localization is more anterior within the retrochiasmal pathways, with the optic tract or proximal optic radiations most likely to be implicated. In this portion of the visual pathways, the crossing axons from one eye are in the process of becoming juxtaposed with their paired axon from the fellow eye, and a partial lesion may disproportionately affect more of the fibers from one eye than the other.

The lower fibers of the geniculocalcarine pathway (from the inferior retinas) swing in a wide arc over the temporal horn of the lateral ventricle and then proceed posteriorly to join the upper fibers of the pathway on their way to the calcarine cortex (Fig. 12-2). This arc of fibers is known variously as the Meyer or Archambault loop, and a lesion that interrupts these fibers will produce a contralateral *superior homonymous quadrantanopia* (upper temporal deficit in the contralateral eye and upper nasal deficit in the ipsilateral eye; Fig. 12-2*E*). This clinical effect was first described by Harvey Cushing, so that his name also was in the past applied to the loop of temporal visual fibers. Parietal lobe lesions affect the inferior quadrants of the visual fields more than the superior ones.

A precise retinotopic map of the contralateral homonymous visual field is represented in the primary visual cortex of the occipital lobe. If the entire optic tract or calcarine cortex on one side is destroyed, the homonymous hemianopia is complete. However, with infarction of the occipital lobe from occlusion of the posterior cerebral artery, the macular region, represented in the most posterior part of the striate cortex, may be spared by virtue of collateral circulation from branches of the middle cerebral artery. In this circumstance, there is a 5- to 10-degree island of vision around the fixation point on the side of the hemianopia (*macular sparing*). With other types of lesions that affect the occipital cortex and do not spare the pole, this effect does not occur. Lesions of both occipital poles, which occur rarely from severe hypotension, result in bilateral central scotomas. The representation of the contralateral upper visual field is in the bank of neurons below the calcarine fissure and vice versa, thus explaining how superior or inferior quadrantic defects can localize to the occipital cortex. If all the calcarine cortex or all the subcortical geniculocalcarine fibers on both sides are completely destroyed, the bilateral hemianopias cause cerebral, or *"cortical,"* blindness (see the following text and Chap. 21).

An *altitudinal defect* is one that is confined by a horizontal border and crosses the vertical meridian. *Homonymous altitudinal hemianopia* is usually caused by lesions of both occipital lobes below or above the calcarine sulcus, and rarely to a lesion of the optic chiasm or nerves. The most common cause of this rare phenomenon is still occlusion of both posterior cerebral arteries. Herniation of the occipital lobe over the tentorial margin can produce a homonymous superior altitudinal defect by selectively compressing the inferior branches of the posterior cerebral arteries. A monocular altitudinal hemianopia, by contrast, is almost invariably an optic neuropathy, usually the nonarteritic anterior ischemic type that arises from occlusion of the posterior ciliary vessels.

In certain instances of homonymous hemianopia, the patient is capable of some visual perception in the hemianopic fields, a circumstance that permits the study of the vulnerability of different visual functions. The tendency for patients with occipital lesions to have greater sensitivity for kinetic stimuli than for static ones was described by Riddoch in 1917. Sometimes colored targets may be detected in the hemianopic fields, whereas achromatic ones cannot. But even in seemingly complete hemianopic defects, in which the patient consciously admits to being blind, it has been shown that rare patients may still react to visual stimuli with accuracy above chance when forced-choice techniques are used. This type of residual visual function has been called "blindsight" by Weiskrantz. One study showed that 20 percent of their patients with no ability to discriminate patterns in the hemianopic field nonetheless could still reach accurately and look at a moving light in the "blind" field (Blythe). These residual visual functions are generally attributed to the preserved function of retinocollicular or geniculoprestriate cortical connections, but in some cases, they may be a result of sparing of small islands of calcarine neurons.

Yet other instances of complete homonymous hemianopia may be characterized by preservation of vision in the *monocular temporal crescent*, which is the peripheral portion of the visual field, between 60 and 90 degrees from the fixation point (Benton; Meienberg). This portion of the visual field is represented in the most anterior part of the visual striate cortex. In particular, the temporal crescent is sensitive to moving stimuli, allowing the patient to avoid collisions with people and objects.

Functional, Nonorganic Visual Loss

Nonorganic visual loss may be suspected based on discordance between reported symptoms and observations of the patient's activities when he thinks he is unobserved, and a diagnosis can often be confirmed by a number of examination maneuvers. If the patient claims total blindness, functional visual loss can be suggested by observing the physiologic optokinetic nystagmus that often occurs reflexively in response to looking at a rotating drum or strip, or by noting that the patient's eyes follow their own image in a mirror that is moved in front of them. If the patient claims to have total vision of just one eye, a functional etiology is suggested by the use of red-green glasses and an acuity chart with red and green letters, where each eye can only see letters with the color of its lens. The patient cannot tell which letters should be visible to them, and the intact acuity in the involved eye is exposed. Other findings to suggest nonorganic visual loss of one eye are normal pupillary responses without a relative afferent defect and a normal optokinetic response in the nonseeing eye (with the good eye covered). The visual evoked potential from the allegedly blind eye is also normal. Nonorganic *homonymous hemianopia* is rare, but malingerers may occasionally display mostly all manner of field defects (Keane). The severely constricted nonorganic tubular field defect that does not expand as the testing distance is increased has already been mentioned. Star and spiral-shaped visual field results obtained by manual (Goldmann) perimetry are also indicative of a nonorganic etiology.

Cerebral Forms of Blindness and Visual Agnosia (See Also Chap. 21)

The ability to recognize visually presented objects and words depends on the integrity not only of the visual pathways and primary visual area of the cerebral cortex

(area 17 of Brodmann) but also numerous additional cortical areas extending from the occipital lobe into the temporal and parietal lobes. Blindness that is the result of destruction of both visual and adjacent regions of the occipital lobes is termed *cortical* or *cerebral blindness*. In some cases of cortical blindness, the patient fails to recognize their blindness despite overt manifestations of the defect (Anton syndrome).

In distinction to these forms of visual loss, there is a less-common category of visual impairment in which the patient cannot understand the meaning of what he sees, referred to as *visual agnosia*. Primary visual perception is more or less intact, and the patient may accurately describe the shape, color, and size of objects and draw copies of them. Despite this, he cannot identify the objects unless he hears, smells, tastes, or palpates them. The failure of visual recognition of words alone is called *pure word blindness,* or *alexia*. Visual-object agnosia rarely occurs as an isolated finding: It is generally combined with alexia, homonymous hemianopia, or both. These abnormalities arise from lesions of the dominant occipital cortex and adjacent temporal and parietal cortex (angular gyrus) or from a lesion of the left calcarine cortex combined with one that interrupts the fibers crossing from the right occipital lobe (see Fig. 21-6). In the latter case, fibers responsible for writing are spared, and the patient remains with a syndrome of alexia without agraphia.

Failure to understand the meaning of an entire picture, even though some of its parts are recognized, is referred to as *simultanagnosia* and is found in bilateral lesions of the occipital–parietal junction. When combined with deficits in visual control of hand and eye movements (optic ataxia and ocular apraxia), the resulting condition is referred to as Balint syndrome. A failure to recognize familiar faces is called *prosopagnosia* and typically results from occipital–temporal lesions. These and other variants of visual agnosia (including visual neglect) and their pathologic bases are dealt with more fully in Chap. 21.

Other cerebral disturbances of vision include various types of distortion in which images seem to recede into the distance (teleopsia), appear too small (micropsia), or, less frequently, seem too large (macropsia). If such distortions are perceived with only one eye, a retinal lesion should be suspected. If perceived with both eyes, they usually signify disease of the temporal lobes, in which case the visual disturbances tend to occur in attacks and are accompanied by other manifestations of temporal lobe seizures (see Chap. 15). Palinopsia, a persistence of repetitive afterimages, similar to the appearance of a celluloid movie strip, occurs with right parietooccipital lesions; it has been a consequence of seizures in the cases we have encountered, but instances associated with static disorders (tumor, infarction) have been described as well. Patients describe the images as "trailing" or "echoing." With parietal lobe lesions, objects may appear to be askew or even turned upside down. Lesions of the vestibular nucleus or its immediate connections produce the illusion that objects are tilted or turned upside down (tortopsia) or that straight lines are curved. Presumably, this is the result of a mismatch between the visual image and the otolithic, vestibular input to the visual system.

Abnormalities of Color Vision

Normal color vision depends on the integrity of cone cells, which are most numerous in the macular region. When activated, they convey information to special columns of cells in the striate cortex. Three different cone pigments with optimal sensitivities to short (blue), middle (green), and long (orange-yellow) wavelengths are said to characterize these cells. Transmission to higher centers for the perception of color is effected by neurons and axons that encode at least two pairs of complementary colors: red-green in one system and yellow-blue in the other. In the optic nerves and tracts, the fibers for color are of small caliber and seem to be preferentially sensitive to injury; thus, dyschromatopsia is a common feature of many optic neuropathies. The visual fields for blue-yellow are smaller than those for white light, and the red and green fields are smaller than those for blue-yellow.

Diseases may affect color vision by abolishing it completely (*achromatopsia*) or partially by quantitatively reducing one or more of the three attributes of color—brightness, hue, and saturation. Alternatively, only one of the complementary pairs of colors may be lost or reduced, usually the red-green axis. The disorder may be congenital and hereditary or acquired. The most common form, and the one to which the term *color blindness* is usually applied, is a male sex-linked inability to see red and green while normal visual acuity is retained. The main problem arises in relation to traffic lights, but patients learn to use the position of the light as a guide. Several other genetic abnormalities of cone pigments and their phototransduction have been identified as causes of achromatopsia. The defect cannot be seen by inspecting the retina. A failure of the cones to develop or a degeneration of cones may cause a loss of color vision, but in these conditions, visual acuity is often diminished, a central scotoma may be present, and, although the macula also appears to be normal ophthalmoscopically, fluorescein angiography shows the pigment epithelium to be defective. Whereas congenital color vision defects are usually protan (red) or deutan (green), leaving yellow-blue color vision intact, most acquired lesions affect all colors, at times disparately. Lesions of the optic nerves usually affect red-green more than blue-yellow; the opposite is true of retinal lesions. An exception is a rare, dominantly inherited, optic atrophy, in which the scotoma mapped by a large blue target is larger than that for red.

Acquired deficits of color perception, with preservation of form vision, can result from focal damage (usually infarction) of the visual association cortex inferior to the primary visual cortex (Damasio). Color vision may be lost in the opposite homonymous visual field. If the lesion also involves the inferior bank of the primary visual cortex, then a contralateral superior quadrantanopia is superimposed on the altered color vision in that hemifield. Very rarely, a full-field Achromatopsia results from bilateral occipitotemporal lesions involving the fusiform and lingual gyri, also associated with visual agnosia (especially prosopagnosia).

Other Visual Disorders

In addition to the loss of perception of form, movement, and color, lesions of the visual system may also give rise to a variety of positive sensory visual experiences. The simplest of these are called phosphenes, referring to flashes of light and colored spots in the absence of luminous stimuli. Mechanical pressure on the normal eyeball may induce them at the retinal level, as every child discovers. Or they may occur with disease of the visual system at many different sites. As mentioned earlier, elderly patients commonly complain of flashes of light in the peripheral field of one eye, most evident in the dark (*lightning streaks of Moore*); these are related to vitreous tags that rest on the retinal equator, and may be quite benign, or may be residual evidence of retinal detachment. Autoimmune and cancer-associated retinopathy is frequently associated with photopsias prior to visual loss. Retinal toxicity from digitalis causes chromatopsia with a characteristic "yellowish vision" and may also cause photopsias.

In patients with migraine, cortical spreading depression through the occipital lobe gives rise to the bright zigzag lines of a fortification spectrum. Stimulation of the cortical visual pathways accounts for stereotyped, repetitive simple or unformed visual hallucinations in epilepsy. Formed or complex visual hallucinations (of people, animals, landscapes) are observed in a variety of conditions, notably in old age when vision fails (Charles Bonnet syndrome, discussed in "Visual Hallucinations" in Chap. 21), with infarcts of the occipitoparietal or occipitotemporal regions (release hallucinations), in the withdrawal state following chronic intoxication with alcohol and other sedative-hypnotic drugs (see Chap. 41), and with lesions in the diencephalon ("peduncular hallucinosis"). These disorders are also discussed in Chap. 21.

Occasionally, patients with a parietal lesion may perceive transposition of images, flipped across the vertical or horizontal axes (*visual allesthesia*), or a visual image may persist for minutes to hours or reappear episodically after the exciting stimulus has been removed (*palinopsia* mentioned earlier). *Polyopia*, the perception of multiple images when a single stimulus is presented, is said to be associated predominantly with right occipital lesions and can occur with either eye. Usually, there is one primary and a number of secondary images, and their relationships may be constant or changing (Bender and Krieger). *Oscillopsia*, or illusory movement of the environment, is a perception caused by nystagmus and occurs mainly with lesions of the labyrinthine-vestibular apparatus; it is described with disorders of ocular movement. In patients describing intermittent *monocular* oscillopsia, myokymia of one superior oblique muscle should be considered (see "Fourth Nerve Palsy" in Chap. 13).

Chapter 21 further discusses the clinical effects and syndromes that result from occipital lobe lesions.

Amblyopia (Amblyopia Ex Anopsia)

As noted in the introductory part of this chapter, the generic term "amblyopia" has been adopted for a special circumstance in which a normal eye fails to acquire its potential visual acuity because images are not properly projected onto the fovea during a formative period of cerebral development. It is a disorder, as in the exaggerated quip by van Noorden and Campos, "in which the patient sees nothing and the doctor sees nothing," meaning that the pupillary response and fundus are observed to be normal despite the visual deficit. The degradation of vision and disuse of the fovea may be the result of a number of processes, including misaligned ocular axes (strabismus), reduced monocular inputs (deprivation, from ptosis or cataract), or unequal refractive errors (anisometropia; discussed in Chap. 13). The period of risk is during the first 7 years but is greatest in the earlier part of this epoch, and the visual loss may still be rectifiable beyond the time.

The developmental deficiency in the occipital cortex that gives rise to amblyopia has been extensively studied in animals and humans (van Noorden and Campos). Neurologists should be aware that screening children for the disorder is highly valuable even if treatment is not always successful. The correction of refractive errors, cataracts, and other correctible ocular problems are attended to first. Attempts are then made to force the utilization of the disadvantaged eye in preference to the normal one; patching and atropine drops are the typical methods to accomplish this (Holmes and Clarke).

Disorders of Ocular Movement and Pupillary Function

Ocular movement and vision are virtually inseparable. Normal visual experience depends not only on the integrity of the afferent visual pathways, but also on the mechanisms controlling various types of eye movements. Coordinated eye movements interspersed with periods of stable fixation are essential to stabilize visual images on the two retinas. Specialized networks mediate volitional and reflexive fast eye movements (saccades), tracking of a moving object (pursuit), and reflexive eye movements in response to movements of the body or head (vestibulo-ocular reflexes).

Abnormalities of ocular movement are of three basic types. One category can be traced to a lesion of the extraocular muscles themselves, the neuromuscular junction, or to the cranial nerves that supply them (*nuclear* or *infranuclear palsy*). The second type is a derangement in the specialized neural mechanisms that enable the eyes to move together (*supranuclear* and *internuclear palsies*). Perhaps more common but not primarily neurologic is a third group of disorders, *congenital strabismus*, in which there is ocular misalignment relating to an imbalance of the yoked muscles of extraocular movement. This early ocular misalignment is one cause of a developmental reduction in vision (amblyopia), as discussed at the end of the previous chapter.

SUPRANUCLEAR CONTROL OF EYE MOVEMENT

Anatomic and Physiologic Considerations

In no aspect of human anatomy and physiology is the sensory guidance of muscle activity more instructively revealed than in the neural control of coordinated ocular movement. Knowledge of the central and peripheral mechanisms subserving normal eye movements allows for precise localization of lesions within these pathways. To focus the eyes voluntarily, to stabilize objects for scrutiny when one is moving, to bring into sharp focus near and far objects—all require the perfect coordination of six sets of extraocular muscles and three sets of intrinsic muscles (ciliary muscles, sphincters, and dilators of the iris). The neural mechanisms that govern these functions reside mainly in the midbrain and pons, but are greatly influenced by centers in the medulla, cerebellum, basal ganglia, and the frontal, parietal, and occipital lobes of the brain. Much of the anatomy and physiology of the pathways concerned with fixation and stable ocular movements has been learned both from clinical–pathologic correlations in humans and from experiments in monkeys.

Accurate binocular vision is achieved by coordianted actions of all the ocular muscles. The term *duction* denotes the movement of one eye in a single direction, whereas the synchronous movement of both eyes is a *version.* The commonly used term *conjugate gaze* indicates that the eyes are aligned as they move in the same direction. *Convergent* movements bring the eyes toward each other, as required when one looks at a near object. At the same time, the pupils constrict and the ciliary muscles relax to thicken the lens and allow near vision (the accommodative-near reflex, or triad). *Divergence* is required for distant vision.

Rapid voluntary conjugate movements termed *saccades* serve to rapidly shift ocular fixation, bringing new images onto the foveae. They are initiated in the frontal eye fields (Brodmann area 8, see Fig. 21-2), which mediates eye movements in the opposite direction via pathways that cross and are relayed to the contralateral pons. The peak velocity of these saccades may exceed 700 degrees per second. Saccades are so rapid that there is generally no subjective awareness of movement during the change in eye position. Voluntary saccadic movements can be elicited by instructing an individual to look in a particular direction (commanded saccades) or to move the eyes to a target (refixation saccades). These two movements are sometimes differently affected in neurologic disease. Saccades may also be elicited reflexively, as when a sudden sound or the appearance of an object in the peripheral field of vision attracts attention and triggers an automatic movement of the eyes in the direction of the stimulus. The interval between the appearance of a target and the initiation of a reflexive saccade is approximately 200 ms. Reflexive saccades are mediated by the superior colliculi and do not require inputs from the frontal eye fields. The neurophysiologic activity of pontine neurons that produces a saccade has a “pulse-step” pattern. A sudden increase in neuronal firing (the pulse) is necessary to overcome the inertia and viscous drag of the eyes to move them into their new position; this is followed by a sustained new firing level

(the step) that is required to maintain the eyes in their new, eccentric position (*gaze holding*).

Pursuit movement stabilize the image of an object that is moving relative to the position of the head, thus maintaining a continuous clear image of the object on the fovea. Pursuit movements are much slower and smoother than saccades, generally accurate up to a velocity of 100 degrees per second. Unlike saccades, pursuit movements to each side are generated in the *ipsilateral* parietooccipital cortex, with modulation by the ipsilateral cerebellum (especially flocculus and nodulus of the vestibulocerebellum).

When following a moving target, as the visual image slips off the foveae, the firing rate of the governing motor neurons increases in proportion to the speed of the target, so that eye velocity matches target velocity. If the eyes fall behind the target, supplementary catch-up saccades are required for refixation. In this situation, the pursuit movement is not smooth, but becomes jerky ("saccadic" pursuit). A lesion of one cerebral hemisphere may cause pursuit movements to that side to break up into saccades. Diseases of the basal ganglia also commonly disrupt pursuit into a ratchet-like saccadic pursuit in all directions.

Optokinetic nystagmus refers to the normal physiologic eye movements that arise when one is observing a series of visual targets entering the visual field, such as watching trees from a moving car or the stripes on a rotating drum. It is characterized by cycles of pursuit of one moving object periodically interrupted by involuntary refixation with quick saccades to refocus the eyes to the next object moving into view. The clinical observation of asymmetric impairment of optokinetic nystagmus may disclose a lesion of the ipsilateral posterior parietal lobe. It may also be found that a frontal lobe lesion eliminates the quick refixation phase away from the side of the lesion, thereby causing the eyes to continue to follow the target until it is out of view.

Vestibular modulation of eye movements is of major importance in stabilizing images on the retina during head and body movement. The *vestibuloocular reflex* (VOR) describes the prompt, short latency movement of the eyes that is equal and opposite to movement of the head. During sustained rotation of the head, the VOR is supplemented by the optokinetic system, which maintains compensatory eye movements for a more prolonged period. Impairment of the VOR impairs vision owing to movement of images across the retina during movements of the head, for example, those occurring with walking. Unilateral loss of the VOR, which can be detected by assessing the maintenance of visual fixation while the patient's head is passively thrust with a small amplitude but high-velocity movement, strongly implicates a disease of the vestibular apparatus or eighth nerve on the side toward the rotation of the head. When objects are tracked using coordinated eye and head movements (such as watching a bird soaring), the VOR must be suppressed, otherwise the eyes would remain fixed in space as the head moved. To accomplish normal physiologic suppression of the VOR, the smooth pursuit signal that is invoked by the moving visual target cancels the unwanted vestibular signal that would have the eyes maintain their original fixation by moving opposite to the direction of the head (Leigh and Zee). Normal ability to suppress the VOR can be assessed by having the patient fixate on their own outstretched thumb while they are rotated in an exam chair. If suppression of the VOR is intact they will maintain fixation on their thumb as they are moved; if it is not, the VOR will bring the eyes opposite the direction they are turning and a series of saccadic eye movements will be used for the eyes to catch up with the moving thumb. As discussed further on, the inability to suppress the VOR occurs in a variety of diseases, most notably progressive supranuclear palsy or severe multiple sclerosis.

Horizontal Gaze

Saccades

As mentioned, the signal for volitional horizontal saccades originates in the eye field of the opposite frontal lobe (area 8 of Brodmann, see Fig. 21-2), which is modulated by the adjacent supplementary motor eye field and by the posterior visual cortical areas. The cortical-to-pontine pathways for saccadic horizontal gaze have been traced in the monkey (Leichnetz). These fibers traverse the internal capsule and separate at the level of the rostral diencephalon into two bundles. A primary "capsular–peduncular" bundle, which descends ventrally through the most medial part of the cerebral peduncle, undergoes a partial decussation in the low midbrain and terminates mainly on neurons of the opposite paramedian pontine reticular formation (PPRF), which then project to the adjacent sixth nerve nucleus (Fig. 13-1). A "transthalamic" bundle is predominantly uncrossed and courses dorsally through the internal medullary lamina and paralaminar parts of the thalamus to terminate diffusely in the pretectum, superior colliculus, and periaqueductal gray matter. An off-shoot of these fibers (the prefrontal oculomotor bundle) projects to the rostral part of the oculomotor nucleus, the ipsilateral rostral interstitial nucleus of the medial longitudinal fasciculus (riMLF), and to the interstitial nucleus of Cajal (INC), which are involved in vertical eye movements.

Pursuit

The pathways for smooth pursuit movements are less well defined. One originates in the posterior parietal cortex and the adjacent temporal and anterior occipital cortex (area MT of the monkey), descending to the ipsilateral dorsolateral pontine nuclei (Krauzlis). Also contributing to smooth pursuit movements are projections from the frontal eye fields to the ipsilateral dorsolateral pontine nuclei. The latter, in turn, project to the flocculus and dorsal vermis of the cerebellum, which further calibrate pursuit movements.

Brainstem (Internuclear) Pathways and Ocular Motor Nuclei

Conventionally, the term *ocular motor nuclei* refers to the nuclei of the third, fourth, and sixth cranial nerves; the term *oculomotor nucleus* refers to the third nerve nucleus alone. Ultimately, all pathways that mediate horizontal saccadic, pursuit, vestibular, and optokinetic movements converge on the pontine tegmental center for horizontal gaze, the PPRF. The PPRF projects to the sixth nerve nucleus to command horizontal eye movement (see Fig. 13-1). Vestibular

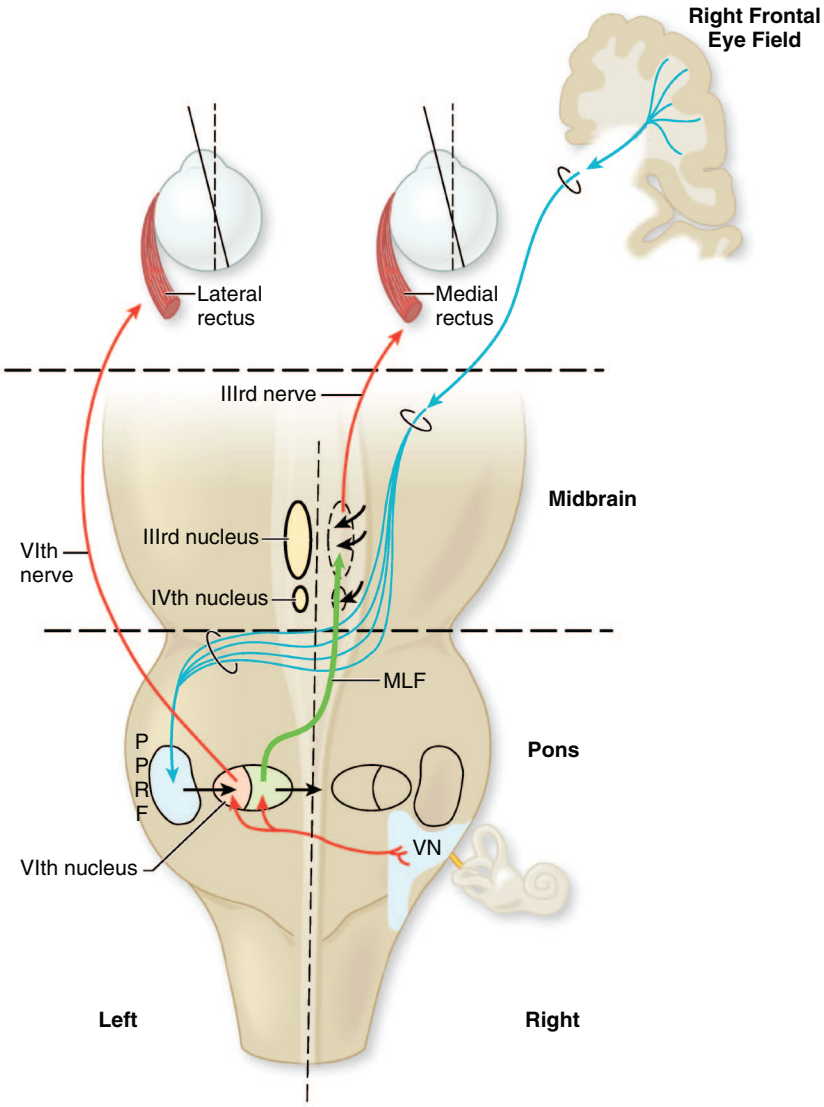

Figure 13-1. The supranuclear pathways subserving horizontal gaze to the left. The pathway originates in the right frontal cortex, descends in the internal capsule, decussates at the level of the rostral pons, and descends to synapse in the left pontine paramedian reticular formation (PPRF). Further connections with the ipsilateral sixth nerve nucleus and contralateral medial longitudinal fasciculus are also indicated in red. The right MLF (green line) is labeled between the abducens and oculomotor nuclei and the vestibular nuclei (VN) are shown on the right. LR, lateral rectus; MLF, medial longitudinal fasciculus; MR, medial rectus.

inputs and some supranuclear neural signals that encode smooth pursuit may bypass the PPRF and project directly to the abducens nuclei (Hanson et al). Also required for horizontal ocular versions are the nuclei prepositus hypoglossi and their commissure, the medial vestibular nuclei, and pathways in the pontine and tegmentum of the brainstem that interconnect the ocular motor nuclei.

The abducens nucleus contains two groups of neurons, each with distinctive morphologic and physiologic properties: (1) the abducens motor neurons, which innervate the ipsilateral lateral rectus muscle, and (2) internuclear neurons, which project via the contralateral *medial longitudinal fasciculus* (*MLF*). The heavily myelinated fibers of the MLF emanate from the sixth nerve nucleus, cross in the pons, and ascend to the contralateral medial rectus subnucleus of the third nerve. In this way, the abduction of one eye is yoked to adduction of the opposite one to produce conjugate horizontal gaze (see Fig. 13-1). The MLF also conveys inputs that connect the vestibular nuclei to the ocular motor nuclei. Some fibers from the medial vestibular nucleus travel via the MLF into the upper segments of the cervical spinal cord, where they contribute to the control of head position by influencing tonic reflexive activity of neck muscles in response to vestibular inputs.

Conjugate lateral gaze is accomplished by the nearly simultaneous activation of the ipsilateral lateral rectus and the contralateral medial rectus. Interruption of the MLF results in impaired adduction of the eye ipsilateral to the lesion during horizontal gaze in the opposite direction, a sign referred to as *internuclear ophthalmoplegia* (*INO*), the details of which are discussed further on.

Control of eye movements depends on a hierarchy of pathways that do not project directly to ocular motor nuclei but to adjacent *premotor* or *burst neurons* that discharge at

high frequencies immediately preceding a saccade (Leigh and Zee). The premotor or burst neurons for horizontal saccades lie within the PPRF and those for vertical saccades in the riMLF (see below). Another class of neurons called *omnipause cells*, lying in the midline of the pons, is involved in the inhibition of unwanted saccadic discharges.

Vertical Gaze

In contrast to horizontal gaze, which is generated by unilateral aggregates of cerebral and pontine neurons, vertical eye movements, with few exceptions, are under bilateral control of the cerebral cortex and upper brainstem. The groups of neurons and fibers that govern upward and downward gaze, as well as torsional saccades, are situated in the pretectal areas of the midbrain and involve three integrated structures—the riMLF, the INC, and the nucleus and fibers of the posterior commissure (Fig. 13-2).

The *riMLF* lies at the junction of the midbrain and thalamus, at the rostral end of the medial longitudinal fasciculus, just dorsomedial to the rostral pole of the red nucleus. It functions as the premotor nucleus with burst cells that produce fast (saccadic) vertical versional and torsional movements. Input to the riMLF arises both from the PPRF and the vestibular nuclei. Each riMLF projects mainly ipsilaterally to the oculomotor and trochlear nuclei, but also connected to the opposite riMLF via fibers that traverse the posterior commissure. Bilateral lesions of the riMLF or their interconnections in the posterior commissure are more common than unilateral ones, and cause a loss either of downward saccades or of all vertical saccades.

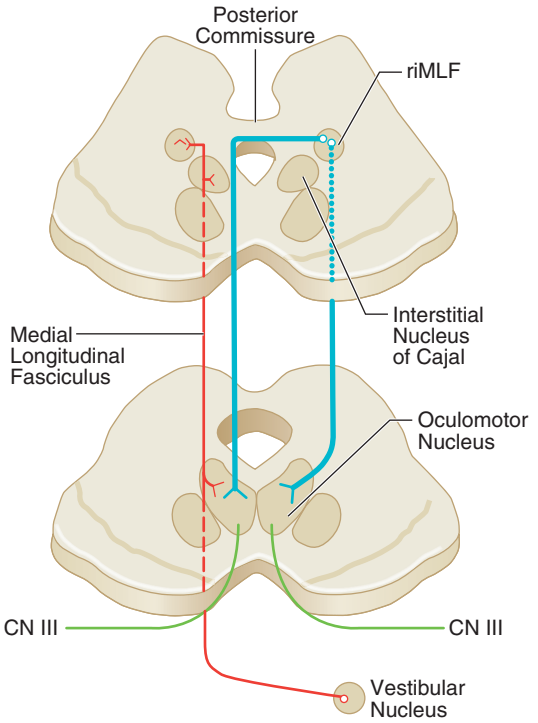

Figure 13-2. Pathways for the control of vertical eye movements. The main structures are the interstitial nucleus of Cajal (INC), the rostral interstitial nucleus of the medial longitudinal fasciculus (riMLF), and the subnuclei of the third nerve, all located in the dorsal midbrain. Voluntary vertical movements are initiated by the simultaneous activity of both frontal cortical eye fields. The riMLF serves as the generator of vertical saccades and the INC acts tonically to hold eccentric vertical gaze. The INC and riMLF connect with their contralateral nuclei via the posterior commissure, where fibers are subject to damage. Projections for upgaze cross through the commissure before descending to innervate the third nerve nucleus (blue line on left), while those for downgaze may travel directly to the third nerve (blue line on right), thus accounting for the higher frequency of selective upgaze palsies (see text). The MLF (red line) carries signals from the vestibular nuclei, mainly ipsilaterally, to stabilize the eyes in the vertical plane (VOR) and maintain tonic vertical position.

The *INC* is a small collection of cells that lies just caudal to the riMLF on each side. Each nucleus projects to the motor neurons of the opposite elevator muscles (superior rectus and inferior oblique) by fibers that cross through the posterior commissure, and it projects ipsilaterally and directly to the depressor muscles (inferior rectus and superior oblique). The cells of the INC allow maintenance of eccentric vertical gaze, especially after a saccade, and are integral to the vestibuloocular reflex. Lesions of the INC produce a vertical gaze-evoked and torsional nystagmus, an ocular tilt reaction, and slowed conjugate (mainly vertical) eye movements.

Lesions of the *posterior commissure* interrupt signals crossing to and from the INC and the riMLF. A lesion here characteristically produces a paralysis of upward gaze and of convergence, often associated with mild mydriasis, accommodative loss, convergence nystagmus, and lid retraction (Collier sign). This constellation is the *Parinaud syndrome*, also referred to as the pretectal, dorsal midbrain, or sylvian aqueduct syndrome (see "Vertical Gaze Palsy" further on). In some instances, only a restricted combination of these signs is seen. With acute lesions of the commissure, there is a tonic downward deviation of the eyes and lid retraction ("setting-sun sign").

The MLF is the main conduit of signals that control vertical gaze from the vestibular nuclei in the medulla to the midbrain centers. For this reason, with INO, along with the characteristic adductor paresis on the affected side, vertical pursuit and the VOR are also often impaired. These deficits are most evident when bilateral INO is present. Vertical deviation of the ipsilateral eye (*skew*) may be seen in cases of unilateral INO, as discussed further on.

Vestibulocerebellar Influences on Eye Movements

The vestibulocerebellum makes important contributions to the execution of accurate smooth pursuit and saccadic movements (see also Chaps. 5 and 14). The flocculus and posterior vermis of the cerebellum receive abundant sensory projections from proprioceptors of the cervical musculature (responsive to head velocity), the retinas (sensitive to target velocity), proprioceptors of eye muscles (eye position and eye velocity), auditory and tactile receptors, and the superior colliculi and PPRF. Cerebellar efferents that subserve ocular movement project onto the vestibular nuclei. The latter, in turn, influence gaze mechanisms through several projection systems: Horizontal movements are modulated by direct projections from the vestibular nuclei to the contralateral sixth nerve nucleus, and vertical movements are modulated by projections

traveling via the contralateral MLF to the third and fourth nerve nuclei.

Patients with cerebellar (floccular) lesions are unable to hold eccentric positions of gaze and must make repeated saccades to look at a target that is away from the neutral position (*gaze-evoked nystagmus*). This phenomenon is explained by the fact that with acute, one-sided lesions of the vestibulocerebellum, the inhibitory discharges of the Purkinje cells onto the ipsilateral medial vestibular nucleus are removed, and the eyes deviate away from the lesion (Leigh and Zee; Lewis and Zee). When gaze to the side of the lesion is attempted, the eyes drift back to the midline, and fixation can be corrected only by a saccadic jerk. The head and neck may also turn away from the lesion (the occiput toward the lesion and the face away). In addition, the vestibuloocular reflexes, which coordinate eye movements with head movements, are improperly adjusted (Thach and Montgomery).

In addition to causing nystagmus, lesions of the flocculus and posterior vermis are associated with deficits in smooth pursuit movements and an inability to suppress the vestibuloocular reflex by fixation (Baloh et al). Floccular lesions are also an important cause of downbeat nystagmus.

Testing of Conjugate Gaze

Testing of saccades is performed by asking the patient to look quickly toward targets on each side as well as up and down. Inaccurate saccadic movements, particularly overshooting of the eyes (*hypermetria*), are characteristic of a cerebellar lesion. Slowness of saccadic movements is mainly the result of disease of the basal ganglia such as Huntington and Wilson diseases, ataxia-telangiectasia, progressive supranuclear palsy, multiple system atrophy, and certain lipid storage diseases. Lesions involving the PPRF may also be accompanied by slow saccadic movements to the affected side. Hypometric, slow saccades occurring only in the adducting eye indicate an incomplete internuclear ophthalmoparesis caused by a lesion of the ipsilateral MLF. When the earliest sign of a progressive eye movement disorder is slow saccades in the vertical plane, the likely diagnosis is progressive supranuclear palsy, but the same sign may occur in Parkinson disease and several less common processes that affect the basal ganglia, as discussed further on under "Vertical Gaze Palsy." Slow vertical saccades are also found in Niemann-Pick disease type C.

In addition to abnormalities of saccades velocity, saccadic latency or reaction time (the interval between the impulse to move and movement) is prolonged in Huntington chorea and Parkinson disease. Saccadic latency is also increased in corticobasal ganglionic degeneration (see Chap. 38), in which case it seems to correspond to the degree of motor apraxia. The obligate need to initiate eye movements with a blink can be a subtle sign of disordered supranuclear control of conjugate movements that is evident in these same diseases and in other processes including frontal lobe lesions.

Yet another saccadic disorder takes the form of an inability to initiate voluntary movements, either vertically or horizontally. This abnormality may be congenital in nature, as in the ocular "apraxia" of childhood described by Cogan (discussed further on) and in ataxia-telangiectasia. An acquired difficulty in the initiation of saccadic movements may be seen in patients with Huntington disease or with a lesion of the contralateral frontal lobe or ipsilateral pontine tegmentum.

Pursuit eye movements are assessed by having the patient visually track an object moving slowly before them, such as the examiner's thumb. Fragmentation of smooth pursuit movement is characterized by a jerky irregularity of tracking, often referred to as "saccadic pursuit." Impaired pursuit can arise from vestibulocerebellar and extrapyramidal disorders. The former is commonly the result of sedative drug intoxication—with barbiturates, diazepam, and others as well as from a lesion of the vestibulocerebellar apparatus. In addition, asymmetrical impairment of smooth pursuit movements is indicative of a parietal or a frontal lobe lesion. Pursuit is impaired toward the side of a parietal lesion and away from a frontal lesion. This clinical phenomenon can be elicited by optokinetic testing as explained further on.

Vestibuloocular Reflex (VOR) Testing

The VOR is tested by moving the patient's head either horizontally or vertically while the individual maintains visual fixation on a distant stationary point. When the VOR is functioning normally, the eyes move automatically in the opposite direction to head turning (in fact they remain motionless in relation to the room and move only relative to the head). If the vestibular system is impaired, a head thrust will not elicit the normal contraversive eye movement. Instead, the eyes turn with the head, and the patient subsequently makes a "catch-up" saccade to return the eyes to the target of fixation. The saccade that refixates the eyes is observed more easily than is the slippage of the eyes from the target.

Stimulation of the labyrinths by caloric or electrical activation also elicits reflexive eye movements, as described in Chap. 16 on Coma. When cold water is instilled into one ear, it simulates the physiology of the head turning in the opposite direction. The eyes, therefore, make a reflexive slow movement toward the cold stimulus. In an awake patient, this is accompanied by fast-phase movements (nystagmus) in the opposite direction, away from the cold stimulus.

Normally, movement of the head at a rate of one to two cycles per second does not cause blurring of vision because of the rapidity with which the VOR accomplishes compensatory eye movements. *Dynamic visual acuity* is tested by having the patient read an eye chart while the head is rotated back-and-forth. A substantial drop in acuity occurring with head movements at this speed is indicative of failure of the VOR. Zee has described yet another means of testing the VOR in which the examiner observes the optic nerve head while the patient rotates the head back-and-forth. With a normal VOR, the optic disc does not appear to move since the eye's position in space has remained unchanged. However, if the VOR is impaired, the optic nerve head appears to oscillate.

Visual Fixation Reflex (Suppression of the Vestibuloocular Reflex)

The ability to *suppress the VOR*, as described earlier, is an important aspect of coordinating eye and head movements to track a moving object. This ability can be tested by rotating the patient in a chair while he fixates on the thumb of his outstretched hand. There should be no loss of fixation at moderate rotational speed. Nystagmus during this maneuver, reflecting the inability to suppress the VOR and maintain fixation, is an abnormal finding. Impaired suppression of the VOR occurs with various disorders affecting cerebellar and brainstem circuits that maintain gaze stability; progressive supranuclear palsy and multiple sclerosis are two examples where this finding can be prominent.

Testing the Near Response (Accommodative Triad)

The near response consists of three elements that occur together when an individual makes an effort to focus on a near object: convergence of the eyes, which aligns their visual axes on the target; pupillary miosis, which serves to increase the optical depth of focus of the image projected onto the retina; and accommodation, which refers to the change in the conformation of the crystalline lens following constriction of the ciliary muscle, increasing the focusing power of the eye. Convergence movements are tested by asking the patient to look at an object as it is brought toward the eyes. In instances where it is difficult to engage the patient's full effort at convergence, a stronger stimulus is visual fixation on the thumb of their own outstretched arm as it is brought toward their face. The absence or impairment of these movements may suggest a lesion in the rostral midbrain as a component of the Parinaud syndrome. However, these fusional movements are frequently impaired in the elderly and in confused or inattentive patients and should not always be interpreted as the result of disease. Some clinical scenarios show that the components of the near triad may be separable. Botulism, for example, impairs accommodation but convergence and miosis remain intact.

Impairment of Conjugate Gaze

Horizontal Gaze Palsy

Strictly speaking, gaze palsy refers to a complete loss of both saccadic and pursuit movements of both eyes to one side. Gaze paresis refers to a milder limitation, with incomplete loss of the same capacities. When gaze palsy is the result of impaired supranuclear inputs to the brainstem gaze centers, it may be overcome by reflexive mechanisms, referring mainly to the VOR. In contrast, nuclear and infranuclear lesions cause an insurmountable impairment of gaze that cannot be overcome except by direct physical movement of the globes (forced ductions).

As a rule, the horizontal gaze palsies of cerebral and pontine origin are readily distinguished by the side of an accompanying hemiparesis. When there is a tonic deviation of the eyes resulting from a cerebral lesion, the eyes look toward the lesion and away from the hemiparesis. The opposite pertains to brainstem gaze palsies, that is, gaze is impaired toward the side of the lesion, and the eyes are turned toward a hemiparesis. Gaze palsies of pontine origin need not have an accompanying hemiparesis but are usually associated with other signs of pontine disease, particularly peripheral facial palsies and INO on the same side as the paralysis of gaze. In the case of a cerebral lesion (but not a pontine lesion), the eyes may turn to the paralyzed side if they are fixated on a target and the head is rotated passively to the opposite side (i.e., by utilizing the VOR).

Horizontal gaze palsy of cerebral origin An acute lesion of one frontal lobe, such as an infarct, usually causes impersistence or paresis of contralateral gaze (more so than an actual palsy of gaze), and the eyes may for a limited time turn involuntarily toward the side of the cerebral lesion. In most cases of acute frontal lobe damage, the gaze palsy is incomplete and temporary, lasting for a week or less. Almost invariably, it is accompanied by hemiparesis. It should be emphasized that cerebral gaze paralysis is not attended by strabismus or diplopia, that is, gaze remains conjugate. The usual causes of gaze paresis are vascular occlusion with infarction, hemorrhage, and abscess or tumor of the frontal lobe.

Observation of the Bell phenomenon, with forced closure of the eyelids, may show that the eyes move predominantly toward the side of the hemiparesis (*Cogan spasticity of conjugate gaze*), although this finding is variable and of limited clinical value. Similarly, during sleep, the eyes may deviate conjugately away from the side of the lesion toward the side of the hemiplegia.

Occasionally, a deep cerebral lesion, particularly a thalamic hemorrhage extending into the midbrain, will cause the eyes to deviate conjugately to the side opposite the lesion (referred to as "wrong-way" gaze); the exact basis for this anomalous phenomenon is not established, but may relate to selective impairment of the descending oculomotor tracts described above, specifically the "capsular–peduncular" tract, which partially decussates, and the "transthalamic" tract, which is predominantly uncrossed (Tijssen).

A seizure originating in the frontal lobe may transiently drive the eyes to the opposite side, giving the impression of gaze palsy. In the postictal period, the direction of the gaze deviation may reverse with the eyes directed ipsilateral to the seizure focus. Occasionally an occipital seizure produces deviation of the eyes to the same side.

Vertical Gaze Palsy

Midbrain lesions affecting the pretectum and the region of the posterior commissure interfere with conjugate vertical eye movements (Hommel and Bogousslavsky). Paralysis of vertical gaze is a prominent feature of the *Parinaud* or *dorsal midbrain syndrome* described earlier. Upward gaze in general is affected far more frequently than downward gaze because some of the fibers subserving upgaze cross rostrally and posteriorly between the riMLF and INC and are thus subject to interruption before they descend to the oculomotor nuclei. In contrast, the pathways for downgaze apparently project directly downward to oculomotor nuclei from the riMLF and INC, without decussating in the dorsal midbrain, and thus may be spared with lesions in this location.

The range of upward gaze becomes reduced with normal aging, as well as in states of drowsiness and with increased intracranial pressure (Chamberlain). In a patient

Table 13-1

DISEASES EXHIBITING UPGAZE OR VERTICAL GAZE PALSY

Midbrain infarction and hemorrhage
Tumor in the region of the dorsal midbrain (e.g., pinealoma)
Advanced hydrocephalus with enlargement of third ventricle
Progressive supranuclear palsy
Parkinson disease
Lewy body disease
Cortical basal ganglionic degeneration
Whipple disease
Metabolic diseases of childhood (Niemann-Pick type C, Gaucher, Tay-Sachs)
Any cause of bilateral internuclear ophthalmoplegia (e.g., multiple sclerosis)

who cannot elevate the eyes voluntarily, the presence of reflex upward deviation of the eyes in response to flexion of the head ("doll's-head maneuver") or to voluntary forceful closure of the eyelids (*Bell phenomenon*) indicates that the nuclear and infranuclear mechanisms for upward gaze are intact and that the defect is supranuclear. However useful this rule may be, in some instances of disease of the peripheral neuromuscular apparatus—such as Guillain-Barré syndrome and myasthenia gravis—voluntary attempts at upgaze are unsuccessful, but the strong stimulus of eye closure may cause upward deviation, thereby spuriously suggesting a lesion of the upper brainstem. In addition, approximately 15 percent of normal adults do not show a Bell phenomenon.

Several degenerative processes exhibit selective or prominent upgaze or vertical gaze palsies, as mentioned earlier (Table 13-1). In progressive supranuclear palsy, a highly characteristic feature is a selective paralysis of vertical gaze, with the more specific feature being downward paralysis of saccades and later, restriction of all vertical movements. Parkinson and Lewy-body diseases (see Chap. 38), corticobasal ganglionic degeneration (see Chap. 38), Niemann Pick Type C, and Whipple disease of the brain (see Chap. 31) may also produce vertical gaze palsies as these diseases progress.

Other Supranuclear Disorders of Gaze

Another unusual disturbance of gaze is the *oculogyric crisis*, or *spasm*, which consists of a tonic spasm of conjugate deviation of the eyes, usually upward and less frequently, laterally or downward. Recurrent attacks, sometimes associated with spasms of the neck, mouth, and tongue muscles and lasting from a few seconds to an hour or two, were highly characteristic of postencephalitic parkinsonism in the past. Now this phenomenon is observed as an acute reaction in patients being given metoclopramide, phenothiazine, and related neuroleptic drugs. The drug-induced form may be terminated by the administration of medications with anticholinergic properties such as benztropine and diphenhydramine.

Congenital oculomotor apraxia (described by Cogan) is characterized by an inability to make normal voluntary horizontal saccades when the head is stationary. Unusual eye and head movements are obligately tied together during attempts to change the position of the eyes. To look at an object to either side, the patient may thrust the head to overshoot the target; the eyes turn in the opposite direction, and as they return to the central position, they fixate on the target. Both voluntary saccades and the quick phase of vestibular nystagmus are defective. This same phenomenon is also seen in ataxia-telangiectasia (see Louis-Bar disease, Chap. 37) and with agenesis of the corpus callosum.

Convergence insufficiency may give rise to diplopia and blurred vision with tasks requiring near vision, such as reading. The examination shows full ocular movements but impaired ability of the eyes to achieve or sustain normal convergence, and a large measurable exodeviation of the eyes when fixating on a near target. It is often idiopathic, but frequently arises in the setting of movement disorders such as Parkinson disease, and is sometimes associated with head trauma or other conditions such as multiple sclerosis.

The entity of *divergence insufficiency* causes horizontal diplopia at a distance with a measurable esodeviation of the eyes. This disorder may relate to mechanical changes in the position of the globe within the orbit, rather than impairment of a particular "divergence center" in the brain, since anatomic and clinical evidence do not support the existence of such a neuronal population with this specific function. Many cases of horizontal diplopia at distance, occurring in older individuals with some degree of atrophy of orbital fat and esodeviation of the eyes at distance despite full ocular ductions, can be attributed to an entity referred to as *sagging eye syndrome*, in which mechanical displacements of the ocular muscles occur due to physical changes of the orbital contents (Goseki and colleagues). A particular type of divergence paralysis can occur with infarcts or hemorrhage in the thalamus or rostral midbrain, characterized by incomplete bilateral ocular abduction ostensibly owing to heightened convergence tone (*pseudosixth palsy* or *convergence spasm*).

NUCLEAR AND INFRANUCLEAR DISORDERS OF EYE MOVEMENT

Anatomic Considerations

The nuclei of the *third* (*oculomotor) nerve* consist of several paired groups of motor nerve cells adjacent to the midline, ventral to the aqueduct of Sylvius at the level of the superior colliculi. A centrally located group of cells that innervate the pupillary sphincters and ciliary bodies (muscles of accommodation) is situated dorsally in the Edinger Westphal nucleus; this is the parasympathetic portion of the oculomotor nucleus that subserves pupillary reactions to light and the near vision response. Ventral to this nuclear group are cells that mediate the actions of the levator of the eyelid, superior and inferior recti, inferior oblique, and medial rectus, in this dorsal–ventral order. This functional arrangement has been determined in cats and monkeys by extirpating individual extrinsic ocular muscles and observing the retrograde cellular changes (Warwick). Subsequent studies using radioactive tracer techniques have shown that medial rectus neurons occupy three disparate locations within the oculomotor nucleus rather than being confined to its ventral tip (Büttner-Ennever and Akert). These experiments also indicated that the medial rectus, inferior rectus, and the inferior oblique are innervated

strictly ipsilaterally from the oculomotor nuclei, whereas the superior rectus receives only crossed fibers, and the levator palpebrae superioris (lid elevators) has bilateral innervations. Vergence movements are under the control of medial rectus neurons and not, as was once supposed, by an unpaired medial group of cells (nucleus of Perlia).

The fibers of the third-nerve nucleus course ventrally in the midbrain, crossing the medial longitudinal fasciculus, red nucleus, substantia nigra, and medial part of the cerebral peduncle successively. Lesions involving these structures therefore interrupt oculomotor fibers in their intramedullary (fascicular) course and give rise to several crossed syndromes with ipsilateral ocular palsy. With regard to the oculomotor subnuclei, schematic arrangements of their projections have been derived from various sources, mainly experimental but some clinical (Ksiazek and colleagues, Fig. 13-3). The emerging fibers can be considered as situated in medial, lateral, and rostrocaudal groups, with the pupillary fibers occupying the rostromedial aspect. This location of axons destined for the pupil continues through the third nerve. This information becomes useful in recognizing that combined pupillary and inferior and medial rectus palsies on one side may be the result of a fascicular lesion of the oculomotor nerve.

The oculomotor nerve, soon after it emerges from the brainstem, passes between the superior cerebellar and posterior cerebral arteries. The nerve (and sometimes the posterior cerebral artery) may be compressed at this point by herniation of the uncal gyrus of the temporal lobe through the tentorial opening (see Chap. 16). Just posterior and superior to the cavernous sinus, the oculomotor nerve crosses the terminal portion of the internal carotid artery at its junction with the posterior communicating artery. An aneurysm at this site frequently damages the third nerve; this serves to localize the site of compression or bleeding. When infraclinoid retrocavernous compressive lesions affect the oculomotor nerve, they tend to also involve all three divisions of the trigeminal nerve. In the posterior portion of the cavernous sinus, the first and second trigeminal divisions are involved along with the ocular motor nerves; in the anterior portion, only the ophthalmic division of the trigeminal nerve tends to be affected.

As the oculomotor nerve enters the orbit, it divides into superior and inferior branches, although a functional separation of nerve bundles occurs well before this anatomic bifurcation. The superior branch supplies the superior rectus and the voluntary (striated) part of the levator palpebrae (the involuntary part is known as Müller's muscle, which is smooth muscle and has sympathetic innervation); the inferior branch supplies the pupillary and ciliary muscles and all the other extrinsic ocular muscles except, of course, the superior oblique and the lateral rectus, which are innervated by the trochlear and abducens nerves, respectively. *Superior branch lesions* of the oculomotor nerve caused by an aneurysm or diabetes result in ptosis and uniocular upgaze paresis.

The *sixth* (*abducens*) *nerve* arises at the level of the lower pons from a paired group of cells in the floor of the fourth ventricle, adjacent to the midline. The intrapontine portion of the facial nerve loops around the sixth nerve nucleus before it turns anterolaterally to make its exit; a lesion in this location therefore causes an ipsilateral paralysis of the lateral rectus and facial muscles. It is important to note that the efferent fibers of the oculomotor and abducens nuclei have a considerable intramedullary, that is, fascicular, portion (Fig. 13-4*A* and *B*). Abducens palsy due to a lesion affecting its fascicle in the pons is accompanied by other clinical deficits that indicate the

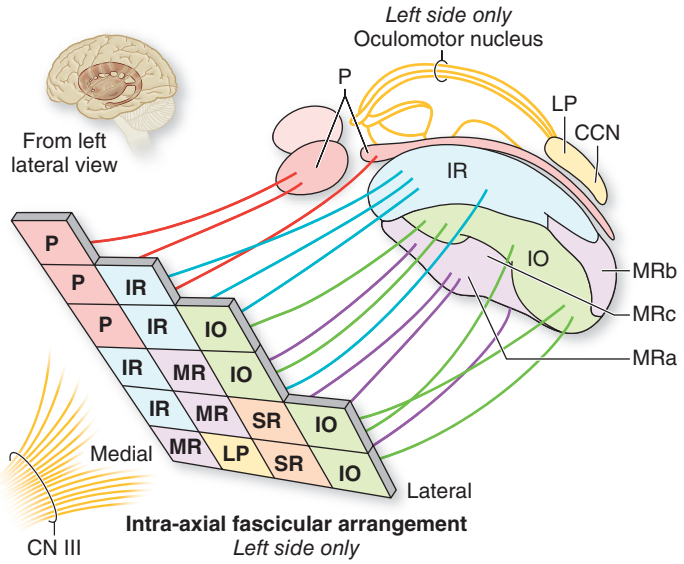

Figure 13-3. Topographic arrangement of oculomotor fascicular fibers in the mesencephalon. Figure 13-4. *A*. Midbrain in horizontal section, indicating the effects of lesions at different points along the intramedullary course of the third-nerve fibers. A lesion at the level of oculomotor nucleus results in homolateral third-nerve paralysis and homolateral anesthesia of the cornea. A lesion at the level of red nucleus results in homolateral third-nerve paralysis and contralateral ataxic tremor (Benedikt and Claude syndromes). A lesion near the point of exit of third-nerve fibers results in homolateral third-nerve paralysis and crossed corticospinal tract signs (Weber syndrome; see Table 44-2). *B*. Brainstem at the level of the sixth-nerve nuclei, indicating effects of lesions at different loci. A lesion at the level of the nucleus results in homolateral sixth and seventh-nerve paralyses with varying degrees of nystagmus and weakness of conjugate gaze to the homolateral side. A lesion at the level of corticospinal tract results in homolateral sixth-nerve paralysis and crossed hemiplegia (Millard-Gubler syndrome).

pontine localization, such as contralateral weakness. After leaving the brainstem, the nerve sweeps upward along the clivus and then pierces the dura just lateral to the posterior clinoid process and runs in the lateral wall of the cavernous sinus, which courses adjacent to the internal carotid artery and first and second divisions of the fifth nerve (Fig. 13-5 and see "Cavernous Sinus Thrombosis" in Chap. 33).

The cells of origin of the *fourth* (*trochlear) nerve* are just caudal to those of the oculomotor nerves in the lower midbrain. Unlike all other cranial nerves, the fourth nerve emerges from the dorsal surface of the lower midbrain and then decussates a short distance from its origin, just caudal to the inferior colliculi. The nerves proceed circumferentially and ventrally around the midbrain and then course in the perimesencephalic cistern toward the posterior cavernous sinus. Each nucleus therefore innervates the *contralateral* superior oblique muscle. The long extraaxial course and the position of the nerves adjacent to the brainstem is a putative explanation for the common complication of fourth-nerve palsy in head injury (see Chap. 34). The superior oblique muscle forms a tendon that passes through a pulley structure (the trochlea) and attaches to the upper aspect of the globe behind the axis of rotation. When the eye is adducted, the muscle mainly causes depression with some intorsion of the eye; in abduction, it primarily causes intorsion.

Diplopia and Strabismus

Under normal conditions, all the extraocular muscles participate in every movement of the eyes; for proper movement, the contraction of any muscle requires relaxation of its antagonist. Clinically, however, an eye movement can be thought of in terms of the one muscle that is predominantly responsible for an agonist movement in that direction, for example, outward movement of the eye requires the action of the lateral rectus; inward movement, action of the medial rectus. The action of the superior and inferior recti and the oblique muscles varies according to the position of the eye. When the eye is turned outward, the main elevator is the superior rectus and the main depressor is the inferior rectus. When the eye is turned inward, the main elevator and depressor are the inferior and superior oblique muscles, respectively. The actions of the

ocular muscles in different positions of gaze are illustrated in Fig. 13-6 and Table 13-2.

The term *binocular diplopia* refers to the symptom of double vision caused by a misalignment of the visual axes of the two eyes. It is only present when both eyes are open and can see. Put another way, covering one eye obliterates double vision that stems from misalignment of the eyes. In contrast, *monocular diplopia* persists when one eye is closed and is often due to lenticular or retinal disease or is nonorganic.

Strabismus, strictly speaking, refers to a muscle imbalance that results in misalignment of the visual axes, but the term is used most often to describe a congenital variety of misalignment. Strabismus may be caused by weakness of an individual eye muscle (*paralytic strabismus*) or by an imbalance of muscular tone, presumably because of a faulty "central" mechanism that normally maintains a proper angle between the two visual axes (*nonparalytic strabismus*). Almost everyone has a slight tendency toward strabismus that is referred to as a *phoria* and is normally overcome by the fusion mechanisms. A misalignment that is manifest during binocular viewing of a target and cannot be overcome is called a *tropia*. The prefixes *eso-* and *exo-* indicate that the phoria or tropia is directed inward or outward, respectively, and the prefixes *hyper-* and *hypo-*, that the deviation is upward or downward. Paralytic strabismus is primarily a neurologic problem and the cause may be localized based on the pattern of ocular misalignment; nonparalytic strabismus most often does not have a discrete neurologic cause and does not have localizing value. Tropias and phorias can readily be detected by means of the simple "cover" and "cover–uncover" tests. When fusion is disrupted by covering one eye, the occluded eye will deviate; uncovering that eye results in a quick corrective movement designed to reestablish the fusion mechanism. Nonparalytic strabismus is characterized by a misalignment that is *comitant*, meaning it is of the same amplitude in all directions of gaze. In contrast, paralytic strabismus creates an *incomitant* misalignment, which is of greatest magnitude with gaze in the direction of action of the weak muscle(s) and less magnitude with gaze in the opposite direction.

Nonparalytic Strabismus

Although the term *strabismus* strictly refers to any ocular misalignment, it tends to be used more often to refer to the nonparalytic type. It is normal for neonates to have a slight exotropia that corrects by about 3 months of age. Large malalignments (> 15 degrees) are considered abnormal, even at birth. Most children with developmental esotropic strabismus present between ages 2 and 3 years, whereas those with exotropia show the condition in a broader range of preschool years. Esodeviations are initially intermittent and then become persistent; exodeviations are commonly intermittent. In both cases, eye movements are full and the child initially alternates fixation.

One type of esotropia, called *accommodative esotropia*, is an acquired problem in children that relates to hypermetropia (farsightedness) with compensatory engagement of the near response that drives the eyes to cross. Refractive correction for the hypermetropia within 6 months of the onset of the strabismus restores vision and usually leads to realignment of the eyes. Large degrees of esotropia that are not the result of hypermetropia are best treated by eye muscle surgery to realign the eyes.

In contrast, persistent *exotropic* strabismus in a child can be associated with a developmental delay (as detailed in Chap. 37) or with ocular pathology. It does, however, frequently occur in neurologically normal children. If mild, intermittent exotropia is initially treated by one of a number of nonsurgical means such as patching and visual exercises to stimulate convergence; surgical correction is reserved for unresponsive cases (Donahue).

Table 13-2

ACTIONS OF THE EXTRAOCULAR MUSCLES

MUSCLE	PRIMARY ACTION	SECONDARY ACTION	OCULOMOTOR NERVE
Medial rectus	Adduction	—	III
Lateral rectus	Abduction	—	VI
Superior rectus	Elevation	Intorsion	III
Inferior rectus	Depression	Extorsion	III
Superior oblique	Intorsion	Depression	IV
Inferior oblique	Extorsion	Elevation	III

(See also Fig. 13-5.)

Once binocular fusion is established, usually by 6 months of age, any type of ocular muscle imbalance will cause diplopia, as images then fall on disparate or noncorresponding parts of the two functionally active retinas. During the critical period for visual development, particularly the first 2 years of life, a child can eliminate diplopia by suppressing the image from one eye. After a variable period, the suppression becomes permanent, and the individual has permanently reduced visual acuity in that eye because its representation in the visual cortex is diminished (*amblyopia ex anopsia*, as described in Chap. 12).

Nonparalytic strabismus may create misleading ocular findings in the neurologic examination. Sometimes a slight phoric misalignment of the eyes is first noticed after a head injury or a febrile infection, or it may be exposed by any other neurologic disorder or drug intoxication that impairs fusional mechanisms (vergence).

Clinical Effects of Lesions of the Third, Fourth, and Sixth Nerves

Third (Oculomotor) Nerve

A complete *third nerve palsy* may include significant ptosis, as the levator palpebrae is the major muscle that elevates the eyelid, accompanied by an inability to rotate the eye upward, downward, or inward that corresponds to the weakness of the medial, superior, and inferior recti and the inferior oblique muscles. The remaining actions of the fourth and sixth nerves give rise to a position of the eye described by the mnemonic "down and out," meaning in the infraducted and abducted position. The patient experiences diplopia in which the image from the affected eye is projected upward and medially. In addition, one finds a dilated, nonreactive pupil (iridoplegia) and paralysis of accommodation (cycloplegia) because of interruption of the parasympathetic fibers in the third nerve.

Of note, the extrinsic and intrinsic (pupillary) eye muscles may be affected separately in certain diseases. For example, a lesion affecting the central portion of the oculomotor nerve, as occurs in diabetic ophthalmoplegia, typically spares the pupil, as the parasympathetic preganglionic pupilloconstrictor fibers lie near the surface (Kerr). Very little pathological material exists to study the precise lesion that is responsible for a microvasculopathic cranial nerve palsy, but an instance in which a patient diagnosed with third nerve palsy then soon died of other causes allowed the rare opportunity to study the issue carefully. Asbury and colleagues studied over 10,000 serial sections of the third nerve in this case, and in its segment in the cavernous sinus found a region of myelin pallor which they attributed to focal ischemia in a borderzone of the vaso nervorum vascular supply (Asbury).

Conversely, compressive lesions of the nerve usually dilate the pupil as an early manifestation. After injury, regeneration of the third nerve fibers may be aberrant, in which case some of the fibers that originally moved the eye in a particular direction now reach another muscle or the iris; in the latter instance the pupil, which is unreactive to light, may constrict when the eye is turned up and in.

Fourth (Trochlear) Nerve

A lesion of the *fourth nerve*, which innervates the superior oblique muscle, is the most common cause of isolated symptomatic vertical diplopia (Keane; Palla and Straumann). Paralysis of the superior oblique muscle results in weakness of downward movement of the affected eye in the adducted position (Fig. 13-7*E*), so that the patient complains of special difficulty in reading or going downstairs. Examination of the eye movements may disclose subtle upward deviation that occurs on attempted adduction of the eye with horizontal gaze. Double vision from an isolated fourth neve palsy is made worse with ipsilateral head tilt. Compensatory head tilting to the opposite shoulder (Bielschowsky sign) is thus characteristic of fourth-nerve lesions; this maneuver causes intorsion of the unaffected eye and ameliorates the double vision. Lesions affecting the trochlear nucleus (rather than the nerve itself) will cause paresis of the contralateral superior oblique muscle; here, the patient will tilt their head toward the side of the lesion to ameliorate the diplopia. Bilateral trochlear palsies, as may occur after head trauma, give a characteristic alternating hyperdeviation depending on the direction of gaze (unilateral traumatic trochlear paresis is still the more common finding with head injury). In the presence of a third nerve palsy, one can assess the function of the fourth nerve by evaluating whether the eye intorts on attempted down gaze.

Sixth (Abducens) Nerve

Lesions of the *sixth nerve* result in a paralysis of the abducens muscle and a resultant weakness of lateral or outward movement leading to a crossing of the visual axes. The affected eye deviates medially, that is, in the direction of the opposing muscle. Diplopia is experienced as horizontal separation that is greatest when viewing in the direction of the sixth nerve palsy and in the distance (Fig 13-7*A*). With incomplete sixth nerve palsies, turning the head toward the side of the paretic muscle overcomes the diplopia.

Many causes of *combined ocular motor palsies*, which are discussed in a later section, are listed in Table 13-3 and are illustrated in Fig. 13-7 and in the following text.

The Analysis of Diplopia

The signs of the oculomotor palsies, as described previously, can manifest in various degrees of completeness. With complete palsies, the affected muscle can often be surmised from the resting dysconjugate positions of the globes. With incomplete paresis, having the patient perform common versional movements will usually disclose the faulty muscle(s) as the eyes are turned into the field of action of the paretic muscle. The muscle weakness may be so slight, however, that no strabismus or defect in ocular movement is obvious, yet the patient experiences diplopia. It is then necessary to use the patient's report of the relative positions of the images of the two eyes or use methods that assess the pattern of ocular misalignment to determine the localization of the problem. It is frequently the case that patients with significant ocular misalignment from do not report diplopia, ostensibly because the false image

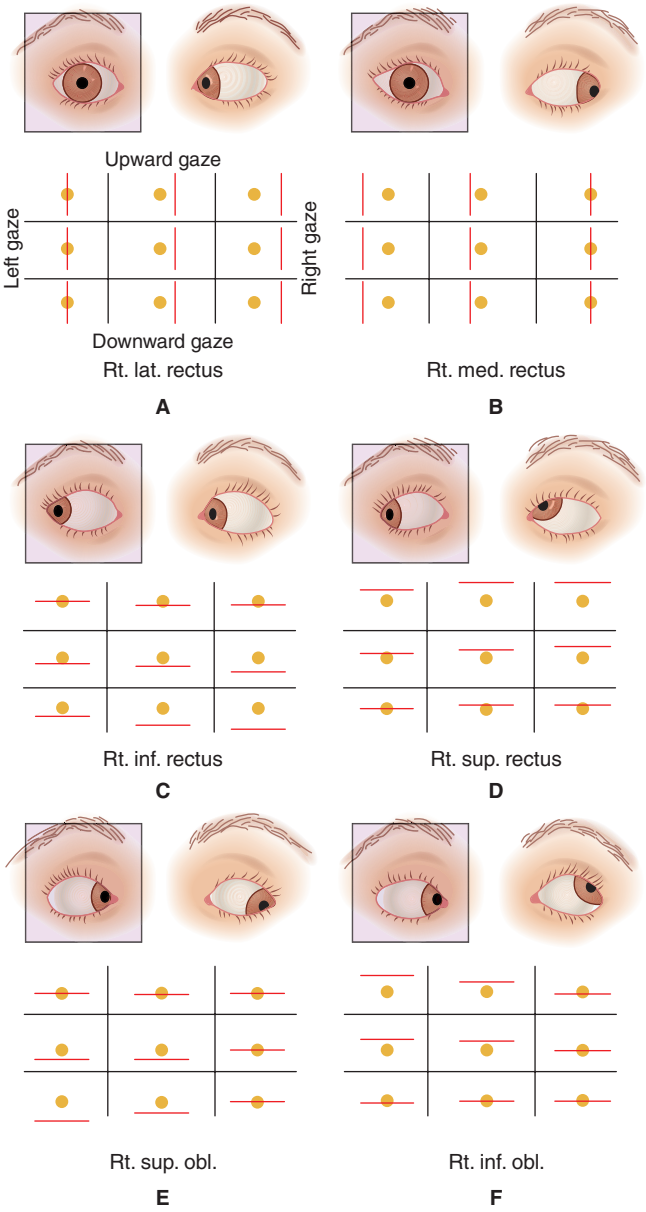

Figure 13-7. Diplopia fields with individual muscle paralysis. The red Maddox rod is in front of the right eye and gives rise to the straight line image, and the fields are projected as the patient sees the images. *A*. Paralysis of right lateral rectus. The vertical red line is displaced to the right and the separation of images increases on looking to the right. *B*. Paralysis of right medial rectus. Horizontal crossed diplopia increasing on looking to the left. *C*. Paralysis of right inferior rectus. Right eye does not move downward when eyes are turned to the right. Vertical diplopia (with the red line displaced inferiorly) increasing on looking to the right and down. *D*. Paralysis of right superior rectus. Right eye does not move upward when eyes are turned to the right. Vertical diplopia (with red line displaced superiorly) increasing on looking to the right and up. *E*. Paralysis of right superior oblique. Right eye does not move downward when eyes are turned to the left. Vertical diplopia (with red line displaced inferiorly) increasing on looking to the left and down. *F*. Paralysis of right inferior oblique. Right eye does not move upward when eyes are turned to the left. Vertical diplopia (with red line displaced superiorly) increasing on looking to the left and up.

becomes easier to perceptually ignore when the visual axes are widely separated.

Two rules are applied to identify the affected ocular muscle in the analysis of diplopia:

1. *The direction in which the images are maximally separated indicates the action of the muscles at fault.*

   For example, if the greatest horizontal separation is in looking to the right, either the right abductor (lateral rectus) or the left adductor (medial rectus) muscle is weak; conversely, if maximal when gazing to the left, the left lateral rectus or the right medial rectus are implicated (see Fig. 13-6*A* and *B*). As a corollary, if the separation is mainly horizontal, the paresis will be found in one of the horizontally acting recti (a small vertical disparity should be disregarded); if the separation is mainly vertical, the paresis will be found in the vertically acting muscles, and a small horizontal deviation should be disregarded.

2. *The image projected farther from the center is attributable to the eye with the paretic muscle.*

   The following maneuver for the analysis of diplopia allows this determination to be made simply. The patient is asked to follow an object or light into the six cardinal positions of gaze. When the position of maximal separation of images is identified, one eye is covered and the patient is asked to identify which image disappears. The *red-glass* test is an enhancement of this technique. A red glass is placed in front of the patient's right eye (the choice of the right eye is arbitrary, but if the test is always done in the same way, interpretation is simplified). The patient is then asked to look at a flashlight (held at a distance of 1 m), to turn the eyes sequentially to the six cardinal points in the visual fields, and to indicate the positions of the red and white images and the relative distances between them. The positions of the two images are plotted as the patient indicates them to the examiner (i.e., from the patient's perspective; Fig. 13-7). This allows the identification of both the field of maximal separation and the eye responsible for the eccentric image. If the white image on right lateral gaze is to the right of the red (i.e., the image from the left eye is projected outward), then the left medial rectus muscle is weak.

   If the maximum vertical separation of images occurs on looking downward and to the *left* and the white image is projected farther down than the red, the paretic muscle is the left inferior rectus; if the red image (from the right eye) is lower than the white, the paretic muscle is the right superior oblique. As already mentioned, correction of vertical diplopia by a tilting of the head implicates the superior oblique muscle of the opposite side (or the ipsilateral trochlear nucleus). Separation of images on looking up and to the right or left will similarly distinguish paresis of the inferior oblique and superior rectus muscles. Most patients are attentive enough to open and close each eye and determine the source of the image thrown most outward in the field of maximal separation.

   There are several alternative methods for studying the relative positions of the images of the two eyes (Leigh and Zee; Glaser). One, refinement of the red-glass test, is the *Maddox rod*, in which the occluder consists of

Table 13-3

MAIN CAUSES OF INDIVIDUAL AND COMBINED OCULOMOTOR PALSIES

Lesions of the Third (Oculomotor) Nerve

Nuclear and intramedullary (fascicular)
- Infarction (midbrain stroke)
- Demyelination
- Tumor
- Trauma
- Wernicke disease

Radicular (subarachnoid space and tentorial edge)
- Aneurysm (posterior communicating or basilar)
- Meningitis (infectious, neoplastic, granulomatous)
- Diabetic infarction
- Tumor
- Raised intracranial pressure (shift and herniation of medial temporal lobe, hydrocephalus, pseudotumor cerebri)

Cavernous sinus and superior orbital fissure
- Diabetic infarction of nerve
- Aneurysm of internal carotid artery
- Carotid-cavernous fistula
- Cavernous thrombosis (septic and bland)
- Tumor (pituitary, meningioma, nasopharyngeal carcinoma, metastasis)
- Pituitary apoplexy
- Sphenoid sinusitis and mucocele
- Herpes zoster
- Tolosa-Hunt syndrome

Orbit
- Trauma
- Fungal infection (mucormycosis, etc.)
- Tumor and granuloma
- Orbital pseudotumor

Uncertain localization
- Migraine
- Postinfectious cranial mono- and polyneuropathy

Lesions of the Fourth (Trochlear) Nerve

Nuclear and intramedullary (fascicular)
- Midbrain hemorrhage and infarction
- Tumor
- Arteriovenous malformation
- Demyelination

Radicular (subarachnoid space)
- Traumatic
- Tumor (pineal, meningioma, metastasis, etc.)
- Hydrocephalus
- Pseudotumor cerebri and other causes of increased intracranial pressure
- Meningitis (infectious, neoplastic, granulomatous)

Cavernous sinus and superior orbital fissure
- Tumor
- Tolosa-Hunt syndrome
- Internal carotid aneurysm
- Herpes zoster
- Diabetic infarction

Orbit
- Trauma
- Tumor and granuloma

Lesions of the Sixth (Abducens) Nerve

Nuclear (characterized by gaze palsy) and intramedullary (fascicular)
- Möbius syndrome
- Wernicke syndrome
- Infarction (pontine stroke)
- Demyelination
- Tumor
- Lupus

Radicular (subarachnoid)
- Aneurysm
- Trauma
- Meningitis
- Tumor (clivus, fifth- and eighth-nerve schwannoma, meningioma)

Petrous
- Infection of mastoid and petrous bone
- Thrombosis of inferior petrosal vein
- Trauma

Cavernous sinus and superior orbital fissure
- Carotid aneurysm
- Cavernous sinus thrombosis
- Tumor (pituitary, nasopharyngeal, meningioma)
- Tolosa-Hunt syndrome
- Diabetic or arteritic infarction
- Herpes zoster

Orbit
- Tumor and granulomas

Uncertain localization
- Migraine
- Viral and postviral
- Transient in newborns

a transparent red lens with series of parallel cylindrical bars that transform a point source of light into a red line perpendicular to the cylinder axes. The position of the red line is easily compared by the patient with the position of a white point source of light seen with the other eye. Another technique, the *alternate cover test*, requires less cooperation than the red-glass test and is, therefore, a passive maneuver that is more useful in the examination of children and inattentive patients. It does, however, require sufficient visual function to permit central fixation with each eye. The test consists of rapidly alternating an occluder or the examiner's hand from one eye to another and observing the deviations from and return to the point of fixation, as described earlier in the discussion of tropias and phorias. Measuring the prismatic correction needed to neutralize the ocular misalignment in each field of gaze with a prism bar allows the quantification of deviation and provides a method to follow diplopia over time. The more sophisticated Lancaster test uses red/green glasses and a red and green bar of laser light projected on a screen to accomplish essentially the same result but has the advantage of reflecting the actual position and torsion of each eye. In all these tests, the examiner is aided by knowledge of the cardinal actions of the ocular muscles shown in Fig. 13-6 and Table 13-2.

Monocular diplopia occurs most commonly in relation to diseases of the cornea and lens and occasionally the retina; usually the images are overlapping or superimposed rather than discrete. In some cases, no abnormality can be found and the symptom has a nonorganic basis. Monocular diplopia has been reported in association with cerebral disease (Safran et al), but this is a rare occurrence. Occasionally, patients with homonymous scotomas caused by a lesion of the occipital lobe will see multiple images (polyopia) in the defective field of vision, particularly when the target is moving.

Causes of Individual Third, Fourth, and Sixth Nerve Palsies (Table 13-3)

Ocular palsies may have a central cause—that is, a lesion of the nucleus or the intramedullary (fascicular) portion of the cranial nerve—but more often they are peripheral. Weakness of ocular muscles because of a lesion in the brainstem is usually accompanied by involvement of other cranial nerves and by signs referable to the "crossed" brainstem syndromes of a cranial nerve palsy on one side and weakness or other deficits on the opposite side (see Table 33-3 and Chap. 44). Peripheral lesions, which may or may not be solitary, have a great variety of causes.

In the series reported by Rucker (1958, 1966), who analyzed 2,000 cases of oculomotor nerve palsies, the most common sources of individual ocular motor palsies were tumors at the base of the brain or skull (primary, metastatic, meningeal carcinomatosis), head trauma, ischemic infarction of a nerve (generally associated with diabetes), and aneurysms of the circle of Willis, in that order. The sixth nerve was affected in about half of the cases; third-nerve palsies were about half as common; and the fourth nerve was involved in less than 10 percent of cases. In 1,000 unselected cases (Rush and Younge), trauma was a more frequent cause than neoplasm and the frequency of aneurysm-related cases was fewer. Less-common causes of paralysis of the oculomotor nerves include variants of Guillain Barré syndrome, herpes zoster, giant cell arteritis, carcinomatous or lymphomatous meningitis, sarcoidosis and Tolosa-Hunt syndrome, as well as fungal, tuberculous, syphilitic, and other forms of meningitis.

Ophthalmoplegic migraine is a relatively rare entity characterized by recurrent episodes of headache with cranial nerve palsy that resolves in the span of weeks to months. Diagnostic evaluations in these patients are generally unremarkable, but detailed imaging may disclose in some patients a small expansion or enhancement of the cranial nerve. The exact pathophysiologic mechanisms of this condition remain obscure. This entity is diagnosed in children after several similar episodes occur. Some of those individuals may continue to have episodes in adulthood, but the entity of ophthalmoplegic migraine should generally not be diagnosed for presentations beginning in adulthood, where other diagnoses must be strongly considered.

Myasthenia gravis, discussed in Chap. 46, must always be considered in cases of ocular muscle palsy, particularly if several muscles are involved and if fluctuating ptosis is a prominent feature. Thyroid ophthalmopathy, discussed further on, presents in a similar fashion but usually with proptosis and eyelid retraction.

Third Nerve Palsy

The third nerve is commonly compressed by aneurysm, tumor, or temporal lobe herniation. In a series of 206 cases of third-nerve palsy (Wray and Taylor), neoplastic diseases accounted for 25 percent and aneurysms for 18 percent. Of the neoplasms, 25 percent were parasellar meningiomas and 4 percent were pituitary adenomas. The palsy is usually chronic, progressive, and painless. As emphasized earlier, enlargement of the pupil is a sign of extramedullary third nerve compression because of the peripheral location in the nerve of the pupilloconstrictor fibers. By contrast, infarction of the nerve in diabetics usually spares the pupil, as the damage is situated in the central portion of the nerve. The oculomotor palsy that complicates diabetes (the cause in 11 percent in the Wray and Taylor series) develops over a few hours and is accompanied by pain, which may be severe, in the forehead and around the eye. The prognosis for recovery (as in other nonprogressive lesions of the oculomotor nerves) is usually good.

In chronic compressive lesions of the third nerve (distal carotid, basilar, or, most commonly, posterior communicating artery aneurysm; pituitary tumor, meningioma, cholesteatoma) the pupil is almost always affected by way of dilatation or reduced light response. However, the chronicity of the lesion may permit aberrant nerve regeneration. This is manifest by pupillary constriction on adduction of the eye or by retraction of the upper lid on downward gaze or adduction.

Rarely, children or young adults have recurrent attacks of ocular palsy in conjunction with an otherwise typical migraine (ophthalmoplegic migraine). The muscles (both extrinsic and intrinsic) innervated by the oculomotor, or less commonly, by the abducens nerve, are affected. Possibly, spasm of the vessels supplying these nerves or compression by edematous arteries causes a transitory ischemic paralysis but these are speculations. Arteriograms done after the onset of the palsy usually disclose no abnormality. Although the oculomotor palsy of migraine tends to recover, after repeated attacks there may be permanent partial paresis.

Fourth Nerve Palsy

A fair number of cases of fourth nerve palsies remain idiopathic even after careful investigation. The fourth nerve is particularly vulnerable to head trauma. The reason for this vulnerability has been speculated to be the long, crossed course of the nerves. The fourth and sixth nerves are practically never involved by aneurysm. Herpes zoster ophthalmicus may affect any of the ocular motor nerves but particularly the trochlear, which shares a common sheath with the ophthalmic division of the trigeminal nerve. Diabetic infarction of the fourth nerve occurs, but far less frequently than infarction of the third or sixth nerves. Trochlear-nerve palsy may also be a false localizing sign in cases of increased intracranial pressure, but again, not nearly as often as abducens palsy. Trochlear-nerve palsies have been described in patients with lupus erythematosus and with Sjögren syndrome, but their basic pathology is not known. Some cases of fourth-nerve palsy are idiopathic.

Superior oblique myokymia is an unusual but easily identifiable movement disorder, characterized by recurrent episodes of vertical diplopia, monocular blurring of vision with oscillopsia, and a tremulous sensation in the affected eye; in this way it simulates a palsy. If the episodes occur during the examination, the globe is observed to make small arrhythmic torsional movements. Compression of the fourth nerve by a small

looped branch of the basilar artery has been suggested as the cause, analogous to several other better documented vascular compression syndromes affecting cranial nerves. This notion is supported by findings on MRI (Yousry). Rare instances presage pontine glioma or demyelinating disease. The condition can be responsive to topical beta-blockers commonly used to treat glaucoma, or oral anticonvulsant medications such as carbamazepine or gabapentin.

Sixth Nerve Palsy

Microvascular disease is a common cause of sixth nerve palsy in diabetics, in which case there is usually pain near the lateral canthus of the eye at the onset. An idiopathic form that occurs in the absence of diabetes is also well known. Isolated unilateral or bilateral sixth nerve palsy with global headache can be the initial manifestation of raised intracranial pressure from any source—including brain tumor, meningitis, and pseudotumor cerebri; rarely, it may appear after lumbar puncture, epidural injections, or insertion of a ventricular shunt.

As the abducens nerve passes near the apex of the petrous bone it is in close relation to the trigeminal nerve. Both may be implicated by inflammatory or infectious lesions of the petrous (apex petrositis), manifest by facial pain and diplopia (*Gradenigo syndrome)*. Among the causes of this syndrome is osteomyelitis of the petrous bone. Fractures at the base of the skull and petroclival tumors may have a similar effect, and sometimes head injury alone is the only assignable cause. Occasionally, the sixth nerve is compressed by a congenitally persistent trigeminal artery. A congenital form of bilateral abducens palsy is associated with bilateral facial paralysis (Möbius syndrome) as discussed in Chap. 37. Patients with the Duane retraction syndrome type 1 (abnormal formation of the sixth nerve) have limited abduction, and on adduction show characteristic retraction of the globe because of co-contraction of the medial rectus and lateral rectus muscles.

Cavernous Sinus Syndrome, Tolosa-Hunt syndrome, and Orbital Pseudotumor

Some of the diseases discussed previously are associated with a degree of pain, often over the site of an affected nerve or muscle or in the immediately surrounding area. But the development over days or longer of a *painful unilateral ophthalmoplegia* should raise suspicion for other conditions such as aneurysm, tumor, or inflammatory and granulomatous process in the anterior portion of the cavernous sinus or the adjacent superior orbital fissure (Table 13-4). In the *cavernous sinus syndrome*, involvement of the ocular motor nerves on one or both sides is accompanied by periorbital pain and chemosis (see Fig. 13-5*B*). In a series of 151 such cases, the third nerve (typically with pupillary abnormalities) and sixth nerve were affected in almost all and the fourth nerve in one-third; complete ophthalmoplegia, usually unilateral, was present in 28 percent (Keane). Sensory loss in the distribution of the ophthalmic division of the trigeminal nerve was often present, a finding that is helpful in the differentiation of cavernous sinus disease from other causes of orbital edema and ocular muscle weakness.

Table 13-4

CAUSES OF PAINFUL OPHTHALMOPLEGIA

Vascular
- Intracavernous carotid artery aneurysm
- Posterior communicating or posterior cerebral artery aneurysm
- Cavernous sinus thrombosis (septic and aseptic)
- Carotid-cavernous fistula
- Diabetic oculomotor mononeuropathy
- Temporal arteritis
- Ophthalmoplegic migraine

Neoplastic
- Pituitary adenoma
- Pituitary apoplexy
- Pericavernous meningioma
- Metastatic nodules to dura of cavernous sinus
- Giant-cell tumor of orbital bone
- Nasopharyngeal tumor invading cavernous sinus or orbit

Inflammatory and infectious
- Tolosa-Hunt syndrome
- Orbital pseudotumor
- Sinusitis
- Mucocele
- Herpes zoster
- Mucormycosis
- Sarcoidosis

Trauma and neoplastic invasion are the most frequent causes of the cavernous sinus syndrome. Thrombophlebitis, intracavernous carotid aneurysm or fistula, fungal infection, meningioma, and pituitary tumor or hemorrhage account for a smaller proportion (see "Septic Cavernous Sinus Thrombophlebitis" and "Cavernous Sinus Thrombosis" in Chap. 33). A dural arteriovenous fistula is another rare cause.

The idiopathic granulomatous painful condition of the cavernous sinus has been termed *Tolosa-Hunt syndrome*; a similar process affecting structures of the orbit is known as *orbital pseudotumor*. Orbital pseudotumor causes an inflammatory enlargement of the extraocular muscles, which often also encompasses the globe and other orbital contents (Fig. 13-8). It is often accompanied by injection of the conjunctiva and lid and slight proptosis. One or more muscles may be involved and there is a tendency to relapse and later to involve the opposite globe. Visual loss from compression of the optic nerve is a rare complication. Associations with connective tissue disease have been reported and IgG4-related sclerosis has increasingly been identified as a cause. Ultrasonography examination or CT scans of the orbit show enlargement of the orbital muscles including the tendons, as opposed to thyroid ophthalmopathy in which the muscles are enlarged but the muscle tendons are typically spared.

The inflammatory changes of Tolosa-Hunt syndrome are limited to the superior orbital fissure and can sometimes be detected by MRI; coronal views taken after gadolinium infusion show the lesion to best advantage. However, sarcoidosis, lymphomatous infiltration, and a small meningioma may produce similar radiographic findings and granulomatous (temporal) arteritis rarely causes ophthalmoplegia.

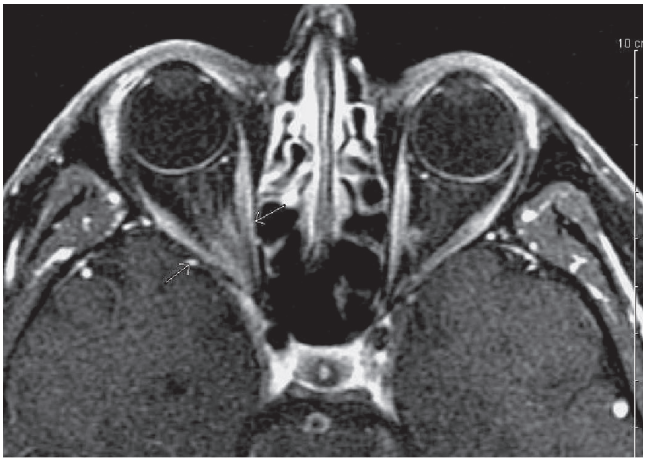

Figure 13-8. MRI of orbital pseudotumor showing bilateral swelling of the extraocular muscles and adjacent orbital contents. A "streaming" appearance of the fat as shown in the right retro-orbital compartment is characteristic. The process in this patient responded to corticosteroids.

Treatment

Both orbital pseudotumor and Tolosa-Hunt syndrome are treated with corticosteroids. A marked response with reduction in pain and improved ophthalmoplegia in 1 or 2 days is typical; however, (Kline and Hoyt) tumors of the parasellar region that cause ophthalmoplegia may also respond, albeit not to the same extent. In both diseases, we have generally given prednisone 60 mg and tapered the medication slowly; although there are no data to guide the proper treatment, corticosteroids should be continued for several weeks or longer. The absence of a response to steroids should cause reconsideration of the diagnosis of Tolosa-Hunt syndrome. In cases with relapsing disease on attempted withdrawal of corticosteroids, initiation of additional steroid-sparing immunosuppressive medications can be an effective strategy.

Acute Ophthalmoplegia (Table 13-5)

Total or nearly complete loss of eye movements of both eyes that evolves within a few days raises a limited number of diagnostic possibilities. An analysis of 60 such cases, found the responsible lesion to lie within the brainstem in 18 (usually infarction and less often Wernicke disease), in the cranial nerves in 26 (Guillain-Barré syndrome or tuberculous meningitis), within the cavernous sinus in 8 (tumors or infection), and at the neuromuscular junction in 8 (myasthenia gravis and botulism) (Keane). Our experience has tended toward the Miller Fisher variant of Guillain-Barré syndrome, as did a later series (Keane 1986, 2007), and myasthenia. The ophthalmoplegic form of Guillain-Barré syndrome is frequently associated with circulating antibodies to GQ1b ganglioside (see Chap. 44). There may be an accompanying paralysis of the dilator and constrictor of the pupil ("internal ophthalmoplegia") that is not seen in myasthenia.

Table 13-5

CAUSES OF COMPLETE OPHTHALMOPLEGIA

Brainstem lesions
Wernicke disease*
Pontine infarction*
Infiltrating glioma
Acute disseminated encephalomyelitis and multiple sclerosis
Cranial nerve lesions
Guillain-Barré syndrome*
Neoplastic meningitis
Granulomatous meningitis (tuberculous, sarcoid)
Cavernous sinus thrombosis
Tolosa-Hunt syndrome
Orbital pseudotumor*
Neuromuscular junction syndromes
Myasthenia gravis*
Thyroid ophthalmopathy
Lambert-Eaton syndrome
Botulism*
Congenital myasthenic syndromes ("slow-channel" disease)
Muscle disease
Progressive external ophthalmoplegia (mitochondrial and dystrophic types)
Oculopharyngeal dystrophy
Congenital polymyopathies (myotubular, nemaline rod, central core)

*Acute syndromes are noted by an asterisk.

Unilateral complete ophthalmoplegia has an even more limited list of causes, largely related to local disease in the orbit and cavernous sinus, mainly infectious, neoplastic, or thrombotic.

Chronic and Progressive Bilateral Ophthalmoplegia

This is most often caused by the mitochondrial myopathy known as progressive external ophthalmoplegia ("external" refers to the extra-ocular muscles, in contrast to the internal ocular muscles that mediate pupillary constriction and accommodation of the lens). The mitochondrial defect may show a mendelian (autosomal) inheritance pattern, as occurs with POLG1 and twinkle gene mutations in nuclear DNA, or may be the result of a mutation in mitochondrial DNA and show maternal inheritance only (see Chap. 45). Other causes include myasthenia gravis or Lambert-Eaton syndrome. The congenital myopathies are typically named for the morphologic characteristic of the affected limb musculature, and may include the central core, myotubular, and nemaline types. Another cause is the slow channel congenital myasthenic syndrome (see Chap. 46). Among the degenerative conditions, progressive supranuclear palsy may ultimately produce complete ophthalmoplegia, after first affecting vertical gaze. Thyroid ophthalmopathy as a cause of chronic ophthalmoparesis is discussed below.

Mechanical-Restrictive Ophthalmoparesis Including Thyroid Ophthalmopathy

Several causes of pseudoparalysis of ocular muscles that are due to mechanical restriction of the ocular muscles are distinguished from the neuromuscular and brainstem diseases discussed previously. The mechanical restriction of motion can be confirmed by *forced duction tests,* in which

the eye is physically pulled or pushed using forceps or a cotton swab applied to the sclera after anesthetizing the eye. Processes that infiltrate the orbit, such as lymphoma, carcinoma, and granulomatosis may limit the range of motion of individual or all the ocular muscles.

In *thyroid orbitopathy* (also referred to as *thyroid eye disease)*, a swollen and tight inferior or superior rectus muscle may limit upward and downward gaze, and involvement of the medial rectus limits abduction. The inferior rectus is involved in approximately 60 percent of cases, the medical rectus in 50 percent, and the superior rectus in 40 percent (Wiersinga). In most instances of thyroid ophthalmopathy, the diagnosis is suggested by associated proptosis, but in the absence of the latter sign, and particularly if the ocular muscles are affected on one side predominantly, there may be difficulty. The extraocular muscle enlargement can be demonstrated by CT scans and ultrasonography. In up to 20 percent of cases, the patient may be euthyroid or hypothyroid (Bahn). Teprotumumab, a monoclonal antibody against the insulin-like growth factor 1 receptor (which has been shown to be overexpressed by orbital fibroblasts in thyroid eye disease), has emerged as an effective treatment strategy to reduce proptosis and diplopia (Smith et al, 2017). This disorder is discussed further in Chap. 45.

Mixed Conjugate Gaze and Ocular Muscle Paralysis

We have already considered two types of neural paralysis of the extraocular muscles: paralysis of conjugate movements (gaze) and paralysis of individual ocular muscles. Here we discuss a third, more complex one—namely, mixed gaze and ocular muscle paralysis. The mixed type is a sign of an intrapontine or mesencephalic lesion that may have a variety of causes.

Internuclear Ophthalmoplegia and Other Pontine Gaze Palsies

With a complete lesion of the left MLF, the left ipsilateral eye fails to adduct when the patient looks to the right; this condition is referred to as left *internuclear ophthalmoplegia* (INO; Fig. 13-1). Reciprocally, with a lesion of the right MLF, the right eye fails to adduct when the patient looks to the left and the patient has a right INO. Quite often, rather than a complete paralysis of adduction, there are only slowed adducting saccades in the affected eye while the other eye quickly arrives at its fully abducted position. This slowing is best observed by having the patient make quick, large amplitude side-to-side refixation movements between two targets. Because the two medial longitudinal fasciculi lie close together adjacent to the midline, they are frequently affected together, yielding a bilateral INO.

A second component of INO is nystagmus that is limited to, or most prominent in, the opposite (abducting) eye. The intensity of nystagmus varies greatly from case to case. Several explanations have been offered to account for this dissociated nystagmus. The favored one invokes Hering's law in which activated pairs of yoked muscles receive equal and simultaneous innervation; because of an adaptive increase in innervation of the weak adductor, there is a commensurate increase in innervation to the strong abductor. A mismatch in the generated pulse and step signals results in dissociated nystagmus manifesting in that eye. Zee and colleagues evaluated this concept by assessing whether short-term patching of one eye altered the central adaptive response and therefore modulated the extent of abducting nystagmus in patients with INO. In several cases, they found that patching the affected eye for several days caused the abducting nystagmus in the fellow eye to diminish. Conversely, patching the unaffected eye lead to increased abducting nystagmus in the fellow eye.

The MLF also contains axons that originate in the vestibular nuclei and govern vertical eye position, for which reason an INO is also often accompanied by a skew deviation (supranuclear vertical misalignment of the eyes). Vertical nystagmus and impaired vertical pursuit are other common features, especially with bilateral INO.

When the MLF is affected by a lesion in the pons, convergence is spared and the alignment of the eyes in primary gaze is normal. In some cases, both eyes take an abducted position, giving rise to the "wall-eyed bilateral INO," or WEBINO syndrome. Lesions involving the MLF in the high midbrain impair convergence and also cause exotropia because of proximity to the medial rectus subnucleus. Abducting nystagmus tends to be slight in this mesencephalic type.

Cogan categorized INO based on the ability of the patient to perform convergence. He referred to a *posterior INO* when convergence was spared, implying that the lesion was caudal and the medial rectus subdivision of the oculomotor nuclear complex was preserved. He referred to an *anterior INO* when convergence was impaired, although this finding does not always require a rostral lesion that includes the medial rectus subnucleus; some patients with INO may have difficulty voluntarily initiating convergence on a near target, particularly when there is an associated skew deviation causing vertical diplopia as well.

In contrast, the term "posterior INO of Lutz" refers to the rare presentation of *abduction* (not adduction) paresis for pursuit and saccades that can be overcome by vestibular stimulation, as described by Lutz in 1923. The responsible lesion is proposed to be between the PPRF and the sixth nerve nucleus.

Etiology The main cause of *unilateral INO* is a small paramedian pontine infarction or a demyelinating plaque of multiple sclerosis (which also commonly causes bilateral INO, as noted below) (Keane, 2005). Other lesions to be considered, which may account for about one-quarter of cases in total, are trauma, infiltrative tumors, infections, or other lesions of the brainstem and fourth ventricular region. Occasionally, an INO occurs with subdural hematoma or hydrocephalus. In addition, adductor weakness from myasthenia gravis can simulate an INO, even to the point of showing nystagmus in the abducting eye.

Bilateral INO is most often the result of a demyelinating lesion (multiple sclerosis) in the posterior part of the midpontine tegmentum. Pontine myelinolysis, pontine infarction from basilar artery occlusion, Wernicke disease,

or infiltrating tumors are other causes. Brainstem damage following compression by a large cerebral mass has on occasion produced the syndrome.

An ipsilateral gaze palsy is the simplest oculomotor disturbance that results from a lesion in the paramedian tegmentum. More complex is the *one-and-a-half syndrome* that involves the pontine center for gaze plus the adjacent ipsilateral MLF on one side, combining a horizontal gaze palsy and INO on the same side. It is usually the result of a vascular or, less often, demyelinating lesion. The gaze palsy is, of course, on the side of the lesion and the eyes are deviated in the opposite direction. As a result, one eye lies fixed in the midline for all horizontal movements; the other eye makes only abducting movements and may demonstrate horizontal abducting nystagmus (see Fisher; also Wall and Wray). Unlike the situation of an INO alone, the mobile eye rests abducted because of the gaze palsy, a sign that has been termed "*paralytic pontine exotropia*." In some cases, the patient is able to adduct the eye ("nonparalytic exotropia," a condition which has other causes). An incomplete version of the one-and-a-half syndrome displays only bilateral nystagmus on gaze in one direction (due to paresis of gaze) and nystagmus only in the abducting eye with gaze directed to the other side (due to the lesion in the MLF on the same side).

Thrombotic occlusion of the upper part of the basilar artery ("*top of the basilar*" syndromes) causes a variety of important eye movement abnormalities. These include upgaze or complete vertical gaze palsy, skew deviation, and so-called pseudoabducens palsy, mentioned earlier (Caplan).

Skew deviation Skew deviation is a disorder in which there is vertical deviation of one eye above the other that is caused by an imbalance of the *supranuclear* vestibular inputs to the ocular motor system. Unlike fourth nerve palsy, where the separation of images is incomitant, most pronounced when the affected eye is adducted and turned down, skew deviation is typically comitant, meaning that the amount of ocular misalignment is relatively similar in all directions of gaze. Skew deviation is associated with a variety of lesions of the cerebellum and the brainstem, particularly those involving the MLF. In lesions involving the vestibular nuclei, as occurs in lateral medullary infarction, the eye is lower on the side of the lesion. With lesions of the MLF or INC, which can also cause skew and an ocular tilt reaction, the eye is higher on the side of the lesion. With skew deviation due to cerebellar disease, the eye on the side of the lesion usually rests lower (in two-thirds of cases in Keane's series), but sometimes it is higher than the other eye. The *ocular tilt reaction*, in which skew deviation (supranuclear vertical misalignment of the eyes) is a more dramatic version of skew deviation, which also includes ocular torsion and head tilt. It is attributed to an imbalance of otolithic-ocular and otolithic-colic reflexes.

In some cases, the hypertropic eye has been known to alternate with the direction of gaze ("alternating skew"), with the right eye higher in right gaze and the left eye higher in left gaze. A cerebellar or other posterior fossa lesion is the usual cause. A mechanism for this sign has been proposed based on otolithic influences on cerebellar centers.

Among the most unusual of the complex ocular disturbances is a subjective tilting of the entire visual field that creates an illusion of environmental tilting that may be 45, 90, or even 180 degrees vision (*tortopia,* or in the latter case, *upside-down vision*). Objects normally on the floor, such as chairs and tables, are perceived to be on the wall or ceiling. Presumably the phenomenon arises from imbalanced inputs from the vestibular-otolithic nucleus or its connections in the MLF, which provide gravitational information that is essential for maintaining the normal subjective sense of the visual vertical. Lateral medullary infarction has been a common cause of this tilting of vision; other cases may be migrainous (Ropper, 1983). Ocular lateropulsion, in which the eyes are driven to one side and the patient feels pushed or pulled in the same direction, is another component in some cases of lateral medullary infarction as discussed in Chap. 33.

NYSTAGMUS

Nystagmus refers to involuntary rhythmic movements of the eyes and is of two general types. In the more common *jerk nystagmus*, the movements alternate between a slow component and a fast corrective component, or jerk, in the opposite direction. In *pendular nystagmus*, the oscillations are roughly equal in rate in both directions, although on lateral gaze the pendular type may be converted to the jerk type with the fast component to the side of gaze. Nystagmus reflects an imbalance in one or more of the systems that maintain stability of gaze. The causes may therefore be viewed as originating in (1) structures that maintain steadiness of gaze in the primary position; (2) the system for holding eccentric gaze—the so-called neural integrator; or (3) the VOR system, which maintains foveal fixation of images as the head moves. For clinical purposes, certain types of nystagmus are identified as corresponding to lesions in specific structures within each of these systems, and it is this approach that we take in the following pages. One classification considers nystagmus as the result of a disturbance in the vestibular apparatus or its brainstem nuclei, the cerebellum, or a number of specific regions of the brainstem such as the MLF.

In testing for nystagmus, the eyes should be examined first in the central position and then during upward, downward, and lateral movements. Jerk nystagmus may be horizontal or vertical and is elicited particularly on ocular movement in these planes, or it may be rotatory and, rarely, retractory or vergent. By custom the direction of the nystagmus is designated according to the direction of the fast component (referred to as "beating" to that side).

Drug intoxication is the most frequent cause of jerk nystagmus. Alcohol, barbiturates, other sedative-hypnotic drugs, phenytoin, and other antiepileptic drugs are the common causes. This form of nystagmus is most prominent on deviation of the eyes in the horizontal plane, but it also may appear in the vertical plane.

In many normal individuals, a few irregular jerks are observed when the eyes are moved far to one side ("nystagmoid" jerks), but the movements cease once lateral

fixation is attained. A fine rhythmic nystagmus may also occur normally in extreme lateral gaze (physiologic end-gaze nystagmus), beyond the range of binocular vision; but it is bilateral and disappears as the eyes move a few degrees toward the midline. These latter movements are probably analogous to the tremulousness of skeletal muscles when maximally contracted.

Oscillopsia is the symptom of illusory movement of the environment in which stationary objects seem to move back and forth, up and down, or from side to side. It may be caused by ocular flutter (a cerebellar sign as discussed later) or coarse nystagmus of any type. With lesions of the labyrinths (as in aminoglycoside toxicity), the symptom of oscillopsia is only provoked by motion—for example, walking or riding in an automobile—and indicates an impaired ability of the vestibular system to stabilize ocular fixation during body movement (i.e., impaired VOR function). In these circumstances, cursory examination of the eyes may disclose no abnormalities; however, if the patient's head is rotated slowly from side to side or moved rapidly in one direction while attempting to fixate a target, impairment of normal reflexive smooth eye movements and their replacement by saccadic or nystagmoid movements is evoked (see Chap. 14 for further discussion of these tests). If episodic and involving only one eye, oscillopsia is usually caused by myokymia of an ocular muscle (usually the superior oblique).

Nystagmus of Labyrinthine Origin (See Also Chap. 14)

This is predominantly a horizontal or vertical unidirectional jerk nystagmus, often with a slight torsional component. It is more prominent when visual fixation is eliminated, which can be accomplished with the use of Frenzel lenses (conversely, it is suppressed by fixation). Vestibular nystagmus of peripheral (labyrinthine) origin beats in most cases away from the side of the lesion and increases as the eyes are turned in the direction of the quick phase (Alexander's law). In contrast, as noted below, nystagmus of brainstem and cerebellar origin is most apparent when the patient tries to maintain eccentric fixation and the direction of nystagmus changes with the direction of gaze.

Tinnitus and hearing loss are often associated with disease of the peripheral labyrinthine mechanism. Vertigo, nausea, vomiting, and staggering also may accompany disease of any part of the labyrinthine-vestibular apparatus or its central connections. As a characteristic example, the intense nystagmus of benign positional vertigo (see Chap. 14) is evoked by moving from the sitting to the supine position, with the head turned to one side. In this condition, nystagmus of vertical-torsional type and vertigo develop a few seconds after changing head position and persist for another 10 to 15 s. When the patient sits up, the nystagmus changes to beat in the opposite direction.

Optokinetic Nystagmus

When one is watching a moving object (e.g., the passing landscape from a train window, a rotating drum with vertical stripes, or a strip of cloth with similar stripes), a rhythmic jerk nystagmus called *optokinetic nystagmus* (OKN) normally appears. This phenomenon is explained by a slow involuntary pursuit movement iteratively followed by a quick saccadic movement in the opposite direction to fixate the next new target that is entering the visual field. With unilateral lesions of the parietal region, the slow pursuit phase of the OKN may be lost or diminished when the stimulus—for example, the striped OKN drum—is moving toward the side of the lesion, whereas rotation of the drum to the opposite side elicits a normal response. In contrast, patients with hemianopia caused by an occipital lobe lesion show a normal optokinetic response bilaterally. The loss of the pursuit phase with a parietal lesion presumably results from interruption of efferent pathways from the parietal cortex to the brainstem centers for conjugate gaze. On the other hand, individuals with a frontal lobe lesion will track a moving target in either horizontal direction but show little or no fast-phase correction in the direction opposite the lesion.

An important additional fact about OKN is that the ability to evoke it proves that the patient is not blind. Each eye can be tested separately to exclude monocular blindness. Thus the test is of particular value in the examination of hysterical patients and malingerers who claim that they cannot see, and of neonates and infants (a nascent OKN is established within hours after birth and becomes more easily elicitable over the first few months of life). Demonstration of an intact OKN, however, merely demonstrates that some vision is preserved, and does not prove that the visual function is actually normal.

Caloric-Induced Nystagmus

Labyrinthine stimulation—for example, irrigation of the external auditory canal with warm or cold water, or "caloric testing"—produces a marked nystagmus. Cold water induces a slow tonic deviation of the eyes toward the irrigated ear and a compensatory nystagmus in the opposite direction in a conscious, awake patient; warm water does the reverse. Thus the acronym taught to generations of medical students: COWS, or "cold opposite, warm same," to refer to the direction of the fast phase of the induced nystagmus. The slow tonic ipsiversive component with cold water caloric testing occurs because the semicircular canals on the side are transiently inhibited and the vestibulo-ocular reflex therefore sends both eyes conjugately in that direction (as would occur if the head were turning in the opposite direction). The fast component of the nystagmus represents the corrective movement superimposed on this slow tonic gaze deviation.

Comatose patients with an intact VOR will demonstrate the slow-phase gaze deviation without the fast-phase nystagmus to which this mnemonic refers. Vertical eye movements can also be assessed with caloric stimulation of the labyrinths. When cold water is instilled in both ears, reflexive nystagmus occurs with a downward slow phase and upbeating fast phase (the acronym CUWD, or "cold upbeat, warm downbeat" could be remembered). In general cold caloric testing is preferred to warm caloric testing, to avoid risk of injury to the ear canal that may occur if the water were too hot. Chapter 14 discusses the production of

nystagmus by labyrinthine stimulation and other features of vestibular nystagmus.

Nystagmus Caused by Brainstem and Cerebellar Disease

Brainstem lesions often cause a coarse, unidirectional, *gaze-evoked nystagmus*, which may be horizontal or vertical, meaning that the nystagmus is exaggerated when the eyes sustain an eccentric position of gaze. Unlike the vestibular nystagmus discussed above, the central type usually changes direction depending on the direction of gaze. Vertigo is typically less common or less intense than with labyrinthine nystagmus, and signs of disease of other nuclear structures and tracts in the brainstem are frequent.

Downbeat nystagmus, which is always of central origin, is characteristic of lesions in the medullary–cervical region such as syringobulbia, Chiari malformation, basilar invagination, and demyelinating plaques. It has also been seen with Wernicke disease and may be an initial sign of either paraneoplastic brainstem encephalitis or cerebellar degeneration with opsoclonus. Downbeat nystagmus can occur in patients with lithium intoxication or with profound magnesium depletion (Saul and Selhorst). A study of 62 patients with downbeat nystagmus, found that half were associated with Chiari malformation and various forms of cerebellar degeneration; in most of the remainder, the cause could not be determined (Halmagyi and coworkers). Some cases are associated with antibodies against glutamic acid decarboxylase (GAD), which are also associated with the stiff person syndrome (Antonini).

Spontaneous *upbeat nystagmus* can be observed in patients with demyelinating or vascular disease, tumors, or Wernicke disease. It has been associated with lesions of the midbrain and cerebellum (particularly the anterior cerebellar vermis). Also cited have been cases with a lesion at the pontomedullary junction involving the nucleus prepositus hypoglossi, which receives vestibular connections and projects to all brainstem and cerebellar regions concerned with ocular motor functions (Kato and associates). Smoking tobacco in significant quantities is another recognized cause.

Nystagmus of several types—including gaze-evoked nystagmus, downbeat nystagmus, and "rebound nystagmus" (gaze-evoked nystagmus that changes direction with refixation to the primary position)—occurs with cerebellar disease, particularly with lesions of the vestibulocerebellum or with brainstem lesions that involve the nucleus prepositus hypoglossi and the medial vestibular nucleus. Also, characteristic of cerebellar disease are several closely related disorders of saccadic movement that appear as nystagmus (opsoclonus, flutter, dysmetria) described in the following text. Tumors situated in the cerebellopontine angle may cause a coarse, low-frequency horizontal nystagmus when looking toward the lesion with a fine, high-frequency nystagmus when looking in the opposite direction (*Brun's nystagmus*). Nystagmus that occurs only in the abducting eye is referred to as *dissociated nystagmus* and is a common sign of INO, as discussed earlier.

Infantile (Congenital, Pendular) Nystagmus

This nystagmus can occur either in association with profound visual loss or as an isolated abnormality with relatively preserved visual function. When accompanied by visual loss, it may be associated with conditions such as ocular albinism, Leber's congenital amaurosis, and various other diseases of the retina and refractive media. The defect in infantile nystagmus is postulated to be instability of smooth pursuit or gaze-holding mechanisms. A cardinal feature of this type of nystagmus is that it remains horizontal even during vertical movement. It is mainly pendular (sinusoidal) except in extremes of gaze, when it comes to resemble jerk nystagmus. Eye movement recordings demonstrate that the slow-phase eye movement has an exponentially *increasing* velocity phase that is unique among nystagmus; in other forms of nystagmus the velocity of the eye movements is either constant or decays.

Infantile nystagmus is often suppressed during convergence. Many affected children have a "null position," where the nystagmus is dampened in a particular direction of gaze. These patients, therefore, adopt a compensatory head turn to utilize the null position, where the retinal image is most stable, to its maximum effect. Also characteristic is a paradoxical response to optokinetic testing (see later), in which the quick phase is in the same direction as the drum rotation.

The related condition of *latent nystagmus* refers to nystagmus that occurs when one eye is covered. The nystagmus that occurs is conjugate, present in both eyes, with the fast phase in the direction of the covered eye. The finding may occur when either is covered, or it may be asymmetric and occur only with covering one of the eyes but not the other. Latent nystagmus is considered to be a result of impaired development of binocular stereoscopic vision. It often co-exists with some degree of amblyopia, again reflecting the disruption of visual development early in life. Patients usually do not describe the experience of oscillopsia when the nystagmus occurs (i.e., the conscious perception of the visual environment shaking) because the congenital mechanisms associated with this nystagmus allow for suppression of that aspect of the visual experience. In some individuals with this condition who then lose vision in one eye later in life, the latent nystagmus becomes unmasked constantly and is termed *manifest latent nystagmus*.

Even in adulthood, severe acquired blindness can produce nystagmus of pendular or jerk variety. Both horizontal and vertical components are evident and the characteristic feature is a fluctuation over several seconds of observation in the dominant direction of beating. The oscillations of the eyes are usually very rapid, increase on upward gaze, and may be associated with compensatory oscillations of the head. The formerly common syndrome of "miner's nystagmus" is an associated condition that occurs in patients who have worked for many years in comparative darkness.

Spasmus nutans, a specific type of pendular nystagmus of infancy, is accompanied by head nodding, and occasionally by wry positions of the neck. Most cases begin between the 4th and 12th months of life, never after the 3rd year. The nystagmus may be horizontal, vertical, or rotatory; it is usually more pronounced in one eye than the other (or

limited to one eye) and can be intensified by immobilizing or straightening the head. Most infants recover within a few months or years. Most cases are idiopathic, but the clinical manifestations of spasmus nutans may be mimicked by lesions such as a perichiasmal or third ventricular tumor and rare cases accompany childhood retinal diseases. Although there is no direct connection to the rare childhood condition of bobble-head syndrome, which is caused by lesions in or adjacent to the third ventricle, they are similar in the rhythmic head movements as described in Chap. 29.

Acquired forms of pendular nystagmus may occur with leukodystrophies, including Pelizaeus-Merzbacher syndrome (see Chap. 36), multiple sclerosis (see Chap. 35), and toluene intoxication. In the oculomasticatory myorhythmia of Whipple disease, the nystagmus is conjoined to rhythmic jaw movements (see Chap. 31).

Other Types of Nystagmus

Convergence nystagmus refers to a rhythmic oscillation in which a slow abduction of both eyes is followed by a quick movement of adduction, usually accompanied by quick rhythmic retraction movements of the eyes (*retraction nystagmus*) and by one or more features of the Parinaud–dorsal midbrain syndrome discussed earlier in the chapter. There may also be rhythmic movements of the eyelids or a maintained spasm of convergence, best brought out on attempted elevation of the eyes on command or downward rotation of an OKN drum. These phenomena all point to a lesion of the upper midbrain tegmentum and are usually manifestations of vascular disease, traumatic damage, or a tumor such as a pinealoma that compresses this region.

Seesaw nystagmus is a torsional-vertical oscillation in which the intorting eye moves up and the opposite (extorting) eye moves down, then both move in the reverse direction. It is occasionally observed in conjunction with chiasmatic bitemporal hemianopia caused by sellar or parasellar masses and after pituitary surgery.

Periodic alternating nystagmus (*PAN*) is a remarkable horizontal jerking that periodically (every 90 s, or so) changes direction, interposed with a brief neutral period during which the eyes show no nystagmus, or jerk downward. PAN is seen with lesions in the lower brainstem but has also been reported with Creutzfeldt-Jakob disease, hepatic encephalopathy, lesions of the cerebellar nodulus, carcinomatous meningitis, anti-GAD antibodies, and varied other processes. A congenital form is associated with albinism. It differs from *ping-pong gaze*, which is a saccadic variant with a more rapid alternating of gaze from side to side and usually the result of severe bilateral hemispheric disease.

So-called *oculopalatal tremor* is characterized by an irregular pendular nystagmus that is accompanied by involuntary movements of the palatal and pharyngeal muscles occurring at the same frequency, as discussed in Chap. 4. This syndrome often follows a lesion in the dorsal pons that disrupts the central tegmental tract, which is a component of the anatomical triangle of Guillain-Mollaret, connecting the red nucleus, inferior olive, and contralateral dentate nucleus of the cerebellum. Months after the acute injury, denervation of the inferior olive leads to hypertrophic degeneration, with the increased volume and signal intensity of the inferior olive often visible on MRI.

Other Spontaneous Ocular Movements

Roving conjugate eye movements are characteristic of coma. Horizontal ocular deviations that shift every few seconds from side to side (*ping-pong gaze*) is a form of roving eye movement that occurs with bihemispheric infarctions or sometimes with posterior fossa lesions. Fisher has noted a similar slower, side-to-side pendular oscillation of the eyes ("windshield-wiper eyes"). This phenomenon has been associated with bilateral hemispheric lesions that have presumably released a brainstem oscillatory pacemaker.

Ocular bobbing is a term coined by Fisher to describe a distinctive spontaneous fast downward jerk of the eyes followed by a slow upward drift to the midposition. It is observed in comatose patients in whom horizontal eye movements have been obliterated by large destructive lesions of the pons, less often of the cerebellum. The movements may be dysconjugate in the vertical plane, especially if there is an associated third-nerve palsy on one side.

Other spontaneous vertical eye movements have been given a variety of confusing names: *atypical bobbing*, *inverse bobbing*, *reverse bobbing*, and *ocular dipping*. For the most part, they are observed in coma of metabolic or anoxic origin in which reflexive horizontal eye movements may be preserved (in distinction to ocular bobbing). *Ocular dipping* describes an arrhythmic slow conjugate downward movement followed in several seconds by a more rapid upward movement; it occurs spontaneously but may at times be elicited by moving the limbs or neck. Anoxic encephalopathy has been the most common cause, but a few cases have followed drug overdose (Ropper, 1981).

Oculogyric crisis, formerly associated with postencephalitic parkinsonism, is now most often caused by phenothiazine and related drugs, as discussed earlier.

Saccadic Intrusions (Opsoclonus, Ocular Flutter, and Square Wave Jerks)

This group of phasic or repetitive eye movements is distinguished from nystagmus in that each is composed of abnormal saccades without intervening slow-phase eye movements. *Opsoclonus* is the term applied to rapid, conjugate movements of the eyes in horizontal, rotatory, and vertical directions, often made worse by voluntary movement or the need to fixate the eyes. These bursts of saccadic movements are continuous and chaotic, without an intersaccadic pause (hence the colorful term *saccadomania*). They can be observed even when the eyes are closed, and often persist in sleep. As indicated in Chap. 4, they are usually part of a widespread myoclonus associated with paraneoplastic or parainfectious disease. In adults, lung, breast, and testicular cancer are important considerations, while in children an evaluation for neuroblastoma is essential (see "Paraneoplastic Cerebellar Degeneration" discussed in Chap. 30). Other less frequent causes include HIV, poststreptococcal infection, West Nile virus encephalitis, and rickettsial infections. Opsoclonus may also be observed in

patients who are intoxicated with antidepressants, anticonvulsants, organophosphates, cocaine, lithium, thallium, and haloperidol; in the nonketotic hyperosmolar state; and in cerebral Whipple disease, where the eye movements are coupled with rhythmic jaw movements (oculomasticatory myorhythmia). A benign childhood form can persist for years without explanation and is responsive to adrenocorticotropic hormone (ACTH), as in the "dancing eyes" syndrome of Kinsbourne. In addition, a self-limited benign form exists in neonates.

Ocular flutter refers to intermittent bursts of very rapid oscillations around the point of fixation limited to the horizontal plane; this abnormality is also associated with cerebellar disease. Flutter at the end of a saccade, called *flutter dysmetria* ("fish-tail nystagmus") has the appearance of dysmetria, but careful analysis indicates that it is probably a different phenomenon. Whereas the inaccurate saccades of ocular saccadic dysmetria (an ataxic phenomenon) are separated by a brief pause (intersaccadic interval), flutter consists of consecutive saccades without an intersaccadic interval; that is, back-to-back saccades (Zee and Robinson). All those movements have the same implication of cerebellar cortical disease. One hypothesis relates opsoclonus and ocular flutter to a disorder of the saccadic "pause neurons," but their exact anatomic basis has not been elucidated. Similar movements have been produced in monkeys by creating bilateral lesions in the pretectum. Some normal individuals can voluntarily induce flutter for brief periods, but the movement cannot be sustained (voluntary "nystagmus").

Square wave jerks refer to another type of involuntary saccades that disrupt fixation. The eyes are seen to horizontally move off target by several degrees, pause for approximately 200 ms, and then move back. The term square wave jerks comes from a description of the recording of these eye movements. Square wave jerks can be a normal finding in the elderly, but their frequency becomes increased in many conditions, particularly neurodegenerative disorders such as progressive supranuclear palsy.

Ocular neuromyotonia describes an intermittent diplopia owing to paroxysmal contraction of one or more ocular muscles after their activation. The episodes may last approximately 30 to 60 s until there is cessation of the involuntary sustained contraction of the affected eye muscles. This condition most commonly occurs months to years after radiation that includes the field of the ocular motor nerves (and less characteristically occurs with vascular or tumor compression in the absence of a history of radiation therapy). Like superior oblique myokymia (discussed earlier), ocular neuromyotonia may respond to anticonvulsant medications such as carbamazepine.

Disorders of the Eyelids and Blinking

A consideration of oculomotor disorders would be incomplete without reference to the eyelids and blinking. In the normal individual, the eyelids on both sides are at the same level with respect to the limbus of the cornea and there is a variable prominence of the eyes, depending on the width of the palpebral fissure. The function of the lids is to protect the delicate corneal surfaces against injury and the retinae against glare; this is done by blinking and lacrimation. Eyelid movement is normally coordinated with ocular movement—the upper lids elevate when looking up and descend when looking down. Turning the eyes quickly to the side is sometimes attended by a single blink, which is necessarily brief so as not to interfere with vision. When the blink duration is prolonged, it is indicative of an abnormally intense effort required to initiate the saccade; usually this is because of frontal lobe or basal ganglionic disease.

Closure and opening of the eyelids is accomplished through the reciprocal actions of the levator palpebrae and orbicularis oculi muscles. The eyelids are kept open by the tonic contraction of the levator muscles, which overcomes the elastic properties of the periorbital muscles. Complete opening of the lids is aided by the superior tarsal (Müller) muscle, which is tonically innervated by sympathetic fibers. The eyelids close as a result of relaxation of the levator muscles and contraction of the orbicularis oculi muscles. The levator is innervated by the oculomotor nerve, and the orbicularis by the facial nerve. The trigeminal nerves provide sensation to the eyelids and are also the afferent limbs of corneal and palpebral reflexes. Central mechanisms for the control of blinking, in addition to the reflexive brainstem connections between the third, fifth, and seventh nerve nuclei, include polysynaptic circuits of the cerebrum, basal ganglia, and hypothalamus. Voluntary lid closure is initiated through frontobasal ganglionic connections.

Normal blinking is bilateral and occurs irregularly at a rate of 12 to 20 times a minute, the frequency varying with the state of concentration and with emotion. The natural stimuli for the blink reflex are corneal contact, a tap on the brow or around the eye, visual threat, an unexpected loud sound, and, as indicated above, turning of the eyes to one side. There is normally a rapid adaptation of blinking in response to visual and auditory stimuli but not to corneal stimulation.

Electromyography of the orbicularis oculi reveals two components of the blink response, an early and late one; these features are difficult to appreciate by clinical observation alone. The early monosynaptic response consists of only a slight movement of the upper lids; the immediately following polysynaptic response is more forceful and approximates the upper and lower lids. Whereas the early part of the blink reflex is beyond volitional control, the second part may be inhibited voluntarily.

Blepharospasm, an excessive and forceful closure of the lids with increased frequency, is a common disorder that is seen in isolation or as part of a number of dyskinesias and drug-induced movement disorders. Extremes of this condition may result in functional blindness. Treatment for dry eye syndrome is often attempted but is ineffective; periodic injections with botulinum toxin can alleviate symptoms. The combination of blepharospasm with dystonic grimacing movements of the lower face is termed Meige syndrome.

The opposite problem, reduced frequency of blinking (<10/min), is characteristic of Parkinson disease and progressive supranuclear palsy. In these cases, there is reduced adaptation to repeated supraorbital tapping at a rate of about 1 per second; therefore, the patient continues

to blink with each tap on the forehead or glabella, referred to as the glabellar, or *Myerson sign*.

A lesion of the oculomotor nerve, by paralyzing the levator muscle, causes *ptosis*, that is, drooping of the upper eyelid. In contrast, a lesion of the facial nerve, as in Bell palsy, impairs the ability to close the eyelids because of weakness of orbicularis oculi (lagophthalmos). In some instances of Bell palsy, even after nearly full recovery of facial movements, blink frequency and amplitude may be reduced on the previously paralyzed side. A trigeminal nerve lesion on one side, by reducing corneal sensation, interferes with the blink reflex on both sides, whereas Bell palsy reduces the ipsilateral blink but does not affect the contralateral blink. Aberrant regeneration of the third nerve after an injury may result in a condition wherein the upper lid retracts on lateral or downward gaze (pseudo-von Graefe sign). Aberrant regeneration of the facial nerve after Bell palsy has an opposite effect—closure of the lid with facial movements or speaking. There is also a congenital and sometimes hereditary anomaly in which a ptotic eyelid retracts momentarily when the mouth is opened or the jaw is moved to one side, owing to aberrant connections between the trigeminal and oculomotor nerves (the Marcus Gunn "jaw winking" syndrome). In other cases, inhibition of the levator muscle and ptosis occurs with opening of the mouth ("inverse Marcus Gunn phenomenon," or Marin Amat syndrome).

Unilateral ptosis is a notable feature of third nerve lesions (see above) and of sympathetic paralysis, namely, the Horner syndrome. With the former, weakness of the levator palpebrae can produce marked, or even complete ptosis, whereas with the latter, weakness of the Müller muscle produces only 1 to 2 mm of ptosis. In some cases of Horner syndrome, there is also "inverse ptosis," referring to a slight elevation of the lower eyelid, contributing to the illusion that the eye is slightly retracted (pseudoenophthalmos). Perhaps the most common cause of unilateral static ptosis is a dehiscence of the tarsal muscle attachment; it can be identified by the loss of the upper lid fold just below the brow.

Ptosis is often accompanied by compensatory overaction of the frontalis and the contralateral levator palpebrae muscles. In patients with myasthenia, Cogan described a "lid twitch" phenomenon, in which there is a transient retraction of the upper lid when the patient moves visual fixation from the down position to straight ahead. Brief fluttering of the lid margins on moving the eyes vertically is also characteristic of myasthenia. Another useful clinical rule is that a combined paralysis of the levator, and orbicularis oculi muscles (i.e., the muscles that open and close the lids) indicates myasthenia gravis or a myopathic disease such as myotonic dystrophy. This is because the third and seventh cranial nerves are rarely affected together in peripheral nerve or brainstem disease.

Bilateral ptosis is a characteristic feature of myasthenia gravis and certain muscular dystrophies; congenital ptosis and progressive sagging of the upper lids in the elderly are other common forms. Botulism also produces ptosis, whether naturally acquired of occurring iatrogenically after botulinum toxin treatments. An effective way of demonstrating that mild, ostensibly unilateral ptosis is in fact bilateral is to lift the ptotic side and observe that the opposite lid promptly droops. This reflects the enhanced effort required to maintain patency of the lids.

Retraction of the upper lids (Collier sign), often described as having a staring expression, is observed in thyroid disease, progressive supranuclear palsy, hydrocephalus, and other causes of the dorsal midbrain (Parinaud) syndrome. In thyroid eye disease the "lid-lag" refers to delayed relaxation of the eyelid on attempted downgaze (Von Graefe sign). Proptosis and ocular muscle restriction are present in the full form of the condition. PSP has prominent volitional vertical gaze abnormalities. In hydrocephalus, the downturning of the eyes is often referred to as the "sunset sign." The elements of the dorsal midbrain syndrome have been described earlier in this chapter. The von Graefe sign on downward gaze is usually not present, in distinction to what is observed in thyroid ophthalmopathy. Slight lid retraction has been observed in some patients with hepatic cirrhosis, Cushing disease, chronic steroid myopathy, and hyperkalemic periodic paralysis. Lid retraction can also be a reaction to ptosis on the other side; this is clarified by lifting the ptotic lid manually and observing the disappearance of contralateral retraction as mentioned previously.

Myotonic dystrophy features ptosis as a component of the myopathic facies. In myotonia congenita, forceful closure of the eyelids may induce a strong aftercontraction. In certain extrapyramidal diseases, particularly progressive supranuclear palsy and Parkinson disease, even gentle lid closure may elicit blepharoclonus and blepharospasm on attempted opening of the lids; or there may be a delay in the opening of the tightly closed eyelids. Acute right parietal or bifrontal lesions often produce a phenomenon referred to as *apraxia of lid opening,* describing a disinclination to open the eyelids, even to the point of offering active resistance to forced opening. The closed lids give the false impression of diminished alertness.

THE PUPILS

The testing of pupillary size and reactivity, which can be accomplished by the use of a flashlight and simple printed gauge, often yields vital clinical information. Essential, of course, is the proper interpretation of pupillary reactions, and this requires some knowledge of their underlying neural mechanisms.

The diameter of the pupil is determined by the balance of innervation between the constricting sphincter and radially arranged dilator muscles of the iris. The *pupilloconstrictor* (parasympathetic) fibers arise in the Edinger Westphal nucleus in the high midbrain, join the third cranial (oculomotor) nerve, and synapse in the ciliary ganglion, which lies in the posterior part of the orbit. The postganglionic fibers then enter the globe via the short ciliary nerves. Only 3 percent of these fibers mediate pupillary constriction to light, while the remaining 97 percent are responsible for constriction occurring as part of the near response during accommodation. The sphincter of the pupil comprises 50 motor units (Corbett and Thompson).

The *pupillodilator* (sympathetic) fibers arise in the posterolateral part of the hypothalamus and descend, uncrossed, in the lateral tegmentum of the midbrain, pons, medulla, and cervical spinal cord to the eighth cervical, and first and second thoracic segments, where they synapse with lateral horn neurons. The latter give rise to preganglionic fibers, most of which leave the cord by the second ventral thoracic root and proceed through the stellate ganglion to synapse in the superior cervical ganglion. The postganglionic fibers ascend along the internal carotid artery and traverse the cavernous sinus, where they join the first division of the trigeminal nerve, finally reaching the eye as the long ciliary nerves that innervate the dilator muscle of the iris. Some of the postganglionic sympathetic fibers also innervate the sweat glands and arterioles of the face, and Müller's muscle in the eyelid.

The Pupillary Light Reflex

The most common physiologic stimulus for pupillary constriction is exposure of the retina to light. Reflex pupillary constriction is also part of the act of convergence and accommodation for near objects (near synkinesis).

The pathway for the pupillary light reflex consists of three parts (Fig. 13-9). Signals in the afferent limb originate in the retinal receptor cells, pass through the bipolar cells, and synapse with the retinal ganglion cells. In addition to stimulating rod and cone photoreceptors, light also drives pupillary constriction by stimulating special intrinsically photosensitive retinal ganglion cells (ipRGCs) that contain melanopsin and directly signal the presence of light (Hattar). The light reflex fibers course through the optic nerve and chiasm and then leave the optic tract just rostral to the lateral geniculate body and enter the rostral midbrain, where they synapse in the *pretectal nucleus*. From here, intercalated neurons pass ventrally to the ipsilateral *Edinger-Westphal nucleus* and, via fibers that cross in the posterior commissure, to the contralateral Edinger-Westphal nucleus as well (see Fig. 13-9). The effector arm of the reflex consists of an efferent two-neuron pathway from the Edinger-Westphal nucleus that synapses in the ciliary ganglion, from which the short ciliary nerves innervate the sphincter to cause pupillary constriction. Following initial constriction, the pupil may normally dilate slightly in spite of a light shining steadily in one or both eyes.

Alterations of the Pupils

The pupils tend to be large in children and small in the aged, sometimes markedly miotic but still reactive (senile miosis). An asymmetry of the pupils of 0.3 to 0.5 mm is found in 20 percent or more of normal individuals (Lam). When light is shined into one eye, normally both pupils should constrict; the constriction of the pupil under bright light is termed the direct reflex, and the constriction of the unexposed pupil is termed the consensual reflex. With complete or nearly complete interruption of one optic nerve, both pupils fail to react to direct light stimulation of the blind eye; however, they both constrict with

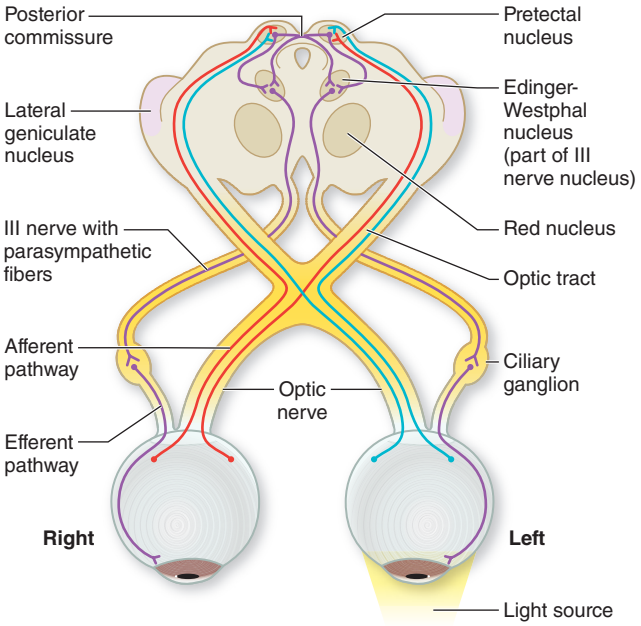

Figure 13-9. Diagram of the pathways subserving the pupillary light reflex. (Reprinted with permission from Bradford CA. *Basic Ophthalmology*, 7th ed, American Academy of Ophthalmology, 1975.)

illumination of the healthy eye. On the other hand, impairment of both the direct and consensual light reflex in one eye with retention of the consensual reflex in the opposite eye places the lesion in the efferent limb of the reflex arc, that is, in the homolateral oculomotor nerve or its nucleus. A lesion of the afferent limb of the light reflex pathway will not affect the near responses of the pupil, and lesions of the visual pathway caudal to the point where the light reflex fibers leave the optic tract will not alter the pupillary light reflex (see Fig. 13-9).

In the right clinical circumstances, the "relative afferent pupillary defect," or *Marcus Gunn pupillary sign,* provides objective evidence of an optic neuropathy. It is identified by performing the "swinging-flashlight test," in which each pupil is alternately exposed to light at 1-s intervals; when an optic neuropathy is present, the pupils both show a poor constriction or even paradoxical dilatation when light is shined into the affected eye. It is best to assess in a dimly lighted room with the patient fixating on a distant target rather than the light source (to avoid pupillary constriction accompanying convergence). A relative afferent pupillary defect will not be present if the patient has previously been affected with an optic neuropathy; its utility is to discern a relative difference in the function of the optic nerve between the two eyes. A relative afferent pupillary defect is usually not produced by most causes of visual loss from ocular abnormalities, such as refractive error, cataract, or diseases of the macula; it can be present with extensive retinal disease that asymmetrically affects one eye over the other.

Hippus, a rapid fluctuation in pupillary size, is a phenomenon that can be seen in normal persons. It can also be observed more commonly in metabolic encephalopathy. It has no particular clinical significance. To distinguish

hippus from the Marcus Gunn afferent pupillary defect, one carefully observes the first movement of the pupils as the light is repeatedly moved from the unaffected to the affected eye; in hippus, half of the initial responses will be dilation and half, constriction, whereas with a relative afferent pupillary defect, all the initial movements are dilation.

Horner Syndrome

Interruption of the sympathetic fibers results in miosis and ptosis, owing to paralysis of the pupillary dilator muscle and of Müller's muscle, respectively. To the ophthalmic findings may be added loss of sweating on the same side of the face and redness of the conjunctiva. The entire complex is called the *Horner syndrome*, *Bernard-Horner syndrome*, or oculosympathetic palsy. The pupillary change may be subtle and may require covering the eyes or dimming the room lights to observe the lack of expected mydriasis on one side.

The lesion causing Horner syndrome may be central, between the hypothalamus and the points of exit of sympathetic fibers from the spinal cord (C8 to T3, mainly T2), or peripheral, in the cervical sympathetic chain, superior cervical ganglion, or along the carotid artery. A congenital form caused by perinatal injury, usually of the sympathetic chain in the neck is seen regularly (Fig. 13-10). A hereditary form of the Horner syndrome (autosomal dominant) is also known, usually but not always associated with a congenital absence of pigment in the affected iris (heterochromia iridis) (Hageman et al).

The pattern of sweating may be helpful in localizing the lesion in the following manner: With lesions at the level of the common carotid artery, loss of sweating involves the entire side of the face. With lesions distal to the carotid bifurcation, loss of sweating is not found or is confined to the medial aspect of the forehead and side of the nose (Morris et al). Retraction of the eyeball (enophthalmos), considered a component of the syndrome, is probably an illusion created by narrowing of the palpebral fissure.

Figure 13-10. Congenital Horner syndrome on the patient's left. In addition to the miosis and ptosis, the patient's left iris is gray in color (heterochromia iridis) and the right, brown.

Bilateral Horner syndrome is a rare occurrence; usually it is found in autonomic neuropathies and in high cervical cord transection. Although difficult to appreciate, bilateral miosis may be detected (using pupillometry or direct observation) by noting a pronounced lag in the redilation of the initially small pupils when light is withdrawn (Smith and Smith, 1999).

Stimulation or irritation of the sympathetic fibers, a rare phenomenon, produces the opposite clinical findings, that is, lid retraction, dilatation of the pupil, and apparent proptosis. Use is made of this phenomenon in the testing of the *ciliospinal pupillary reflex*, which is evoked by pinching the neck (afferent, C2, C3) and effecting pupillary enlargement through cervical efferent sympathetic fibers.

Extreme bilateral constriction of the pupils (miosis) is commonly observed with pontine lesions, presumably because of interruption of the descending pupillodilator fibers. Narcotic ingestion is a common cause of bilateral miosis in clinical practice. The elderly often acquire small pupils, particularly if medication drops for glaucoma are being used.

Interruption of the parasympathetic fibers causes an abnormal dilatation of the pupils (mydriasis), often with loss of pupillary light reflex; in cases of coma, the "blown" pupil (Hutchinson pupil) is the result of a midbrain lesion or direct compression of the oculomotor nerve (see Chap. 16). Other signs of oculomotor palsy are usually conjoined.

As an ancillary test to determine the cause of changes in the size of the pupils, the functional integrity of the sympathetic and parasympathetic nerve endings in the iris may be determined by the use of certain drugs detailed in the next section. Atropinics dilate the pupils by paralyzing the parasympathetic nerve endings. Physostigmine and pilocarpine constrict the pupils, the former by inhibiting cholinesterase activity at the neuromuscular junction and the latter by direct stimulation of the sphincter muscle of the iris. Epinephrine and phenylephrine dilate the pupils by direct stimulation of the dilator muscle. Morphine and other narcotics act centrally to constrict the pupils.

In an eye with intact sympathetic innervation, cocaine dilates the pupils by preventing the reabsorption of norepinephrine into the nerve endings. With Horner syndrome, the normal pupil will dilate but the miotic pupil will remain small, and a difference in size of 0.8 mm or greater is considered diagnostic (Kardon). More recently, apraclonidine, a weak direct alpha-agonist drug has been shown to reliably reverse the anisocoria of Horner syndrome and has become the preferred drug for testing. Normally apraclonidine does not exert significant dilatory effect, but with denervation hypersensitivity that accompanies Horner syndrome, the miotic pupil dilates in response to the drug. One drop (0.5 percent solution) is placed in each eye, the eyes are kept closed for 1 min and the drops are repeated 5 min later. Enlargement of the miotic pupil 30 to 45 min after instillation, especially with the affected pupil becoming larger than the unaffected one, is definite evidence of a Horner syndrome (Koc et al). Ptosis is also reduced, sometimes to a remarkable extent.

Table 13-6

CHARACTERISTICS OF ARGYLL ROBERTSON AND ADIE PUPILS

	SIZE AND SIDE	LIGHT REACTION	ACCOMMODATIVE REACTION	SPECIAL FEATURES
Argyll Robertson pupil	Small, irregular, asymmetrical	No	Yes	Syphilitic, but also diabetic
Adie tonic pupil	Initially fixed, later enlarged to medium size; bilateral	No or poor; only with sustained bright light	Yes, with tonic reaction	Tonic contraction to prolonged accommodation; associated limb areflexia

In diabetes mellitus, where autonomic spinal and cranial nerves are often involved, the pupils are affected in many cases. They are smaller than would be expected for age because of involvement of pupillodilator sympathetic fibers, and mydriasis may be excessive upon instillation of sympathomimetic drugs. The light reflex, mediated by parasympathetic fibers is also reduced, usually to a greater degree than constriction on accommodation (Smith and Smith, 1987).

Argyll Robertson Pupil (Table 13-6)

In almost all the forms of late syphilis, particularly tabes dorsalis, the pupils are bilaterally small, irregular, and unequal; they fail to react to light, although they do constrict with accommodation (light-near dissociation). They do not dilate properly in response to mydriatic drugs. Atrophy of the iris is associated in some cases. This is known as the *Argyll Robertson pupil*.

The exact localization of the lesion is not certain but it is generally believed to be in the tectum of the midbrain proximal to the oculomotor nuclei where the descending sympathetic pupillodilator fibers are in close proximity to the fibers subserving the pupillary light reflex. A similar pupillary abnormality has been observed in the meningoradiculitis of Lyme disease and in diabetes. A dissociation of the light reflex from the accommodation-convergence reaction is also part of the dorsal midbrain syndrome, although miosis, irregularity of pupils, and failure to respond to a mydriatic are usually not present with the latter.

Adie Tonic Pupil (Holmes-Adie Syndrome) (Table 13-6)

The *tonic* pupil, or *Adie pupil,* is caused by a degeneration of the ciliary ganglia and the postganglionic parasympathetic fibers that normally constrict the pupil and affect accommodation. The patient may complain of unilateral blurring of vision or photophobia, and may have noticed that one pupil is larger than the other. At the outset of the syndrome, the affected pupil is enlarged in ambient light and the reaction to light is absent or greatly reduced if tested in a customary manner, although the pupil will slowly constrict with prolonged bright light stimulation. Characteristically, there is a light-near dissociation, that is the Adie pupil responds better to near (accommodation) than it does to light. The most characteristic feature is that once the pupil has constricted, it tends to remain tonically constricted and redilates very slowly (the "tonic" aspect of the syndrome). Once dilated, the pupil remains in this state for many seconds, up to a minute or longer. Paralysis of a segment or segments of the pupillary sphincter is also characteristic of the syndrome; this segmental irregularity can be seen with the high plus lenses of an ophthalmoscope. The affected pupil constricts promptly in response to the common miotic drugs and, due to denervation supersensitivity, is unusually sensitive to a 0.1 percent solution of pilocarpine, a concentration that has only minimal effect on a normal pupil.

The tonic pupil usually appears during the third or fourth decade of life and is much more common in women than in men; it may be associated with absence of knee or ankle jerks (*Holmes-Adie syndrome*). It generally has a benign course and may represent a mild inflammatory ganglionopathy. In rare cases it is observed as an accompaniment of a diffuse ganglionopathy associated with Sjögren disease, other autoimmune or paraneoplastic illnesses, and following recovery from the Guillain-Barré syndrome.

Springing Pupil (Benign Unilateral Mydriasis)

This rare pupillary phenomenon is characterized by transient episodes of unilateral mydriasis for which no cause can be found (the *springing pupil*). Episodes of mydriasis, which are more common in women, last for minutes to days and may recur at random intervals. Oculomotor palsies and ptosis are not present. Sometimes the pupil is distorted into an ovoid or tadpole shape during the attack. Some patients complain of blurred vision and head pain on the side of the mydriasis, suggesting an atypical ophthalmoplegic migraine. In children, following a minor or major seizure, one pupil may remain dilated for a protracted period of time. The main consideration in an awake patient is that the cornea has inadvertently (or purposefully) been exposed to mydriatic solutions, among them bronchodilator drugs, scopolamine, and some organophosphate pesticides.

Differential Diagnosis of Anisocoria (Fig. 13-11)

It is important to recognize that 20 percent of normal persons show an inequality of 0.3 to 0.5 mm or more in pupillary diameter. *Physiologic anisocoria*, (also referred to as "simple anisocoria") generally has the same degree of asymmetry in size in low, ambient, and bright light conditions. It is often variable from day to day and even from hour to hour, and may have disappeared at the time of a second examination (Loewenfeld; Lam et al).

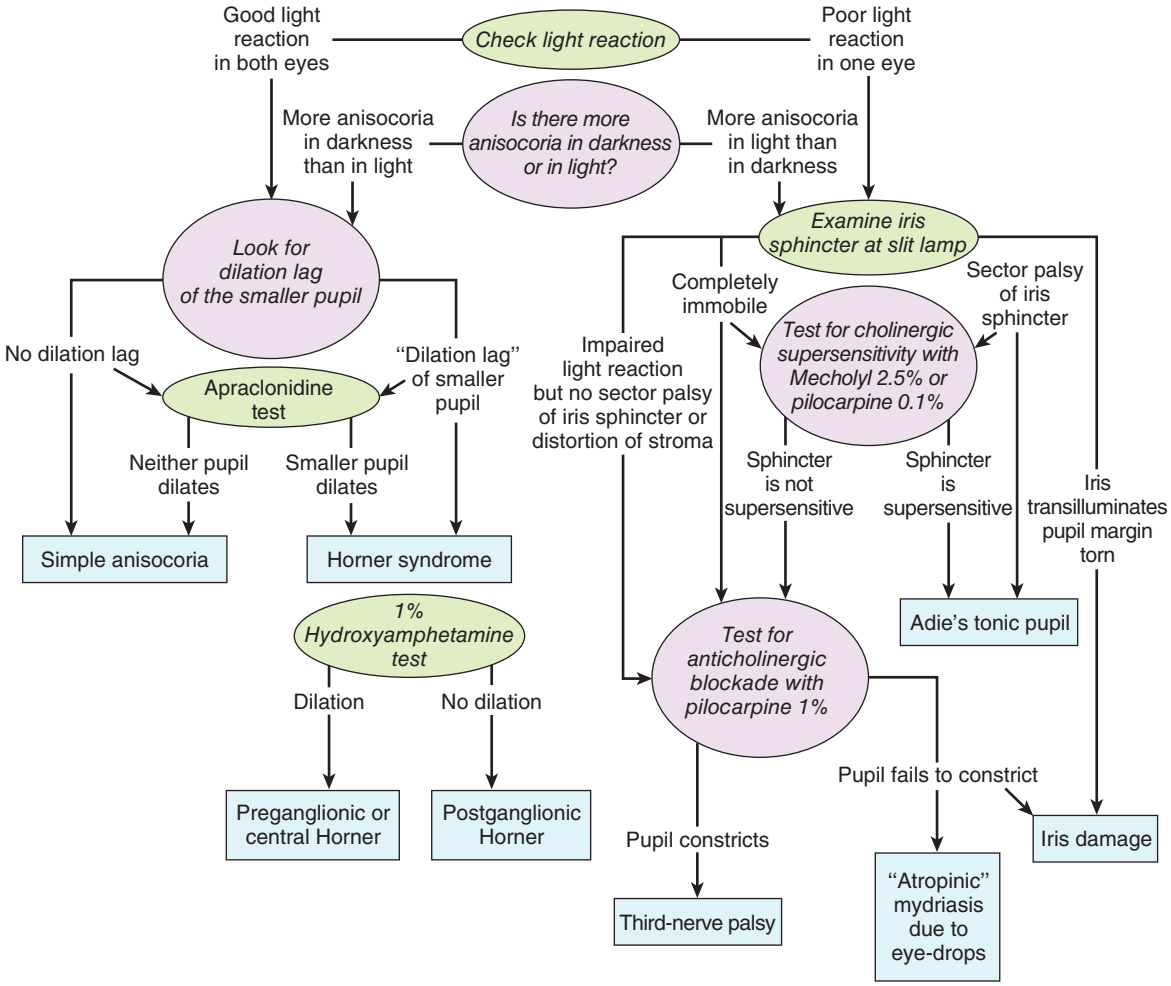

Figure 13-11. A schematic approach for sorting out the nature of anisocoria. (Reproduced with permission from Thompson S, Pilley SF. Unequal pupils. A flow chart for sorting out the anisocorias. *Surv Ophthalmol*. 1976;21(1):45-48)

The first step in the analysis of pupillary asymmetry is to determine which of the pupils is abnormal (Fig. 13-11). An abnormal larger pupil can be identified by a reduced direct and consensual light reaction. If the smaller pupil is causing asymmetry, it will fail to enlarge in response to shading both eyes, or reducing ambient light. More simply stated, light exaggerates the anisocoria caused by a third-nerve lesion, and darkness accentuates the anisocoria in the case of Horner syndrome.

A persistently small pupil always raises the question of Horner syndrome, a diagnosis that may be difficult if the ptosis is slight. In darkness, the Horner pupil dilates more slowly and to a lesser degree than the normal one because it lacks the pull of the dilator muscle (dilation lag). The diagnosis in the past had been confirmed by placing 1 or 2 drops of 2 to 10 percent cocaine in each eye; the Horner pupil dilates not at all or much less than the normal one. A more recently introduced approach that is more dependable and obviates the difficulties in obtaining cocaine is to apply the α-agonist apraclonidine to both eyes and observe the *reversal of miosis* on the affected side of Horner syndrome (the opposite effect to cocaine). Such responses to either drug will occur with a lesion at any point along the sympathetic pathway because lesions of the first- or second-order sympathetic neurons reduce the release of norepinephrine from third-order neurons. The reduction of neurotransmitter at the nerve endings in the ciliary dilator muscle greatly reduces the reuptake blocking effects of cocaine. If the subsequent (24 h after cocaine) application of the adrenergic mydriatic hydroxyamphetamine (1 percent) has no effect, the lesion can be localized to the postganglionic portion of the pathway as this drug releases any norepinephrine that may remain in the third-order neuron. Localization of the lesion to the central or preganglionic parts of the sympathetic pathway depends upon the associated symptoms and signs (see Chap. 26).

Drug-induced iridoplegia is another cause of anisocoria. Not infrequently, particularly among nurses and pharmacists, a mydriatic fixed pupil is the result of accidental or deliberate application of an atropinic or sympathomimetic drug. Failure of 1 percent pilocarpine drops to contract the pupil provides proof that the iris sphincter has been blocked by atropine or some other anticholinergic agent.

Deafness, Dizziness, and Disorders of Equilibrium

Sounds alert us to danger; spoken words are the universal means of communication; music is one of our most exalted aesthetic pleasures. The loss of hearing excludes the individual from many important external stimuli, and adjustment to this deprivation imposes profound challenges. Vestibular function ensures one's ability to stand steadily, stabilize eye position during head movement, and move about gracefully. Hence an understanding of the functions of the eighth cranial nerves and their derangements by disease is as much the concern of the neurologist as the otologist. As a general rule, the association of vertigo and deafness signifies a disease of the end organs for hearing and vestibular function, or of the eighth nerve. The precise locus of the disease is determined by tests of labyrinthine and auditory function, described further on, and by findings on neurologic examination and imaging studies that implicate the primary and secondary connections of the eighth cranial nerve.

ANATOMIC AND PHYSIOLOGIC CONSIDERATIONS

The vestibulocochlear, or eighth, cranial nerve has two separate components: the cochlear nerve, which subserves hearing, and the vestibular nerve, which is concerned with equilibrium (balance) and orientation of the body and eyes to the surrounding world. The acoustic division has its cell bodies in the spiral ganglion of the cochlea. This ganglion is composed of bipolar cells, the peripheral processes of which convey auditory impulses from the specialized neuroepithelium of the inner ear, the spiral organ of Corti. This is the end organ of hearing, wherein sound is transduced into nerve impulses. It consists of approximately 15,000 neuroepithelial (hair) cells that rest on the basilar membrane, which extends along the entire 2.5 turns of the cochlea. Projecting from the inner surface of each hair cell are approximately 60 very fine filaments, or stereocilia, which are embedded in the tectorial membrane, a gelatinous structure overlying the organ of Corti (Fig. 14-1). Sound causes the basilar membrane to vibrate; upward displacement of the basilar membrane bends the relatively fixed stereocilia and provides a stimulus adequate for activating the hair cells. The stimulus is then transmitted to the sensory fibers of the cochlear nerve, which emanate from the base of each hair cell.

Each afferent auditory fiber and the hair cell with which it is connected have a minimum threshold at one frequency ("characteristic" or "best" frequency). The basilar membrane vibrates at different frequencies throughout its length, according to the frequency of the sound stimulus. In this way, the fibers of the cochlear nerve respond to the full range of audible sound and can differentiate and resolve complexes of sounds.

The inner hair cells, numbering about 3,500, are of particular importance, because they synapse with approximately 90 percent of the 30,000 afferent cochlear neurons. The central processes of the primary auditory neurons constitute the cochlear division of the eighth cranial nerve. In addition, the nerve contains approximately 500 efferent fibers, which arise from the superior olivary nuclei (80 percent from the contralateral nucleus and 20 percent from the ipsilateral one) and synapse with the afferent neurons from the hair cells (Rasmussen). The function of this efferent pathway is not clear. It is thought to play some part in the auditory processing generated in the ear itself, possibly to enhance the sharpness of sound perception by a feedback mechanism. The eighth nerve also contains adrenergic postganglionic fibers that are derived from the cervical autonomic chain and innervate the cochlea and labyrinth. Their function has been the subject of investigation but remains unknown.

The semicircular ducts, utricle, and saccule, collectively comprising the vestibular apparatus, contain the sense organs for the detection of angular and linear acceleration. They are filled with an intracellular fluid, endolymph, and are surrounded by cerebrospinal fluid (CSF) (perilymph) within excavated spaces of the temporal bone, the semicircular canals. The latter term, canal, is used interchangeably with the proper description, ducts, to describe the vestibular apparatus.

The vestibular division of the eighth nerve arises from cells in the vestibular, or Scarpa ganglion, which is situated in the internal auditory meatus. This ganglion is also composed of bipolar cells, the peripheral processes of which emanate from hair cells of the specialized sensory epithelium of the labyrinthine apparatus. The sensory epithelium is located on hillocks (cristae) in the dilated openings or ampullae of the semicircular ducts, where they are

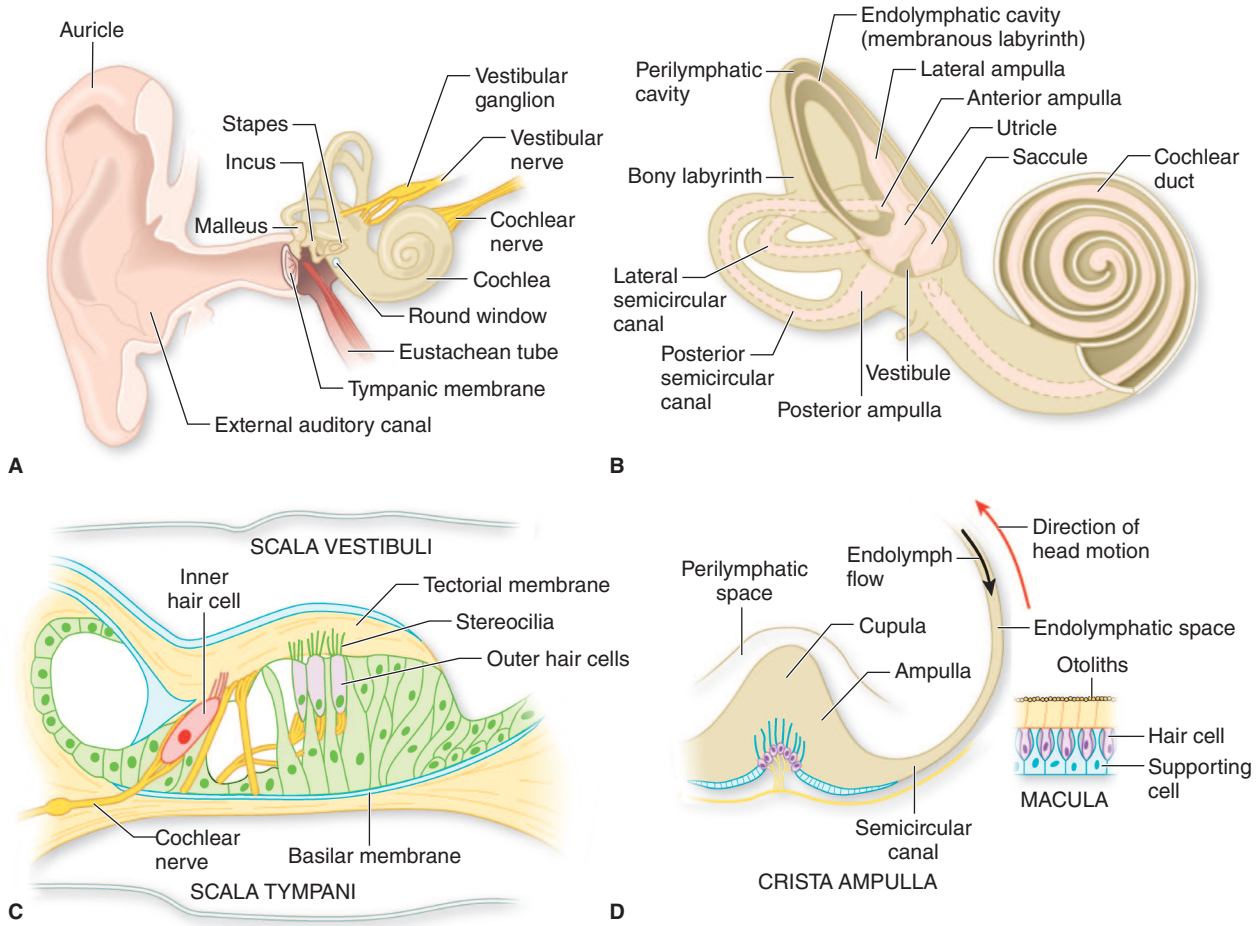

Figure 14-1. The auditory and vestibular systems. *A*. The right ear, viewed from the front, showing the external ear and auditory canal, the middle ear and its ossicles, and the inner ear. *B*. The main parts of the right inner ear, viewed from the front. The *perilymph* is located between the wall of the bony labyrinth and the membranous labyrinth. In the cochlea, the perilymphatic space takes the form of two coiled tubes—the *scala vestibuli* and *scala tympani*. The *endolymph* is located within the membranous labyrinth, which includes the three semicircular ducts, the utricle, and the saccule. *C*. The *organ of Corti*. This is the end organ of hearing; it consists of a single row of inner hair cells and three rows of outer hair cells. The stereocilia of the hair cells are embedded in the tectorial membrane. *D*. Diagram of a crista ampulla, the specialized sensory epithelium of a semicircular canal. The crista senses the displacement of endolymph during head rotation. The direction of head rotation is indicated by the *red arrow*, and endolymph flow by the *black arrow*. The *macula* is the locus of the sensory epithelium in the utricle and saccule. Note that the tips of the hair cells are in contact with the otoliths (calcareous material), which are embedded in a gelatinous mass called the *cupula*.

called the *cristae ampullaris*, and in the utricle and saccule, where they are called *maculae acusticae*. The hair cells of the maculae are covered by the *otolithic membrane*, or *otolith*, which is composed of calcium carbonate crystals embedded in a gelatinous matrix. The sensory cells of the cristae are covered by a sail-shaped gelatinous mass called a *cupula* (Fig. 14-1). The labyrinthine semicircular ducts transduce angular acceleration of the head, and the otoliths transduce linear acceleration, including the effects of gravity.

The central fibers from the cells of the spiral and vestibular ganglia travel in a common trunk, the eighth cranial nerve, which enters the cranial cavity through the internal auditory meatus (accompanied by the facial and intermediate nerves). They traverse the cerebellopontine angle and enter the lateral brain stem at the junction of the pons and medulla. Here the cochlear and vestibular fibers become separated. The cochlear fibers bifurcate and terminate almost at once in the dorsal and ventral cochlear nuclei. The fibers from each cochlear nucleus pursue separate crossing and ascending pathways; they pass to both inferior colliculi (mainly to the opposite side) via the lateral lemnisci. Secondary acoustic fibers project via the trapezoid body and lateral lemniscus to the medial geniculate bodies, a special component of the thalamic sensory system (Fig. 14-2). Some fibers terminate in the trapezoid body and superior olivary complex and subserve such reflex functions as auditory attention, sound localization, auditory startle, and oculopostural orientation to sound.

Both excitatory and inhibitory neurons are located at every level of these pathways. At all levels, there are strong commissural connections through which auditory signals come to be represented bilaterally in the cerebrum. From the medial geniculate bodies, fibers project to the cortex via the auditory radiations—relatively compact bundles that course ventrolaterally through the posterior

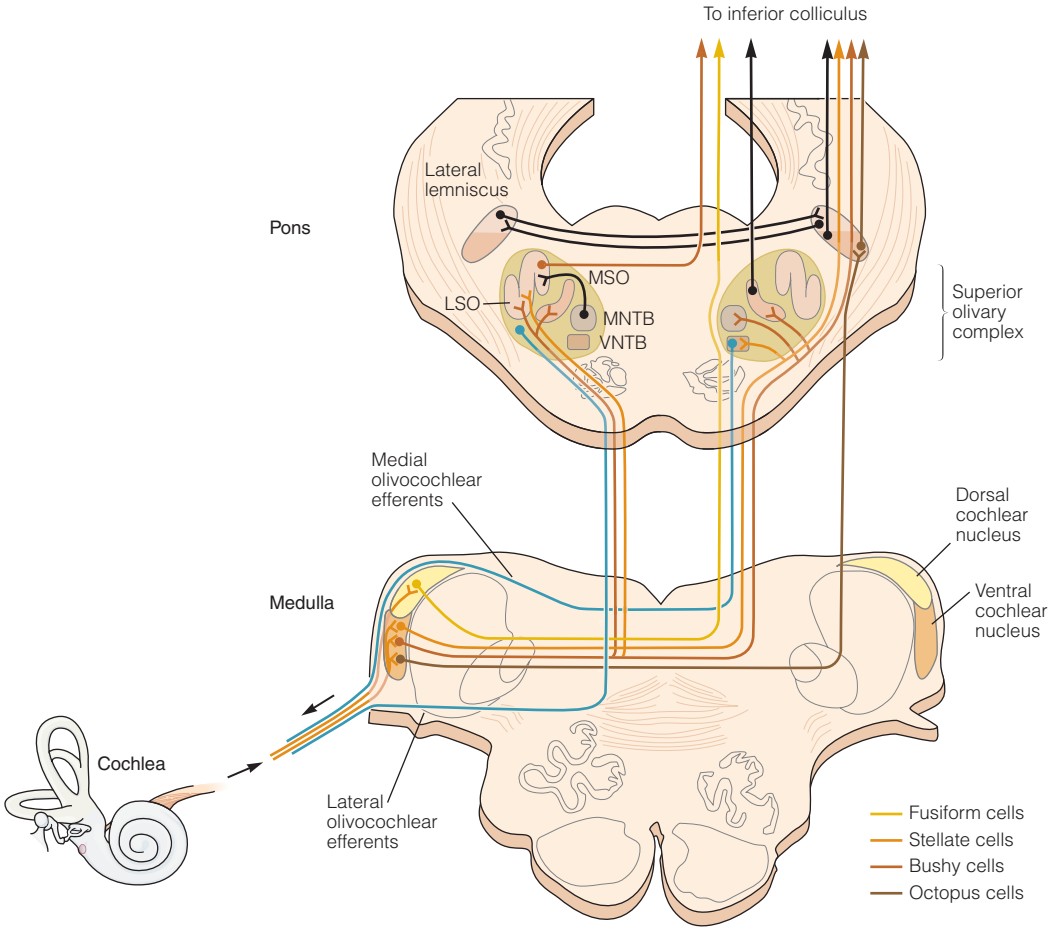

Figure 14-2. The ascending auditory pathways. The lower part of the diagram is a horizontal section through the upper medulla. (Reproduced with permission from Kandel,E R. *Principles of Neural Science*, 6th ed. New York, McGraw-Hill, 2021.)

parts of the putamen before dispersing and ending in the *transverse gyri of Heschl* and other auditory cortical areas (Tanaka et al).

The auditory cortical field comprises the superior temporal gyrus and the upper bank of the Sylvian fissure (Brodmann area 41; see Fig. 22-1), or *primary auditory cortex*, and the surrounding secondary and tertiary cortices in the adjacent temporal lobe. The latter are of particular importance in the interpretation of sound (Celesia) including spoken language. Bilateral temporal lobe lesions involving the geniculocortical fasciculi result in cortical deafness, although such lesions are rare. Unilateral cortical lesions do not affect hearing, but defects in function such as dichotic listening can be detected by specialized tests. At several levels of these ascending fiber systems, there is feedback to lower structures.

The vestibular fibers of the eighth nerve terminate in the four vestibular nuclei: superior (Bechterew), lateral (Deiters), medial (triangular, or Schwalbe), and inferior (spinal, or descending). In addition, some of the fibers from the semicircular ducts project directly to the cerebellum via the juxtarestiform body and terminate in the flocculonodular lobe and adjacent vermian cortex (consequently, these structures are called the "vestibulocerebellum," as noted in Chap. 5). Efferent fibers from this portion of the cerebellar cortex, in turn, project ipsilaterally to the vestibular nuclei and to the fastigial nucleus; fibers from the fastigial nucleus project back to the contralateral vestibular nuclei, again via the juxtarestiform body. Thus, each side of the cerebellum exerts an influence on the vestibular nuclei of both sides (Fig. 14-3; see also Chap. 5).

The lateral and medial vestibular nuclei also have important connections with the spinal cord, mainly via the uncrossed lateral vestibulospinal tract and the crossed and uncrossed medial vestibulospinal tracts (Fig. 14-4). Presumably, vestibular effects on posture are mediated via these pathways—the axial muscles being acted upon predominantly by the medial vestibulospinal tract and the limb muscles, by the lateral tract. The nuclei of the third, fourth, and sixth cranial nerves come under the influence of the vestibular nuclei through the projection pathways, mainly the medial longitudinal fasciculus described in Chap. 13. In addition, all the vestibular nuclei have

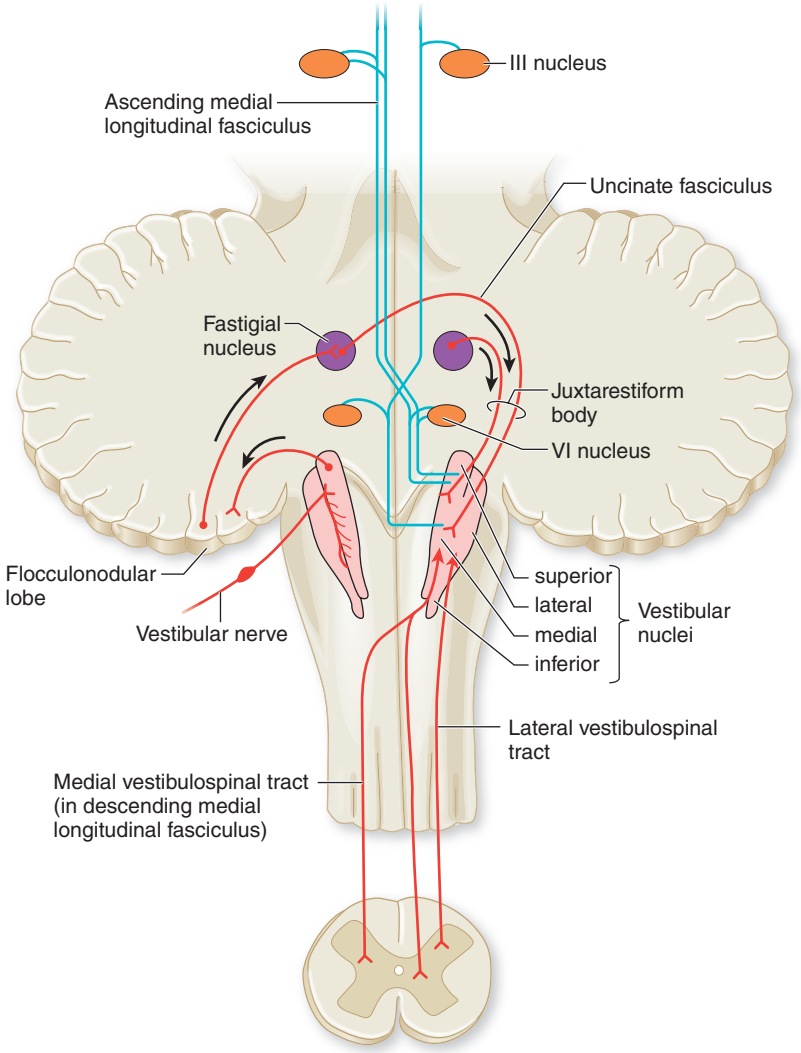

Figure 14-3. A simplified diagram of the vestibulocerebellar and vestibulospinal pathways and connections between vestibular and ocular motor nuclei. The medial longitudinal fasciculi (*blue lines*) are the main pathways for ascending vestibular impulses. (See text and also Fig. 14-1.)

afferent and efferent connections with the pontine reticular formation (Fig. 14-4). The latter connections subserve vestibuloocular and vestibulospinal reflexes that are essential for clear vision and stable posture.

Finally, there are projections from the vestibular nuclei to the cerebral cortex, specifically to the regions of the intraparietal sulcus and superior Sylvian gyrus. In the monkey, these projections are almost exclusively contralateral, terminating near the "face area" of the first somatosensory cortex (area 2 of Brodmann). Lesions in the posterior insula impair the sense of verticality, body orientation, and movement. Whether the vestibular nuclei project to the thalamus in humans is not entirely settled; most anatomists indicate that there are no such direct connections.

These brief remarks convey some notion of the complexity of the anatomic and functional organization of the vestibular system (for a full discussion, see the monographs of Brodal and of Baloh and Honrubia). In view of the proximity of cochlear and vestibular elements, it is understandable that acoustic and vestibular functions are often affected together in the course of disease although each may also be affected separately.

DEAFNESS, TINNITUS, AND OTHER DISORDERS OF AUDITORY PERCEPTION

Deafness

Figures from a National Health Survey (National Institute on Deafness and Other Communication Disorders) indicated that approximately 28 million Americans of all ages had a significant degree of deafness and that 2 million were profoundly deaf. More than one-third of persons older

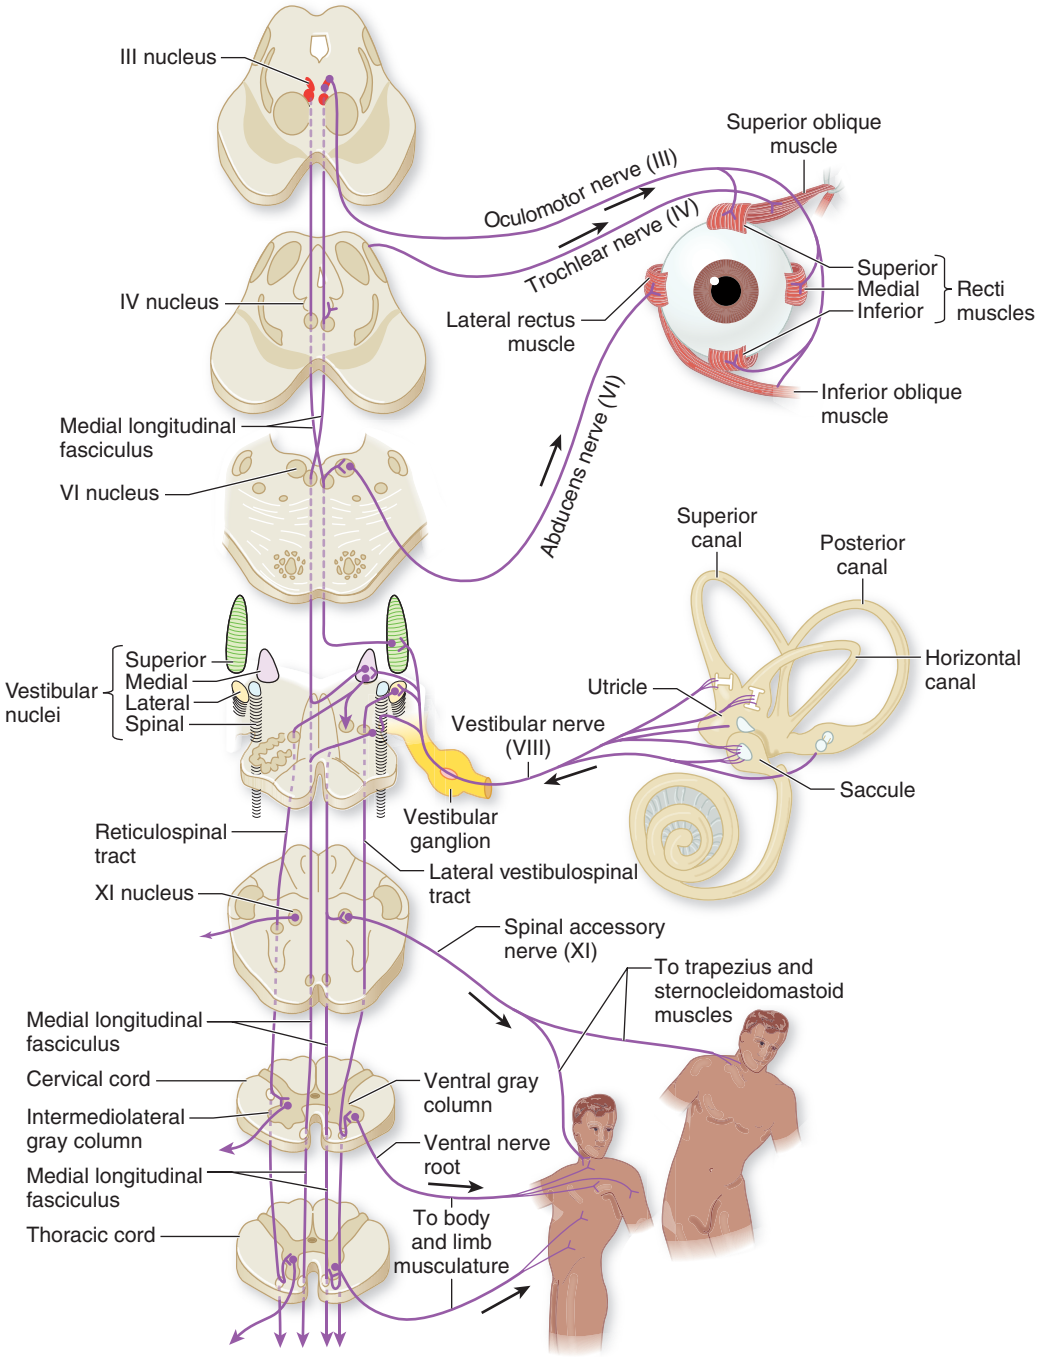

Figure 14-4. The vestibular reflex pathways. (Reproduced by permission from House EL: *A Systematic Approach to Neuroscience*. New York, McGraw-Hill, 1979.)

than age 75 years were handicapped to some extent by hearing loss.

Deafness is of three general types: (1) *Conductive deafness*, caused by a defect in the mechanism by which sound is transformed (amplified) and conducted to the cochlea. These are disorders of the external or middle ear—obstruction of the external auditory canal by atresia or cerumen, thickening of the tympanic membrane from infection or trauma, chronic otitis media, otosclerosis (the main cause of deafness in early adult life), and obstruction of the eustachian tube. (2) *Sensorineural deafness* (also called, imprecisely, *nerve deafness*), which is caused by disease of the cochlea or of the cochlear division of the eighth cranial nerve. Although cochlear and eighth nerve causes of deafness have conventionally been combined in one (sensorineural) category, the neurologist recognizes that the

symptoms and causes of the two are quite different and that it is more practical to think of them as cochlear (end organ) and retrocochlear (nerve) deafness. (3) *Central deafness*, caused by lesions of the cochlear nuclei and their connections with the primary auditory receptive areas in the temporal lobes. For example, complete tone deafness, which is probably inherited as an autosomal dominant trait, is a central disorder.

The two peripheral forms of deafness—conductive and sensorineural deafness—must be distinguished from each other, because important remedial measures are available, particularly for the former. In differentiating them, the tuning-fork tests are often of value. When a vibrating fork, preferably of 512-Hz frequency, is held about 2.5 cm from the ear (test for air conduction), sound waves can be appreciated only as they are transmitted through the middle ear; they will be reduced with disease in this location. When the vibrating fork is applied to the skull (test for bone conduction), the sound waves are conveyed directly to the cochlea, without intervention of the sound-transmission apparatus of the middle ear, and will therefore not be reduced or lost in outer or middle ear disease. Normally air conduction is better than bone conduction, and the sound transmitted though the air is appreciated for about twice as long as that passing through the bone.

These principles form the basis for several simple tests of auditory function. In the *Weber test*, the vibrating fork is applied to the forehead in the midline (or to a central incisor). A normal person hears the bone-conducted sound equally in both ears. In nerve deafness, the sound is localized to the normal ear for the reasons noted above; in conductive deafness, the sound is perceived as louder in the affected ear because interference from ambient sounds is muted on the affected side. In the *Rinne test*, the fork is applied to the mastoid process. At the moment, the patient indicates that the sound ceases, the fork is held at the auditory meatus. In middle ear deafness, the sound cannot be heard by air conduction after bone conduction has ceased (abnormal Rinne test). In nerve deafness, the reverse may be true (normal Rinne test), but more saliently, both air and bone conduction are quantitatively decreased. The *Schwabach test* consists of comparing the patient's bone conduction with that of the normal examiner.

In general, early sensorineural deafness is characterized by a partial loss of perception of high-pitched sounds and conductive deafness by a partial loss of low-pitched sounds. This can be ascertained by the use of tuning forks of different frequencies but most accurately by the use of an audiometer and the construction of an audiogram, which reveals the entire range of hearing at a glance. The audiogram is an essential test in the evaluation of hearing loss and the point of departure for subsequent diagnostic evaluation. A ticking watch (infrequently found on doctor's wrists or pockets any longer) or rubbing the patient's hair together near the ear can be used as a surrogate test of gross hearing for the bedside, but these maneuvers emit mostly high-frequency sound and will not detect low-frequency conductive loss.

A cochlear type of hearing loss can be recognized by the presence of the symptoms of recruitment and diplacusis. *Recruitment* refers to a heightened perception of loudness once the threshold for hearing has been exceeded; thus, the patient's retort "You don't have to shout" when the examiner raises his voice (see below). *Diplacusis* refers to a defect in frequency discrimination that is manifest by a lack of clarity of spoken syllables or by the perception that music is out of tune and unpleasant (described by patients as a "mushiness" of sounds).

Because each cochlear nucleus is connected with the cortex of both temporal lobes, hearing is unaffected by unilateral cerebral lesions as already mentioned. Deafness caused by brain stem lesions is observed only rarely, as a massive lesion is required to interrupt both the crossed and uncrossed projections from the cochlear nuclei—so massive, as a rule, that other neurologic abnormalities usually make the testing of hearing impossible.

Special Audiologic Procedures

A number of special tests prove to be helpful in distinguishing cochlear from retrocochlear (nerve) lesions. Although an absolute distinction cannot be made on the basis of any one test, the results taken together (particularly loudness recruitment, speech discrimination, and tone decay) make it possible to predict the site of the lesion with considerable accuracy. These tests, usually carried out by an otologist or audiologist, include the following:

1. *Loudness recruitment.* This phenomenon, mentioned above, is thought to depend on the selective destruction of low-intensity elements subserved by the external hair cells of the organ of Corti. The high-intensity elements are preserved, so that loudness is appreciated only at high intensities. In testing for loudness recruitment, the difference in hearing between the two ears is estimated and the loudness of the pure-tone stimulus of a given frequency delivered to each ear is then increased by regular increments. In *nonrecruiting deafness* (characteristic of a nerve lesion), the original difference in hearing persists in all comparisons of loudness, since both high- and low-intensity fibers are affected. In *recruiting deafness* (which occurs with a lesion in the organ of Corti—for example, Ménière disease, the more affected ear gains in loudness and may finally be equal to the better one). In bilateral disease, recruitment is assessed by the intensity of the stimulus that causes discomfort, about 100 dB (decibels) in normal persons.
2. *Speech discrimination*. This consists of presenting the patient with a list of 50 phonetically balanced monosyllabic words (e.g., *thin, sin*) at suprathreshold levels. The speech-discrimination score is the percentage of the 50 words correctly repeated by the patient. Marked reduction (less than 30 percent) in the speech-discrimination scores is characteristic of eighth nerve (retrocochlear) lesions.
3. *Audiometry.* Continuous and interrupted tones are presented at various frequencies. Tracings are made,

measuring the increments by which the patient must increase the volume in order to continue to hear the continuous and interrupted tones just above threshold. Clinically, analysis has shown that there are four basic configurations, referred to as types I to IV Békésy audiograms. Type III or IV usually indicate the presence of a retrocochlear lesion, the type II response points to a lesion of the cochlea itself, and type I is considered normal. Related tests, such as threshold tone decay and the short increment sensitivity index, were formerly used to a greater extent than they are currently; therefore, we have not described them here.

4. *Brain stem auditory evoked potentials, or response, see* Chap. 2 (*BAEP, or BAER*). This method provides very refined information as to the integrity of primary and secondary auditory pathways from the cochlea to the superior colliculus. It has the advantage of being accurate in uncooperative and even comatose patients as well as infants who cannot cooperate with audiometry. It is of some value in detecting small acoustic and vestibular schwannomas; in localizing brain stem lesions such as those caused by demyelination; in corroborating the state of brain death, in which all waves, except occasionally the eighth nerve (wave I), responses are abolished; and in assessing sensorineural damage in neonates who have had meningitis or been exposed to ototoxic medications.
5. The *acoustic-stapedial reflex* can be used as a measure of conduction in the auditory (and the facial) nerve. This reflex normally protects the cochleas from excessively loud sound. When the sound of intensity greater than 70 to 90 dB above threshold hearing reaches the inner ear, the stapedius muscles on both sides contract reflexively, relaxing the tympanum and offering impedance to further sound. It may be tested by insufflating the external auditory canal with pressured air and measuring the change in pressure that follows immediately after a loud sound. The response is muted in patients with conductive hearing loss because of the mechanical restriction of ossicular movement, but otherwise the test is sensitive to cochlear and acoustic nerve lesions.

Tinnitus

This is the other major manifestation of cochlear and auditory disease. Tinnitus aurium literally means "ringing of the ears" (Latin tinnire, "to ring or jingle") and refers to sounds originating in the ear, although they need not be ringing in character. Buzzing, humming, whistling, roaring, hissing, clicking, chirping, or pulse-like sounds are also reported. Some otologists use the term tinnitus cerebri to distinguish other head noises from those that arise in the ear, but the term tinnitus when used without qualification refers to tinnitus aurium.

Tinnitus is a remarkably common symptom, affecting more than 37 million Americans, according to Marion and Cevette. It may be defined as any sensation of sound for which there is no source outside the individual. Two basic types are recognized, *tonal* and *nontonal* (nonvibratory and vibratory, in the terminology of Fowler). The tonal type is by far the more common and is what is meant when the unqualified term *tinnitus* is used. It is also called *subjective tinnitus*, because it can be heard only by the patient. The nontonal form is sometimes *objective*, in the sense that under certain conditions, the tinnitus can be heard by the examiner as well as by the patient. In either case, whether tinnitus is produced in the inner ear or in some other part of the head and neck, sensory auditory neurons must be stimulated, for only the auditory neural pathways can transmit an impulse that will be perceived as sound.

According to a large survey conducted by Stouffer and Tyler, about one-third of patients report that persistent tinnitus is unilateral; the others experience it bilaterally or with a lateralized predominance. Many more patients have brief episodes of tinnitus and are concerned enough to bring the symptom to the attention of a physician; some are produced by loud noises or by the ingestion of common drugs, such as aspirin but most such cases are transient and innocuous.

Nontonal and Pulsatile Tinnitus

These head noises are mechanical in origin and are conducted to the inner ear through the various hard or soft structures or the fluid or gaseous media of the body. They are not caused by a primary dysfunction of the auditory neural mechanism but have their origin in the contraction of muscles of the eustachian tube, middle ear (stapedius, tensor tympani), palate (palatal myoclonus), or pharynx (muscles of deglutition), or in vascular structures near the ear. One of the common forms of subjective tinnitus is a self-audible bruit, the source of which is the turbulent flow of blood in the large vessels of the neck or in an arteriovenous malformation or glomus jugulare tumor. The sound is pulsatile and appreciated by the patient as emanating from one side of the cranium, but it is only sometimes detectable by the examiner.

Other noteworthy causes of pulsatile tinnitus are pseudotumor cerebri or raised intracranial pressure of any type, in which the noise is attributed to a pressure gradient between the cranial and cervical venous structures and the resulting venous turbulence; thyroid enlargement with increased venous blood flow. Other causes include intracranial aneurysm; aortic stenosis; and vascular tumors of the skull, such as histiocytosis X. In the case of a vascular tumor or a large arteriovenous malformation, the examiner may hear the bruit over the mastoid process. Obliteration of the sound by gentle compression of the jugular vein on the symptomatic side is a useful indicator of a venous origin. It has been suggested that diseases that raise the cardiac output markedly (such as severe anemia) may cause pulsatile tinnitus. A flow-related carotid bruit—originating from fibromuscular dysplasia, atherosclerotic stenosis, carotid dissection, and enhanced blood flow in a vessel contralateral to a carotid occlusion—has also been incriminated. However, carotid artery stenosis infrequently causes a self-audible bruit. The same holds for diseases of the vertebral artery. In 100 consecutive cases of pulsatile tinnitus collected

by Sismanis and Smoker, the most common causes were intracranial hypertension, glomus tumors, and carotid disease. One must be cautious in overinterpreting this symptom, because normal persons can hear their pulse when lying with one ear on a pillow, and introspective individuals may become excessively worried about it. We have suggested that normal variations in the size and location of the jugular bulb may explain some benign cases (Adler and Ropper).

Another type of tinnitus is the rhythmic clicking of palatal myoclonus caused by intermittent contraction of the tensor tympani or stapedius muscles, termed *middle ear myoclonus* as discussed in Chap. 4 with other forms of tremor. This process has been treated with a variety of medications, including diazepam or, in extremely annoying cases, by section of the offending muscles (Badia et al). Clicking noises caused by palatal myoclonus have also been successfully treated by the injection of botulinum toxin into the soft palatal tissues (Jamieson et al).

In the unusual process of superior canal dehiscence (Llyod Minor syndrome) there are odd auditory experiences including enhanced sensitivity to one's own voice (autophony) and heart sounds, and vertigo induced by sound (Tullio phenomenon). This condition is discussed further on.

Tonal Tinnitus

This is the common persistent form of tinnitus that arises in the middle or inner ear and is associated in a proportion of patients with cochlear damage. For this reason, the first step in analysis after the clinical examination is an audiogram. Under ideal acoustic circumstances (in a soundproof room having an ambient noise level of 18 dB or less), slight tinnitus is present in 80 to 90 percent of adults ("physiologic tinnitus"). The ambient noise level in ordinary living conditions usually exceeds 35 dB and is of sufficient intensity to mask physiologic tinnitus. Tinnitus because of disease of the middle ear and auditory neural mechanisms may also be masked by environmental noise and hence becomes troublesome only in quiet surroundings—at night, in the country, etc.

Most often, subjective tinnitus signifies a disorder of the tympanic membrane, ossicles of the middle ear, inner ear, or eighth nerve. As already remarked, a majority of patients who complain of persistent tinnitus have some degree of deafness as well. Tinnitus that is localized to one ear and is described as having a tonal character (such as a ringing, bell-like, or like a high and steady musical tone) is particularly likely to be associated with impairment of cochlear or neural function. Tinnitus associated with sensorineural hearing loss of high frequency is often described as "chirping," and that of low frequency as "whooshing" or blowing (Marion and Cevette). Tinnitus as a result of middle ear disease (e.g., otosclerosis) tends to be more constant than the tinnitus of sensorineural disorders; it is of variable intensity and lower pitch and is characterized by clicks, pops, and rushing sounds.

As remarked above, the pitch of tinnitus associated with a conductive hearing loss is generally of low frequency (median frequency of 490 Hz, with a range of 90 to 1,450 Hz). That which accompanies sensorineural loss is higher (median frequency of 3,900 Hz, with a range of 545 to 7,500 Hz). This rule does not apply to Ménière disease, in which the tinnitus is usually described as a low-pitched whoosh, buzz, or roar (median frequency of 320 Hz, with a range of 90 to 900 Hz), thus resembling the tinnitus that accompanies a conductive rather than a sensorineural hearing loss (Nodar and Graham). The tinnitus of Ménière disease often fluctuates in intensity, like the hearing loss.

The mechanism of tonal tinnitus has not been established although a number of theories have been postulated. One supposition attributes tinnitus to an overactivity or disinhibition of hair cells adjacent to a part of the cochlea that has been injured. Another postulates a decoupling of hair cells from the tectorial membrane. Yet a third theory is based on the finding of an abnormal discharge pattern of afferent neurons, attributed to ephaptic transmission between nerve fibers that have been damaged by vascular compression (Møller).

Treatment

Relief of unilateral tinnitus in certain selected cases has reportedly been achieved by vascular decompression of the eighth nerve in a manner comparable to hemifacial spasm, superior oblique myokymia, and some cases of trigeminal neuralgia (Jannetta). However, for most forms of tinnitus, there is little effective treatment (see the review by Lockwood et al). Many patients become reconciled to its presence once the benign nature of the disorder is explained to them. It is possible to fit some patients with a special audiologic instrument, like a hearing aid, that masks the tinnitus by delivering a sound of like pitch and intensity. Patients who are likely to benefit can be identified during the audiogram by noting improvement in tinnitus with the application of superimposed tones. Also, a hearing aid that improves audition may suppress or diminish tinnitus. Antiepileptic drugs and tocainide hydrochloride have been suggested as treatments, but have not been helpful in our experience. Some success in reducing the symptom has been achieved with small doses of amitriptyline at night. In extreme circumstances, some groups have experimented with implanted stimulators on the temporal cortex.

If bilateral tinnitus is the basis of persistent complaints, one often discovers that the patient is anxious or depressed, in which case a careful history will reveal the other features of these disorders. Treatment then must be directed to the psychiatric symptoms. In their review, Lockwood and colleagues suggest that all patients with undifferentiated tinnitus be protected from loud sounds and ototoxic drugs (the main ones being aminoglycoside antibiotics, certain loop diuretics, neurotoxic chemotherapies such as cisplatin, and perhaps high doses of aspirin). The American Tinnitus Association website may be helpful to some patients as a source of reassurance (http://www.ata.org).

Tinnitus that is unilateral, pulsatile, or fluctuating and associated with vertigo should be investigated by appropriate neurologic and audiologic studies.

Other Disorders of Auditory Perception

On occasion, pontine lesions may be accompanied by complex auditory illusions, sometimes with the qualities of true hallucinations (pontine auditory hallucinosis) as in the patients, one of whom was ours, described by Cascino and Adams. These consist of alternating musical tones, like those of an organ; a jumble of sound, like a symphony orchestra tuning up; or siren-like or buzzing sounds, like a swarm of bees. These auditory sense disturbances are more complex than neurosensory tinnitus but less formed than temporal lobe hallucinations. They are usually associated with impairment of hearing in one or both ears and other neurologic signs related to the pontine lesion. An unpleasant degree of hyperacusis in the contralateral ear has also been reported with upper pontine tegmental lesions. BAEPs reveal intact cochlear, auditory nerve, and cochlear nuclear responses. As in the case of peduncular visual hallucinosis, patients realize that the sounds are unreal, that is, they have insight into their illusory nature.

Another well-recognized but inexplicable type of auditory hallucinosis occurs in elderly patients with long-standing neurosensory deafness. All day long, or for several hours at a time, they hear songs, symphonies, choral music, or familiar or unfamiliar melodies interrupted only by other ambient noise, sleep, or conversations that engage their attention. The "choice" of music has been referable, not surprisingly, to the individual's earlier life. Our patients, like those reported by Hammeke and colleagues, have been neither depressed nor demented, and antiepileptic and neuroleptic drugs have had no effect. Activation of the right auditory cortex on single-photon emission tomography (SPECT) and magnetoencephalography (Kasai and colleagues). The problem may be analogous to the one of Charles Bonnet syndrome, in which elderly individuals with failing vision experience rich visual hallucinations. We find it puzzling that pontine lesions are implicated in some cases, as mentioned above.

Complex auditory hallucinations may occur as part of temporal lobe seizures arising from a variety of temporal lobe lesions. Conversely, seizures may be induced by musical sounds as well as by other auditory stimuli. These topics are discussed in Chaps. 15 and 21. Paracusis, a condition in which a sound, tune, or a voice is repeated for several seconds, is also a cerebral auditory phenomenon, similar in a sense to the visual phenomenon of palinopsia. The precise anatomy is unknown. The auditory hallucinations of schizophrenia have been extensively studied in relation to activity of the temporal lobes, as discussed in Chap. 49.

Another phenomenon commented on here casually is the phenomenon of repeatedly experiencing parts of a recently heard song or melody, an "ear worm." The problem is self-limiting but occasionally becomes a chronic medical complaint akin to auditory hallucinosis, probably an obsessive complaint but rarely attributed, on uncertain grounds, to temporal lobe seizures.

Middle Ear Deafness

The common causes are otosclerosis, otitis media, and trauma. Of the various types of progressive conductive deafness, otosclerosis is the most frequent, being the cause of about half the cases of bilateral (but not necessarily symmetrical) deafness that have their onset in early adult life, usually in the second or third decade. A predilection to otosclerosis is transmitted as an autosomal dominant trait with variable penetrance. Pathologically, it is characterized by an overgrowth of labyrinthine capsular bone around the oval window, leading to progressive fixation of the stapes. The remarkable advances in microotologic surgery designed to mobilize or replace the stapes and to reconstruct the ossicular chain, have greatly altered the prognosis in this disease; significant improvement in hearing can now be achieved in the majority of patients.

The use of antibiotic drugs has markedly reduced the incidence of purulent otitis media, both the acute and chronic forms, which in former years were common causes of conductive hearing loss in children. Repeated attacks of serous otitis media are, however, still an important cause of this type of deafness.

Fractures of the temporal bone, particularly those in the long axis of the petrous pyramid, may damage middle ear structures; frequently, there is bleeding into the middle ear as well, and a ruptured tympanic membrane. Transverse fractures through the petrous pyramid are more likely to damage both the cochlear–labyrinthine structures and the facial nerve. Other diseases of the temporal bone—such as Paget disease, fibrous dysplasia, and osteopetrosis—may impair hearing by compression of the cochlear nerve. It should be noted that rupture of the tympanic membrane, as for example from blast injury does not cause much hearing loss; in the case of a blast, the cause of reduced hearing is cochlear damage.

Sensorineural Deafness

This has many causes. The common high-frequency sensorineural type of hearing loss in the aged (presbycusis) is probably a result of neuronal degeneration, that is, progressive loss of spiral ganglion neurons (Suga and Lindsay). Explosions or intense, sustained noise in certain industrial settings or from gun blasts or even rock music may result in a high-tone sensorineural hearing loss from cochlear damage. Certain antimicrobial drugs (namely, the aminoglycoside group and vancomycin) damage cochlear hair cells and, after prolonged use, can result in severe hearing loss. If these drugs have been used to treat bacterial meningitis, it may be difficult to determine whether the antibiotic or the infection is the cause. A variety of other commonly used drugs are ototoxic, including certain neurotoxic cancer chemotherapies, especially platinum-containing drugs, usually in a dose-dependent fashion (see Nadol). Quinine and acetylsalicylic acid may impair sensorineural function transiently.

The cochlea of a neonate may have been damaged in utero by rubella in the pregnant mother. Mumps, acute purulent meningitis (particularly from *Pneumococcus* and *Haemophilus*), or chronic infection spreading from the middle to the inner ear may cause nerve deafness in childhood. The meningeal infection spreads along the cochlear aqueduct, a structure that connects the CSF space with the perilymph of the cochlea. Measles vaccination, *Mycoplasma pneumoniae* infection, and scarlet fever have been associated with acute deafness, with or without vestibular symptoms. It is uncertain whether the deafness in these cases is due to direct infection of the cochlea or represents an autoimmune reaction directed to the inner ear. Also, the inner ear contains melanocytes, and their involvement in Vogt-Koyanagi-Harada disease adds dysacusis, tinnitus, and sensorineural deafness to the usual manifestations of vitiligo of the eyebrows, poliosis (depigmented forelock of hair), iritis, retinal depigmentation, and recurrent meningitis. Meningeal hemosiderosis, a rare process that results from repeated bouts of subarachnoid hemorrhage, also causes eighth nerve damage and deafness, presumably as a toxic effect of iron deposition in the meninges adjacent to the nerve. Cases of acute sensorineural hearing loss or reduced acuity have occurred following CSF drainage or lumbar puncture, likely either the result of traction on the cochlear nerve due to pressure gradients, or endolymphatic hydrops (see further on) through a patent cochlear aqueduct. Most cases are transient.

Episodic deafness in one ear, even without vertigo, proves in most instances to be the result of *Ménière disease* (see further on).

Otologists have described a progressive sensorineural type of hearing loss as a late manifestation of congenital syphilis, sometimes occurring despite prior treatment with adequate doses of penicillin. It has been claimed that the long-term administration of steroids may be useful in such cases. The pathologic basis of the hearing loss has not been determined and the causal relationship to congenital syphilis remains to be established.

The *auditory* nerve may be involved by tumors of the cerebellopontine angle or by mycotic, lymphomatous, carcinomatous, tuberculous, Listeria, melioidosis, or other types of chronic meningitis and rarely, in sarcoidosis. Lymphomatous meningitis has a particular predilection to cause unilateral hearing loss; we have seen several such cases in which no other cranial nerves were infiltrated. Carcinomatous meningitis may do the same but almost always in the context of other cranial and spinal nerve palsies (see Chap. 31). Of the solid tumors, the ones that involve the auditory nerve most frequently are schwannomas, neurofibromas, meningiomas, dermoids, and metastatic carcinoma. In neurofibromatosis type II, the involvement by vestibular and acoustic schwannomas is typically bilateral as discussed in Chap. 37. Unilateral deafness may also result from demyelinative plaques, infarction, or tumor involving the cochlear nerve fibers or nuclei in the brain stem. Rarely, deafness is the result of bilateral lesions of the temporal lobes (Chap. 22). The condition called *pure word deafness*, a type of aphasia, is also caused by left temporal lobe disease; despite normal pure-tone perception and audiometry and normal brain stem auditory evoked potentials, spoken words cannot be understood. This condition is discussed in Chap. 23.

Sudden Idiopathic Hearing Loss

Of equal concern to neurologists is the onset in an adult of sudden and permanent unilateral hearing loss without vertigo and lacking all the other features of Ménière disease. Little is known about the pathogenesis of this (idiopathic) syndrome. A vascular causation (occlusion of the cochlear artery or presumed arterial spasm in the course of migraine) has been postulated, on uncertain grounds. We do not know how to interpret the findings of DeFelice and colleagues as well as others, who report that the posterior communicating arteries are absent in a disproportionate number of patients with sudden hearing loss. A few cases are due to complicated herpes zoster and mumps parotitis, but aside from these, there is no proven relationship to the usual viral respiratory infections. An immune-mediated cause may also be operative in some patients, a hypothesis that has led some neurologists and otologists to treat such patients with a brief course of orally administered corticosteroids. In a prospective report of the natural history of 88 cases of acute sensorineural hearing loss, two-thirds recovered their hearing completely within a few days or a week or two (Mattox and Simmons). In the remaining patients, recovery was much slower and often incomplete; in this latter group, the hearing loss was predominantly for high tones and in some cases was associated with varying degrees of vertigo and hypoactive caloric responses.

The same problem has been reported to follow cardiopulmonary bypass surgery and has been ascribed, without confirmation, to microemboli. Less often, such an event follows general anesthesia for nonotologic surgery (Evan et al); the pathogenesis is obscure. None of the currently popular therapeutic agents—such as histamine, calcium channel blockers, anticoagulants, inhalation of carbogen (30 percent carbon dioxide), and corticosteroids—seems to clearly affect the outcome of sudden unilateral or bilateral deafness without vertigo. Nonetheless, as mentioned, corticosteroids are often prescribed, based on the uncertain theory that this illness is analogous to an immune form of vestibular neuritis.

Hereditary Deafness (Table 14-1)

A large number of *genetically determined syndromes* that feature a neural or conductive type of deafness—some congenital and others having their onset in childhood or early adult life—have come to light (see articles by Tekin et al and Gorlin et al). The majority of cases of congenital deafness are inherited as an autosomal recessive trait with no other syndromic features. In most of the remainder, inheritance is autosomal dominant in type and in a small number, it is sex linked.

The singular genetic advance in this field has been the identification in recessive nonsyndromic deafness of a mutation of the connexin-26 gene on chromosome 13

Table 14-1

REPRESENTATIVE GENETIC FORMS OF HEARING LOSS

DESIGNATION	INHERITANCE	GENE DEFECT	TYPE OF HEARING LOSS	ASSOCIATED DEFECTS	FREQUENCY
I. Nonsyndromic					
DFN A	AD	GJB2 (connexin), MYO7, USH, SLC26A4, and allelic variants of these genes; GJB2 accounts for half of cases in most populations (AD)	Progressive sensorineural	Same loci as cause syndromic hearing loss such as Usher and Pendred syndromes, as noted below; 80% of hereditary deafness from recessive gene	Accounts for half of nonsyndromic recessive deafness (connexin)
DFN B	AR (most common)	—	—	—	—
DFN X	X-linked	—	—	—	—
Familial otosclerosis	AD with reduced penetrance	COLIA1	Conductive	—	—
II. Syndromic					
Waardenburg	AD	PAX3 and some due to SOX, WSIV (transcription factors)	Variable sensorineural	Dystopic canthi, heterochromia, iritis, poliosis	Most common dominant syndromic hearing loss; accounts for 3% of childhood hearing loss
Type I	—		—		
Type II	—	—	—	Same as type I but no dystopia	—
Type III	—	—	—	Upper limb defects	—
Type IV	—	EDN (receptors in endothelin pathways)	—	Pigmentary defects and Hirschsprung disease	—
Branchio-oto-renal syndrome	AD	EYA1 in half (transcription factor involved in development of inner ear and kidney)	Conductive (75%), sensorineural and mixed	Second most common dominant form of hearing loss. Brachial cleft cysts, cleft palate, malformations of external ear and of kidney	2%
Stickler	AD	STL 1–3	Progressive sensorineural hearing loss	Cleft palate, epiphyseal dysplasia; severe myopia and retinal detachment in types 1 and 3	—
Neurofibromatosis type 2	AD	NF 2	Acoustic neuromas	Evident on MRI; proclivity to other tumors	—
Usher	AR	USH genes (unconventional myosin and adhesion molecules)	Severe congenital sensorineural hearing loss, vestibular dysfunction; retinitis pigmentosa	Most common recessive types; retinitis pigmentosa after first decade; type 1 has abnormal vestibular function	3%–6%

Table 14-1

REPRESENTATIVE GENETIC FORMS OF HEARING LOSS (*CONTINUED*)

DESIGNATION	INHERITANCE	GENE DEFECT	TYPE OF HEARING LOSS	ASSOCIATED DEFECTS	FREQUENCY
Type I					
Type II	—	—	Moderate to severe hearing loss, late retinitis	—	—
Type III	—	—	Progressive hearing loss and variable retinitis	—	—
Pendred	AR	SLC13A4 in half (same mutation causes nonsyndromic hearing loss)	Profound congenital sensorineural hearing loss; abnormal bony labyrinth (Mondini dysplasia)	Euthyroid goiter	4%
Jervell and Lange-Nielsen	AR	KVQT, KCNE (delayed potassium rectifier inner ear)	Congenital deafness	Prolonged QT interval on ECG; syncope, sudden death	<1%
Refsum	AR	—	Progressive sensorineural deafness	Retinitis pigmentosa, sensory polyneuropathy; elevated phytanic acid	—
Alport	X-linked	X-linked in 85% but also autosomal dominant and recessive forms (basement membrane formation in cochlea, eye, and kidney)	Progressive sensorineural hearing loss	Glomerulonephritis and renal failure	1%
Mohr-Tranebjerg	X-linked	TIMMBA (a translocation protein from cytosol to mitochondria)	Progressive childhood deafness	Visual disability, dystonia, mild retardation	—
Kearns-Sayre	Mitochondrial	MTRNT 1at 3243 site and MTTS 1 of mitochondrial genome	Late-onset progressive sensorineural hearing loss	Diabetes, other features typically associated with mitochondrial mutations—see Chap. 36	—
Bartter IV	—	BSND; Cl^- channel	Congenital, severe	Salt wasting	—

AD, autosomal dominant; AR, autosomal recessive.

(designated GJB2). This mutation is found in half of recessive familial cases of pure deafness; what is more striking is that the same gene abnormality occurs in 37 percent of cases of sporadic congenital deafness, almost certainly from a spontaneous mutation (Estivill et al and Morell et al). The connexin protein is a component of gap junctions and the mutation is theorized to interfere with the recycling of potassium from the cochlear hair cells to the endolymph. As a result of the human genome project, more than 20 other gene loci have been detected that may be related to congenital deafness syndromes; these have been summarized by Tekin and colleagues, but none, except the one for connexin, accounts for more than a very small proportion of cases. These unattached, nonsyndromic types of congenital deafness are denominated by genes in a family called DFN (for DeaFNess); for example, the connexin mutation is in DFNB1. The mutations in this gene can be recessive, dominant, or X-linked. The genetic errors involve either cytoskeletal or structural proteins of the organ of Corti or the ion channel apparatus.

It is remarkable that deafness is a component of over 400 more complex different genetic syndromes (e.g., Waardenburg, branchio-oto-renal, Stickler, Pendred, Usher, Alport, Bartter, among many others listed in the table and those omitted because of their rarity). Among these, the finding of a mutation in a gene called PAX3 in the Waardenburg syndrome in the early 1990s began a flood of other gene defects underlying the many disorders that had been described on clinical grounds over the previous century. The mutations that give rise to some of these diseases, particularly the Usher syndrome, may also cause nonsyndromic congenital deafness. The syndromic forms of genetic deafness have been classified largely on the basis of their associated defects: retinitis pigmentosa, malformations of the external ear; integumentary abnormalities such as hyperkeratosis, hyperplasia or scantiness of eyebrows, albinism, large hyperpigmented or hypopigmented areas, ocular abnormalities such as hypertelorism, severe myopia, optic atrophy, and congenital and juvenile cataracts, cerebellar ataxia, myoclonus, and mental deficiency; skeletal abnormalities; and renal, thyroid, or cardiac abnormalities. Deafness is also a feature of several mitochondrial disorders, particularly the Kearns-Sayre syndrome and occasionally the MELAS (mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes) syndrome. The Wolfram syndrome, of which sensorineural deafness is a major feature, can have either a nuclear or mitochondrial genetic origin. Table 14-1 summarizes this and the other main hereditary syndromes. Chinnery et al have summarized the mitochondrial causes of deafness. Chapters 37 and 39 discuss further the association of neurosensory deafness with degenerative and developmental neurologic disease.

Differing from the degenerations is a group of acoustic aplasias. Four types of inner ear aplasia have been described: (1) *Michel defect*, a complete absence of the otic capsule and eighth nerve; (2) *Mondini defect*, an incomplete development of the bony and membranous labyrinths and the spiral ganglion; (3) *Scheibe defect*, a membranous cochleosaccular dysplasia with atrophy of the vestibular and cochlear nerves; and (4) rare chromosomal aberrations (trisomies) characterized by abnormality of the end organ and absence of the spiral ganglion.

Functional (Hysterical) Deafness

It is possible to distinguish hysterical and feigned deafness from that caused by structural disease in several ways. In the case of bilateral deafness, the distinction can be made by observing a blink (cochleo-orbicular reflex) or an alteration in skin sweating (psychogalvanic skin reflex) in response to loud sound. Unilateral hysterical deafness may be detected by an audiometer, with both ears connected, or by whispering into the bell of a stethoscope attached to the patient's ears, closing first one and then the other tube without the patient's knowledge. The elicitation of the first two waves of the brain stem auditory evoked potentials provides indisputable evidence that sounds are reaching the receptive auditory structures and that the patient should be capable of hearing sounds. A brief episode of deafness with fully preserved consciousness may rarely be caused by seizure activity in one temporal lobe (epileptic suppression of hearing).

DIZZINESS AND VERTIGO

Dizziness and other sensations of imbalance are, along with headache, back pain, and fatigue, among the most frequent complaints in medicine (Kroenke and Mangelsdorff). The significance of these complaints varies greatly. For the most part, they are benign, but there is always the possibility that they signal an ominous neurologic disorder. Diagnosis of the underlying disease demands that the complaint of dizziness be analyzed correctly—the nature of the disturbance of function being determined first and then its anatomic localization. This approach to neurologic diagnosis is invaluable in the patient whose main complaint is dizziness.

The term *dizziness* is applied by the patient to a number of different sensory and psychic experiences—a feeling of rotation or whirling as well as nonrotatory swaying, weakness, faintness, light-headedness, or unsteadiness. Blurring of vision, feelings of unreality, syncope, and even petit mal or other seizure phenomena may be called "dizzy spells." These experiences fall into four categories: (1) vertigo, a physical sensation of motion of self or the environment; (2) near syncope, a sensation of faintness; (3) disequilibrium, a disorder of imbalance of stance or gait; and (4) ill-defined light-headedness, or "giddiness," a symptom that often accompanies anxiety. Hence, close questioning of the patient as to how he is using the term *dizziness* is a necessary first step in clinical work.

Physiologic Considerations

Several mechanisms are responsible for the maintenance of a balanced posture and for awareness of the position of the body in relation to its surroundings and to gravity.

Continuous afferent impulses from the eyes, labyrinths, muscles, and joints inform us of the position of different parts of the body. In response to these impulses, the adaptive movements necessary to maintain equilibrium are carried out. Normally, we are unaware of these adjustments because they operate largely at a reflex level. The most important of the afferent impulses are the following.

1. *Visual information* from the retinae and possibly proprioceptive impulses from the ocular muscles, enable us to judge the distance of objects from the body. This information is coordinated with sensory information from the labyrinths and neck (see below) to stabilize gaze during movements of the head and body.
2. *Impulses from the labyrinths*, which function as highly specialized spatial proprioceptors and register changes in the velocity of motion (either acceleration or deceleration) and position of the body in relation to the gravitational vertical. The cristae of the three semicircular ducts sense angular acceleration of the head in the three planes of roll, pitch and yaw, and the maculae of the saccule and utricle sense linear acceleration and gravitational pull. In each of these structures, displacement of sensory hair cells is the effective stimulus. In the semicircular ducts, this is accomplished by movement of the endolymphatic fluid, which, in turn, is induced by rotation of the head. In the utricle and saccule, the hairs are displaced by the movement of the otoliths in response to gravity, thus generating a force that displaces the otoliths. This end organ is a force transducer that converts the generated force into neural impulses that are conducted down the vestibular nerve to the vestibular nuclei. In either case (angular and linear acceleration), the force causes depolarization of the nerve terminals and initiation of impulses in the vestibular nerve, with the production of two main reflex responses: the vestibuloocular, which stabilizes the eyes, and the vestibulospinal, which stabilizes the position of the head and body.
3. *Impulses from the proprioceptors* of the joints and muscles are essential to all reflex, postural, and volitional movements. Those from the neck are of special importance in relating the position of the head to the rest of the body. The sense organs listed above are connected with the cerebellum and pathways in the brain stem, particularly the vestibular nuclei and, via the medial longitudinal fasciculi, with the ocular motor nuclei. These cerebellar and brain stem structures are the important coordinators of the sensory data and provide for postural adjustments and the maintenance of equilibrium. They are the basis of the mechanisms whereby the perceptions of one's self (the body schema) and one's surroundings (the environmental schema) are matched. Accordingly, any disease that disrupts these neural mechanisms may give rise to vertigo and disequilibrium. The interdependence of the two schemata (self and environment) is ascribed to the fact that the various sense organs—retinal, labyrinthine, and proprioceptive—are usually activated simultaneously by any body movement.

One element of the sense of stable equilibrium derives from the ability to match visual and positional information during motion. Through reflex mechanisms, we come to see objects as stationary, while we are moving (mainly the ocular fixation reflex) and moving objects as having motion when we are either moving or stationary (vestibuloocular reflex). At times, especially when our own sensory information is incomplete, we mistake movement of our surroundings for movements of our own body. A well-known example is the feeling of movement that one experiences in a stationary train when a neighboring train is moving.

A factor that influences equilibrium is the effect of aging on all the afferent structures that subserve stability. The elderly may lose their balance on extending the neck, and their peripheral sensory afferents are often impaired, as are the protective postural mechanisms, making falls more frequent. A destructive lesion of one or both labyrinths may leave an elderly person permanently unbalanced, whereas a younger person largely compensates for the loss.

Clinical Characteristics of Vertigo

A careful history and physical examination usually afford the basis for separating true vertigo from the dizziness caused by near syncope, gait disorder, and anxiety. Any illusion or hallucination of motion in any plane qualifies as vertigo. The recognition of vertigo is usually not difficult when the patient states that objects in the environment have spun around or moved rhythmically in one direction or that a sensation of whirling of the head and body was experienced. A distinction is sometimes drawn between subjective vertigo, meaning a sense of turning of one's body, and objective vertigo, an illusion of movement of the environment, but its significance is limited.

Often, however, the patient is not so explicit and a number of related experiences may be described. The feeling may be described as to-and-fro or up-and-down movement of the body, usually of the head, or the patient may compare the feeling to that imparted by the pitch and roll of a ship. Or the floor or walls may seem to tilt or to sink or rise up. In walking, the patient may have felt unsteady and veered to one side, or may have had a sensation of leaning or being pulled to the ground or to one side or another (pulsion or static tilt), as though being drawn by a strong magnet. This feeling is particularly characteristic of vertigo. Oscillopsia, a rhythmic, jerking, illusory movement of the environment, is another effect of vestibular disorder, especially if induced by movement of the head. Observant patients may actually note this rhythmic movement of the environment due to nystagmus.

Some patients may be able to identify their symptoms only when asked to compare them with the feeling of movement they experience when they come to a halt after rapid rotation. If the patient is unobservant or imprecise in descriptions, a helpful tactic is to provoke sensations by rapid rotation, or by asking the patient to stoop for a minute and straighten up; having him stand relaxed for 3 min and checking his blood pressure for orthostatic effect; and, particularly, having him hyperventilate for 3 min. Should

the patient be unable to distinguish among these several types of induced dizziness or to ascertain the similarity of one of the types to his own condition, the history is probably too inaccurate for purposes of diagnosis.

When the patient's symptoms are mild or poorly described, small items of the history—a desire to keep still and a disinclination to stoop or walk during an attack, a tendency to list to one side, an aggravation of symptoms by turning over in bed or closing his eyes, a sense of imbalance when making a quick turn on foot or in a car, and a preference for one position of the body or head—help to identify them as vertigo. At the other end of the scale are attacks of such abruptness and severity as to virtually throw the patient to the ground. Independently occurring vertiginous attacks of the usual variety mark these falling episodes as part of Ménière disease (see further on). On the other hand, a dizzy sensation that is not made worse markedly by vigorous shaking of the head is unlikely to relate to vertigo, particularly that type due to peripheral vestibular disease.

All but the mildest forms of vertigo are accompanied by some degree of nausea, vomiting, pallor, perspiration, and some difficulty with walking. The patient may simply be disinclined to walk or may walk unsteadily and veer to one side, or he may be unable to walk at all if the vertigo is intense. Forced to lie down, the patient realizes that one position, usually on one side with eyes closed, reduces the vertigo and nausea, and that the slightest motion of the head aggravates them. One common form of vertigo, benign positional vertigo (see further on), occurs with the repositioning that accompanies lying down, sitting up, turning, or looking upward. The source of the gait ataxia associated with vertigo (vertiginous ataxia) is recognized by the patient as being "in the head," not in the control of the legs and trunk. It is noteworthy that the coordination of individual movements of the limbs is not impaired in these circumstances—a point of difference from most instances of cerebellar disease. Loss of consciousness as part of a vertiginous attack nearly always signifies another type of disorder (seizure or faint).

Nonvertiginous Types of Dizziness

It is important to distinguish vertigo from the more common complaints for which the term dizziness is used by patients. These include the feeling of impending fainting (near syncope), a disorder of gait (disequilibrium), and an ill-defined feeling of lightheadedness. Many patients in the last category who initially complain of dizziness will, on closer questioning, describe their symptoms as a "distant feeling," "walking on air," "inability to focus," or some other unnatural sensation in the head. These sensory experiences are particularly common in states characterized by anxiety or panic attacks—often, but not always, with depression.

This constellation of nonvertiginous symptoms has been loosely referred to as "phobic," "functional," and "psychogenic" vertigo. Every clinician encounters numerous such patients. In Brandt's (1996) extensive experience, phobic vertigo (his term) was second only to benign positional vertigo (described below) as a cause of consultation in his dizziness clinic. He relates the disorder to anxiety and panic spells, but finds that it exists more often as an independent entity that is subject to improvement after careful explanation and reassurance. We agree with Furman and Jacobs that the term *psychiatric dizziness*, if used at all, should be restricted to dizziness that occurs as part of a recognized psychiatric syndrome, notably extreme anxiety disorder. Often, there is a component of avoidance of crowds, open spaces, and tight circumstances. There seems to be little point in signifying the nonvertiginous symptoms with separate designations based on the settings in which they commonly occur ("supermarket syndrome," "motorist disorientation syndrome," "phobic postural vertigo," "street neurosis") but they do emphasize the psychogenic nature and may facilitate recognition of the syndrome. Furman and Jacobs have related anxiety-type dizziness to minor degrees of vestibular dysfunction, but we have not found it possible to determine whether there is a genuine labyrinthine disorder in all of these patients.

Oculomotor disorders, such as ophthalmoplegia with diplopia, may be a source of spatial disorientation and brief sensations of vertigo, mild nausea, and staggering. These symptoms are maximal when the patient looks in the direction of action of the paralyzed muscle; it is attributable to the receipt of two conflicting visual images. Some normal persons may experience such symptoms for brief periods when first adjusting to bifocal glasses.

In a peculiar symptom called the *Tullio phenomenon*, a loud sound, or yawning, produces a brief sensation of vertigo or tilting of the environment accompanying eye movements. Some patients with this symptom are found to have an absence or thinning of the bony roof of the superior semicircular canal, which can be detected by thin (1 mm) slice CT. This disorder (Llyod Minor syndrome) is a form of perilymphatic fistula caused by a spontaneous or traumatic dehiscence of the bone of the superior canal. Occasionally, patients with Ménière disease report this symptom.

Other causes of dizziness are more difficult for the physician and patient to define. In severe anemic states, particularly pernicious anemia, and in aortic stenosis, easy fatigability and languor may be attended by lightheadedness, related particularly to postural change and exertion. In the emphysematous patient, physical effort may be associated with weakness and peculiar cephalic sensations, and violent paroxysms of coughing may lead to giddiness and even fainting (tussive syncope) because of impaired venous return to the heart. The dizziness that often accompanies acute hypertension is difficult to evaluate; sometimes, it is an expression of anxiety, or it may conceivably be the result of an unstable adjustment of cerebral blood flow. It is doubtful that chronic hypertension causes dizziness, although many of the medications for its treatment certainly can cause the symptom.

Postural nonvertiginous dizziness is another state in which inadequate vasomotor reflexes prevent a constant cerebral circulation; it is notably frequent in persons with orthostatic hypotension of any cause, for example, in those taking antihypertensive drugs, as well as in patients with a polyneuropathy that has an autonomic component. Such persons, on rising abruptly from a recumbent

or sitting position, experience a swaying type of dizziness, dimming of vision, and spots before the eyes that last for several seconds. The patient is forced to stand still and steady himself by holding onto a nearby object. Occasionally, a syncopal attack may occur at this time (see Chap. 18). Hypoglycemia gives rise to yet another form of dizziness, marked by a sense of hunger and attended by trembling, sweating, and other autonomic symptoms. Drug intoxication—particularly with alcohol, sedatives, and antiepileptic drugs—may induce a nonspecific dizziness and, at advanced stages of intoxication, true vertigo.

In practice, it may nonetheless be difficult to separate these types of dizziness from vertigo, for there may, or may not be, feelings of rotation, impulsion, up-and-down movement, oscillopsia, or other disturbance of motion. The ancillary symptoms of true vertigo—namely, nausea, vomiting, tinnitus and deafness, staggering, and the relief obtained by sitting or lying still—are also absent. Furthermore, it is not an uncommon circumstance to find more than one type of dizziness in an individual who is carefully tested.

The Neurologic and Otologic Causes of Vertigo

The fact that vertigo may constitute the aura of an epileptic seizure supports the view that this symptom may have a cerebrocortical origin. Indeed, electrical stimulation of the cerebral cortex in an unanesthetized patient, either of the posterolateral aspects of the temporal lobe or the inferior parietal lobule adjacent to the Sylvian fissure, may evoke intense vertigo. The occurrence of vertigo as the initial symptom of a seizure is, however, infrequent. In such cases, a sensation of movement—either of the body away from the side of the lesion or of the environment in the opposite direction—lasts for a few seconds before being submerged in other seizure activity. Vertiginous epilepsy of this type should be differentiated from vestibulogenic seizures, in which an excessive vestibular discharge serves as the stimulus for a seizure. The latter is a rare form of reflex epilepsy, in which tests that induce vertigo may provoke the seizure (see Chap. 16).

The issue of *migraine* as a cause of vertigo has occasioned much discussion. Several authoritative clinicians attribute many instances of otherwise unexplained dizziness and vertigo to migraine with aura, but it is not entirely clear whether they are referring to an attack of basilar migraine, usually in children (migrainous vertigo), or to episodes of vague disequilibrium or vertigo at various times in migraineurs, which has been more typical in our experience. A survey by Neuhauser and colleagues found that 7 to 9 percent of patients had conventional migrainous symptoms during or before a vertiginous attack, and in half of those the vertigo was regularly associated with migraine.

Lesions of the cerebellum produce vertigo depending on which part of this structure is involved. Large, destructive processes in the cerebellar hemispheres and vermis, such as cerebellar hemorrhage may, or at times may not, cause vertigo. However, strokes in the territory of the medial branch of the posterior inferior cerebellar artery (which arises distal to the branches to the medulla, and therefore does not involve the lateral medulla) causes intense vertigo and vomiting that is *indistinguishable from that caused by labyrinthine disorder*. In two such pathologically studied cases, a large zone of infarction extended to the midline and involved the flocculonodular lobe (Duncan et al). Falling in these cases was toward the side of the lesion; nystagmus was present on gaze to each side but was more prominent on gaze to the side of the infarct. These findings have been confirmed by CT and MRI (Amarenco et al). Early in the course of an acute attack of vertigo, when it may be difficult to assess the gait and the quality of nystagmus, it may be necessary to exclude a cerebellar infarct or hemorrhage by use of imaging procedures.

Labyrinthine disease, on the other hand, causes predominantly unidirectional nystagmus with the fast phase opposite to the side of the impaired labyrinth, and swaying or falling toward the involved side—that is, the direction of the nystagmus is opposite to that of the falling and past pointing (the latter referring to overshooting a target by the patient's finger with eyes closed, as originally described by Bárány [1921]). Ataxia and dysarthria are, of course, typical of many forms of cerebellar disease but may be minimal or absent in cerebellar hemorrhage and some infarctions as well as being lacking in all forms of vestibular disease.

The topic of vertigo with fluctuating ischemia in the territory of the basilar and vertebral arteries (transient ischemic attack [TIA]) and the problem of subclavian steal syndrome are discussed further on under "Vertigo of Brain Stem Origin" and in Chap. 34. Also common in practice is vertigo caused by the demyelinating lesions of multiple sclerosis, as noted in the later section.

Biemond and DeJong described a kind of nystagmus and vertigo originating in the upper cervical roots and the muscles and ligaments that they innervate (so-called cervical vertigo). Spasm of the cervical muscles, trauma to the neck, and irritation of the upper cervical sensory roots were said to produce asymmetrical spinovestibular stimulation and thus to evoke nystagmus, prolonged vertigo, and disequilibrium. Toole and Tucker demonstrated a reduced flow through these vessels (in cadavers) when the head was rotated or hyperextended. In our view, the existence of "cervical vertigo," or at least these interpretations of it, is open to question. However, we acknowledge having encountered patients with cervical dystonia who describe something akin to vertigo, and this may speak to a relationship between cervical proprioceptors and vertigo.

Causes of vertigo other than Ménière disease that originate in the vestibular nerve are discussed further on.

In summary, for all practical purposes, vertigo indicates a disorder of the vestibular end organs, the vestibular division of the eighth nerve, or the vestibular nuclei in the brain stem and their immediate connections, including the inferior cerebellum. Although lesions of the cerebral cortex, eyes, and perhaps the cervical muscles may give rise to vertigo, they are not common sources of the symptom, and vertigo is rarely the dominant manifestation of disease

in these structures. The clinical problem resolves by deciding which portion of the labyrinthine–vestibular apparatus is involved. Usually, this determination can be made on the basis of the form of the vertiginous attack, the nature of the ancillary symptoms and signs, and tests of labyrinthine function. These tests are described below, followed by a description of the common labyrinthine–vestibular syndromes.

Tests of Labyrinthine Function

The most rudimentary test of labyrinthine function is simply to have the patient shake his head from side-to-side in an attempt to elicit symptoms that simulate the dizziness that has been described and to observe the degree of postural instability during this maneuver. Falling and marked intensification of the dizziness is almost always an indication of labyrinthine disease. Also, nystagmus may be evoked, indicating a vestibular instability. More informative in identifying a diseased labyrinth is the "rapid head impulse" test, which is conducted by asking the patient to fixate on a target and then for the examiner to rotate the patient's head quickly by 10 degrees (an explanation must be given to encourage the patient to relax the neck muscles and remain focused on the fixation point). The eyes are observed for a slippage from the target; this is most evident by a quick saccadic return to the point of focus. Ocular instability is observed when the patient turns his head toward the side of the affected labyrinth. This use of the vestibuloocular reflex is said by Halmagyi and Cremer to be among the most dependable bedside tests of labyrinthine function.

Maneuvers designed to elicit positional vertigo by rapidly changing from a seated to a supine position with the head turned to one side bring about vertigo in a number of conditions but are specifically intended to detect benign positional vertigo and are described further on.

A number of other interesting but less well-validated tests that bring out instabilities in station and gait may be used to supplement the conventional tests for vestibular dysfunction. The Unterberger-Fukada maneuver requires the patient to march in place with eyes closed and arms outstretched. Normally, less than 15 degrees or so of rotation is displayed; asymmetry of labyrinthine function is manifest as excessive rotation away from the diseased side. A related test involves having the patient walk around a chair with eyes closed; an increasing or decreasing radius is indicative of an imbalance between the two sides of the labyrinthine apparatus. Both of these tests, however, often show abnormalities with cerebellar disease as well, in which the patient veers to the affected side. The sensitivity of maneuvers such as these has been questioned. We can only comment that they seem in our experience to demonstrate vestibulocerebellar lesions.

Vestibular (labyrinthine) stimulation can also be produced by rotating the patient in a Bárány chair or any type of swivel chair. The patient is asked not to fixate or is defocused with Frenzel lenses during rotation to avoid the effects of optokinetic nystagmus. The normal response is nystagmus in the direction opposite to rotation. In contrast, if the patient is asked to focus on his own thumb in an outstretched arm, there should be no nystagmus if the rotational velocity is slow; the ability to suppress this vestibuloocular response reflects the integrity of the vestibular organ and nerve on the side toward the direction of rotation. Electronystagmography (ENG) provides a more refined method of detecting disordered labyrinthine function because it permits the accurate recording of eye movements without visual fixation. ENG is usually coupled with caloric stimulation or with modern devices for rotational testing that allow precise control of the velocity, acceleration, and extent of rotation beyond what can be done with a traditional chair.

Irrigation of the ear canal alternately with cold and warm water (caloric testing) may be used to disclose a reduction in labyrinthine function in the form of an impairment or loss of thermally induced nystagmus on the involved side. Caloric testing is accomplished by having the patient lay supine on the examining table with the head tilted forward 30 degrees to bring the horizontal semicircular canal into a vertical plane, the position of maximal sensitivity of this canal to thermal stimuli. Each external auditory canal is irrigated for 30 s, first with water at 30°C (86°F) and then at 44°C (111.2°F), with a pause of at least 5 min between each irrigation. In normal persons, cold water induces a slight tonic deviation of the eyes to the side being irrigated, followed, after a latent period of about 20 s, by nystagmus to the opposite side (direction of the fast phase). Warm water induces nystagmus to the irrigated side. (As noted in Chap. 14, this is the basis for the mnemonic COWS: cold opposite, warm same, referring to the direction of fast phase of the nystagmus.) In normal subjects, the nystagmus usually persists for 90 to 120 s, although the range is considerably larger. Nausea and symptoms of excessive reflex vagal activity may occur in sensitive individuals.

Simultaneous irrigation of both canals with cold water causes a tonic downward deviation of the eyes with nystagmus (quick component) upward. Bilateral irrigation with warm water yields a tonic upward movement and nystagmus in the opposite direction ("cold upward, warm down, referring again to the fast phase of nystagmus; "CUWD"). Caloric testing will reliably answer whether the vestibular end organs react, and comparison of the responses from the two ears will indicate which one is paretic. Recording of eye movements during the test allows quantification of these responses. Galvanic stimulation of the labyrinths is effective but offers no particular advantage over caloric stimulation.

Ménière Disease and Other Forms of Labyrinthine Vertigo

Labyrinthine disorders are the most common causes of true vertigo. Ménière disease is characterized by paroxysmal attacks of vertigo associated with fluctuating tinnitus and deafness. One or the other of the latter two symptoms may be absent during the initial attacks of vertigo, but invariably they assert themselves as the disease progresses and increase in severity during acute attacks. Ménière

disease affects the sexes about equally and has its onset most frequently in the fifth decade of life, although it may begin earlier or later. Cases of Ménière disease usually occur as a sporadic trait, but hereditary forms, both autosomal dominant and recessive, have been described (see reviews by Konigsmark). The main pathologic changes consist of an increase in the volume of endolymph and distention of the endolymphatic system (endolymphatic hydrops). It had been speculated several decades ago that the paroxysmal attacks of vertigo are related to ruptures of the membranous labyrinth and release of potassium-containing endolymph into the perilymph, changes that have a paralyzing effect on vestibular nerve fibers and lead to degeneration of the delicate cochlear hair cells (Friedmann). An immune pathogenesis has also been proposed, based tentatively on the presence of circulating antibodies putatively against heat shock protein in some patients.

In typical Ménière disease, the attacks of vertigo are abrupt and last for several minutes to an hour or longer. The vertigo is unmistakably whirling or rotational and usually so severe that the patient cannot stand or walk. Varying degrees of nausea and vomiting, low-pitched tinnitus, a feeling of fullness in one ear and a diminution in hearing are practically always associated. Nystagmus is present during the acute attack; it is horizontal in type, usually with a rotary component and with the slow phase to the side of the affected ear. On attempting to touch a target with the eyes closed, there is past pointing as well as a tendency to fall toward the affected ear when standing or walking. The patient prefers to lie with the faulty ear uppermost and is disinclined to look toward the normal side, which exaggerates the nystagmus and dizziness. As the attack subsides, hearing improves, as does the sensation of fullness in the ear; with further attacks, however, there is a progressive increase in deafness.

The attacks vary considerably in frequency and severity. They may recur several times weekly for many weeks on end, or there may be remissions of several years' duration. Frequently recurring attacks may give rise to a mild chronic state of disequilibrium and a reluctance to move the head or to turn quickly. With milder forms of the disease, the patient may complain more of head discomfort and of difficulty in concentrating than of vertigo and then may be considered to signify anxiety. Symptoms of anxiety are common in patients with Ménière disease, particularly in those with frequent severe attacks.

A small proportion of patients with Ménière disease experience sudden, violent falling attacks. These episodes have been referred to by the quaint name "otolithic catastrophe of Tumarkin" who attributed them to deformation of the otolithic membrane of the utricle and saccule. Patients characteristically describe a sensation of being pushed or knocked to the ground without warning, or there may be a sudden movement or tilt of the environment just before the fall. Consciousness is not lost, and vertigo of the usual type and its accompaniments are not part of the falling attack, although some patients become aware of these symptoms after falling. The attacks may occur early or late in the course of the disease. Typically, several attacks occur over a period of a year or less and remit spontaneously (Baloh et al). An initial attack must be distinguished from other types of drop attacks, but the occurrence of the more typical vertiginous attacks of Ménière disease, with deafness and tinnitus, clarifies the diagnosis.

The hearing loss in Ménière disease usually precedes the first attack of vertigo but it may appear later. Episodic deafness without vertigo has been called *cochlear Ménière syndrome*. As already mentioned, with recurrent attacks, there is a saltatory progressive unilateral hearing loss (in most series, only 10 percent of cases involve both ears, but Baloh places the figure closer to 30 percent). Early in the disease, deafness affects mainly the low tones and fluctuates in severity; actually, tones below 500 Hz are affected early on, and this loss is not evident to the patient. Without measurable fluctuations in pure-tone audiometric thresholds, the diagnosis is left uncertain. Later the fluctuations cease and high tones are affected. Speech discrimination is relatively preserved. The attacks of vertigo usually cease when the hearing loss is complete but there may be an interval of months or longer before this occurs. Audiometry reveals a sensorineural type of deafness, with air and bone conduction equally depressed. Provided that deafness is not complete, loudness recruitment can be demonstrated in the involved ear (see earlier).

Treatment

During an acute attack of Ménière disease, rest in bed is effective treatment, as the patient can usually find a position in which vertigo is minimal. The antihistaminic agents—cyclizine and meclizine, or transdermal scopolamine—are useful in the more protracted cases. Promethazine is an effective vestibular suppressant, as is trimethobenzamide (given in 200-mg suppositories), which also suppresses nausea and vomiting. For many years, a low-salt diet in combination with ammonium chloride or potassium and diuretics has been used in the treatment of Ménière disease, but the value of this regimen has never been established. The same is true for dehydrating agents such as oral glycerol and more recently introduced calcium channel blockers. Mild sedative drugs may help the anxious patient between attacks. The administration of corticosteroids was at one time popular but they have never been proven effective; transtympanic irrigation with dexamethasone is still practiced by some otologists but neither of these approaches is currently popular.

If the attacks are very frequent and disabling, permanent relief can be obtained by surgical means. Destruction of the labyrinth should be considered only in patients with strictly unilateral disease and who have reached the point of complete or nearly complete loss of hearing. In patients with bilateral disease or significant retention of hearing, the vestibular portion of the eighth nerve can be sectioned. Currently, an endolymphatic–subarachnoid shunt is the operation favored by some surgeons, and selective destruction of the vestibule by a cryogenic probe or transtympanic injection of gentamicin is favored by others. Decompression of the eighth cranial nerve, by separating it from an adjacent vessel, as suggested by Janetta, is

still a controversial measure and probably better suited to the treatment of sustained and disabling but unexplained vertigo, rather than the treatment of Ménière disease. The decision to undertake any surgical procedure must be tempered by the fact that a majority of the patients, who are middle-aged, stabilize spontaneously in a few years.

Benign Paroxysmal Positional Vertigo (BPPV)

This disorder of labyrinthine function is more frequent than Ménière disease and—while it does not have the same implications in the long term, an acute attack can be quite disabling. It is characterized by *paroxysmal vertigo* and nystagmus that occur *only with the assumption of certain positions of the head*, particularly lying down or rolling over in bed, bending over and straightening up, or tilting the head backward. It is common for the patient to report that the paroxysm of vertigo began in the middle of the night or early morning, presumably while shifting position during sleep and rapidly making one ear dependent, on rolling over to get out of bed, or to turn off an alarm. Brandt et al (1994) prefers the descriptive adjective *positioning vertigo* to *positional vertigo*, insofar as the symptoms are induced not by a particular head position but only by rapid changes in head position. This disorder was first described by Bárány (1921) but Dix and Hallpike emphasized its benign nature and were responsible for its further characterization, particularly the discrete positional movements that provoke it. Individual episodes last for less than a minute, but these may recur periodically for several days or for many months—rarely for years. As a rule, examination discloses no abnormalities of hearing or other identifiable lesions in the ear or elsewhere. A thorough summary of the condition has been given (Furman and Cass).

The diagnosis of this disorder is settled at the bedside by moving the patient from the sitting position to recumbency, with the head tilted 30 to 40 degrees over the end of the table and 30 to 45 degrees to one side, as originally described by Dix and Hallpike (Fig. 14-5). This need not be done abruptly but should occur in one smooth motion over a few seconds or less. After a latency of a few seconds, this maneuver provokes a paroxysm of vertigo; the patient may become frightened and grasp the examiner or the table or struggle to sit up. The dysfunctional ear is the one that is downward when vertigo is elicited. We cannot refute the contention made by von Brevern and colleagues that the right labyrinth is more often responsible. The vertigo is accompanied by oscillopsia and nystagmus with the rapid components away from the affected (dependent) ear. The nystagmus is predominantly torsional with an additional vertical component in the eye opposite the affected ear according to Baloh and colleagues. The induced vertigo and nystagmus last no more than 30 to 40 s and usually less than 15 s. *Changing from a recumbent to a sitting position reverses the direction of vertigo and nystagmus* (position-changing nystagmus), and this is perhaps the most certain sign that the disorder originates in the labyrinth. With repetition of the maneuver, vertigo and nystagmus become less apparent, and after three or four trials, they can no longer be elicited (referred to as "fatigue"); they can be reproduced in their original severity only after a protracted period of rest. The head-hanging maneuver does not always evoke vertigo and nystagmus in patients whose histories are otherwise consistent with the diagnosis of benign paroxysmal vertigo; therefore, Froehling and coworkers do not insist on it for diagnosis if the history is compatible but without the sign, we are uncertain how to confirm the diagnosis. It may still be appropriate to prescribe the corrective exercises as a trial.

Such attacks of vertigo may come and go for years, particularly in the elderly, and require no treatment. At the other end of the scale is the rare patient with positional vertigo of such persistence and severity as to require surgical intervention.

In a study of 240 cases of benign positional vertigo, found that 17 percent had their onset within several days or weeks after cerebral trauma and 15 percent after presumed viral neurolabyrinthitis (Baloh et al). The significance of these preceding events is unclear, insofar as they did not appear to influence the clinical symptoms or course of the disorder. The provocative suggestion has been made on the basis of small epidemiologic studies (Jeong and colleagues) that osteoporosis is associated with an increased frequency of the disorder.

Sudden changes in position, particularly of the head, may induce vertigo and nystagmus or cause a worsening of these symptoms in patients with all types of vestibular–labyrinthine disease, including Ménière disease and the types associated with vertebrobasilar stroke, trauma, and posterior fossa tumors. However, only if the paroxysm has the special characteristics noted above—namely, elicitation by change in head position, latency of onset, brevity, reversal of direction of nystagmus on sitting up, fatigability with repetition of the test, and the presence of distressing subjective symptoms of vertigo or its recurrence for months or years without other symptoms—can it be regarded as "benign paroxysmal" in type.

Schuknecht is credited with demonstrating that benign positional vertigo was caused by cupulolithiasis, in which otolithic crystals become detached and attach themselves to the cupula of the posterior semicircular canal. It is now generally believed that the debris, probably detached from the otolith, forms a free-floating clot in the endolymph of the canal (canalolithiasis) and gravitates to the most dependent part of the canal during changes in the position of the head (see Brandt et al).

In 90 percent of cases, the posterior semicircular canal is implicated; the remaining 10 percent are caused by cupulolithiasis in the *lateral canal*. As mentioned, the conventional maneuver to elicit BPPV may not only fail to induce symptoms in cases of lateral canal cupulolithiasis but the corrective maneuver may even inadvertently produce it. The disorder of the lateral canal has been nicely summarized (De la Meilleure and coworkers).

Treatment

The debris is thought to act by inducing currents on the cupula and triggering an attack of vertigo. Based on this presumed mechanism, several canalith repositioning

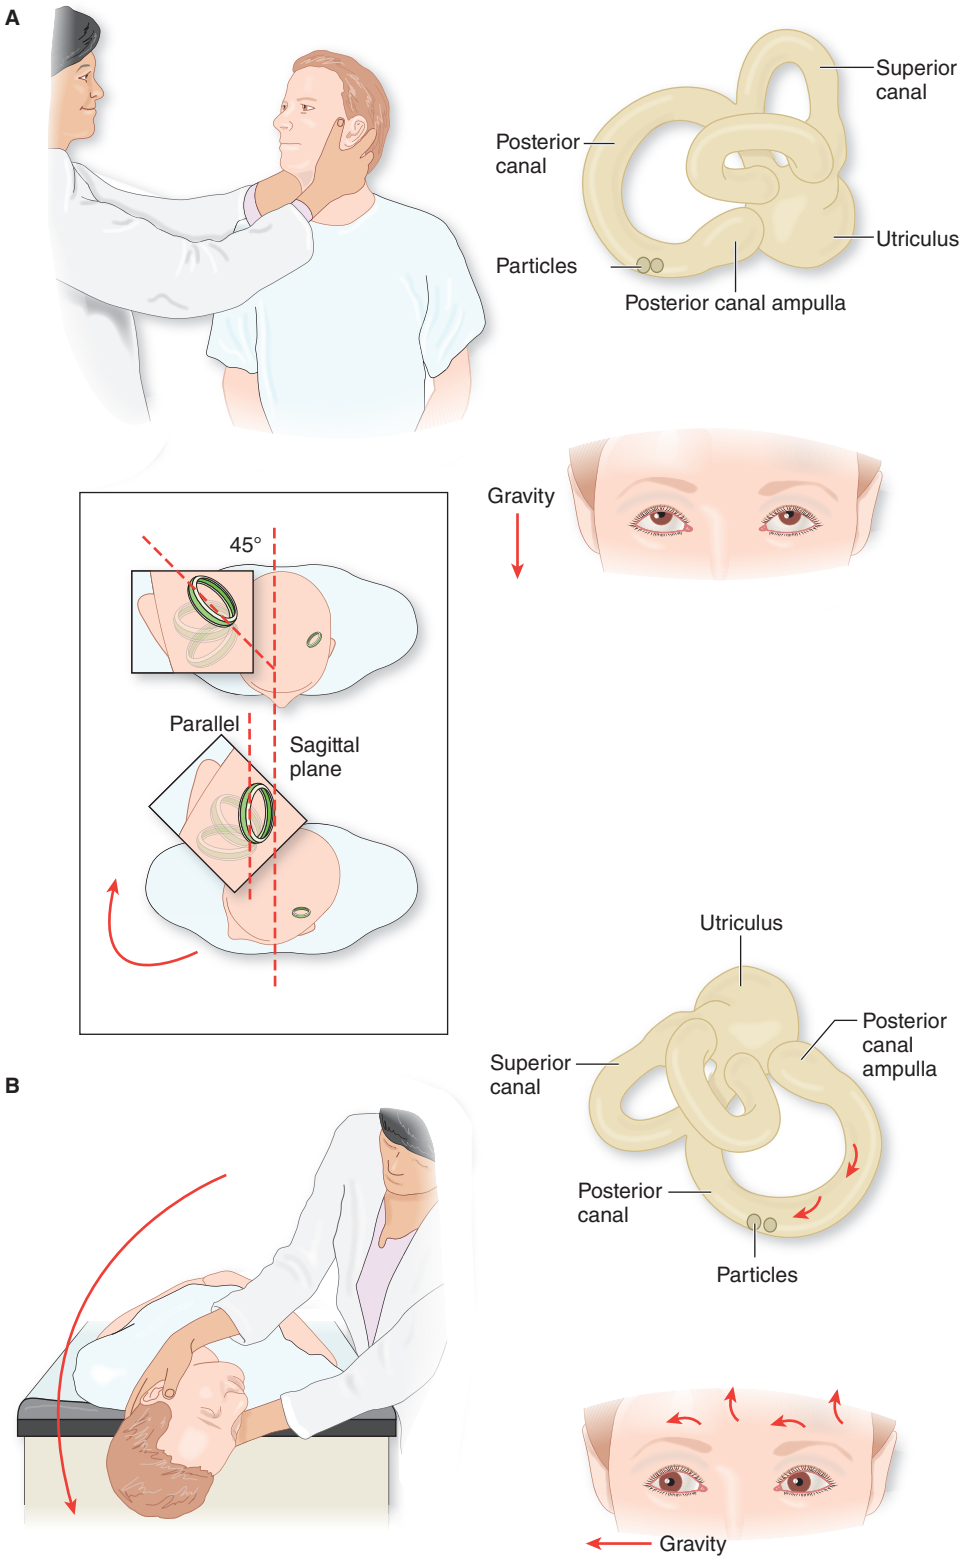

Figure 14-5. Dix-Hallpike maneuver to elicit benign positional vertigo (originating in the right ear). *A*. The maneuver begins with the patient seated and the head turned to one side at 45 degrees, which aligns the right posterior semicircular canal with the sagittal plane of the head. *B*. The patient is then helped to recline rapidly so that the head hangs over the edge of the table, still turned 45 degrees from the midline. Within several seconds, this elicits vertigo and nystagmus that is right beating with a rotary (counterclockwise) component. An important feature of this type of "peripheral" vertigo is a change in the direction of nystagmus when the patient sits up again with his head still rotated. If no nystagmus is elicited, the maneuver is repeated after a pause of 30 s, with the head turned to the left. Treatment with the canalith repositioning maneuver is shown in Fig. 14-6.

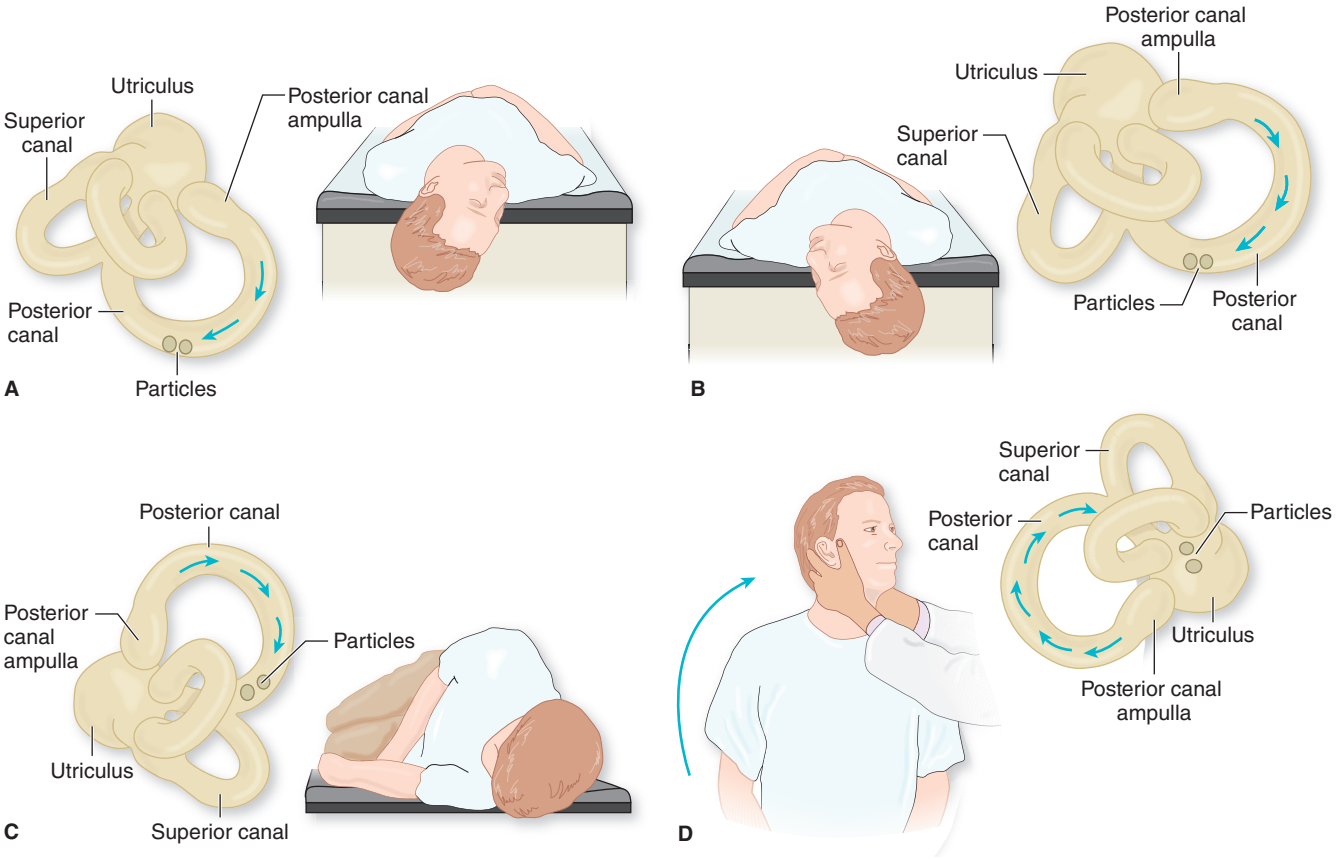

Figure 14-6. Bedside maneuver for the treatment of a patient with benign paroxysmal positional vertigo affecting the right ear. The presumed position of the debris within the labyrinth during the maneuver is shown on each panel. The maneuver is a four-step procedure. First, a Dix–Hallpike test is performed with the patient's head rotated 45 degrees toward the (affected) right ear and the neck slightly extended with the chin pointed slightly upward. *A*. This position results in the patient's head hanging to the right. *B*. Once the vertigo and nystagmus provoked by this maneuver cease, the patient's head is rotated about the rostral–caudal body axis until the left ear is down. *C*. Then the head and body are further rotated until the head is almost facing down. The vertex of the head is kept tilted upward throughout the rotation. The patient should be kept in the final, face-down position for about 10 to 15 s. *D*. With the head kept turned toward the left shoulder, the patient is brought into the seated position.

maneuvers have been devised (Semont et al; Epley), allowing the debris to gravitate out of the semicircular canal and into the vestibule, where it will not induce a current during angular acceleration.

The first part of the Epley canalith repositioning maneuver (Fig. 14-6) is similar to the diagnostic Hallpike maneuver, the only difference being that the patient is positioned without extending the head into the hanging position of the Dix-Hall-pike diagnostic maneuver, first with one ear down and the head turned, then the other ear, in order to establish the side responsible for symptoms. Next, with the patient in the position that causes symptoms, the head is turned in a series of three steps, each separated by about 20 s: first the head is turned 45 to 60 degrees toward the opposite ear; the patient is then turned onto his side and the head turned an additional 45 degrees, until the head is parallel to the ground; then the head is turned once more until it more nearly faces the floor. We have become aware that this last step, which is a necessary part of the maneuver, is sometimes omitted by neurologists. After about 20 s, the patient is returned to the upright position. It was formerly believed that the patient should be instructed to avoid the head-down position for 24 hours, but recent studies have demonstrated that this is probably not necessary. Often a single treatment sequence suffices to terminate a period of positional vertigo (approximately 80 percent respond), but a second sequence carried out immediately after the first probably gains another small group who derive benefit. Additional treatments carried out in the same session are said to add no further benefit. In recalcitrant cases, our otolaryngology colleagues have applied a large vibrator to the temporal bone while the Epley maneuver was being performed, after which the episodes ceased; presumably, this mobilizes the crystals and aids in moving them out of the canal. An incompletely implemented Epley maneuver risks converting the usual posterior semicircular canal cupulolithiasis to one involving the lateral canal, which may be more difficult to treat.

Patients who fail to respond or will not tolerate the Epley maneuver may respond to variations of repositioning such as the Semont maneuver (the patient begins in a sitting

position with the head turned 45 degrees to one side, then drops laterally to a side-lying position on the opposite ear, followed by a brisk swing of the body to drop the opposite side-lying position) or the similar Brandt-Daroff exercises (sitting, to side lying, to sitting, performed repeatedly).

Positional vertigo caused by lateral canalolithiasis causes a purely horizontal nystagmus rather than the torsional and vertical type described above. In this case, another repositioning maneuver that involves rolling from one side to the other is used to liberate and reposition the otolithic debris.

It is important to reiterate that in some patients with positional vertigo, the disorder is neither benign nor paroxysmal. Jannetta and colleagues have described a group of patients in whom symptoms of vertigo and disequilibrium were almost constant (even in the upright position) and disabling and unresponsive to habituation and other medical therapy (*disabling positional vertigo*). They attributed this disorder to cross-compression of the root entry zone of the eighth cranial nerve by an adjacent blood vessel and have reported that decompression of the nerve provides lasting relief of symptoms.

Toxic and Idiopathic Bilateral Vestibulopathy

The common and serious ototoxic effects of the aminoglycoside antibiotics have already been mentioned—both on the cochlear hair cells, with loss of hearing and independently, on the vestibular labyrinths. Prolonged exposure to these agents produces a bilateral vestibulopathy without vertigo. Instead, there tends to be a disequilibrium associated with oscillopsia. The symptoms are especially troublesome when the patient moves. Often the disequilibrium is not discovered until a bedbound patient tries to walk.

Less well appreciated is the occurrence of a slowly progressive vestibulopathy for which no cause can be discerned. The disorder affects men and women alike, with onset in middle or late adult life with the main abnormalities being unsteadiness of gait, which is worse in the dark or with eyes closed, and oscillopsia, which occurs with head movements and is particularly noticeable when walking. Vertigo and hearing loss are absent, as are other neurologic abnormalities. Bilateral vestibular loss can be documented with caloric and rotational testing. Baloh and colleagues, in a report of 22 patients with idiopathic vestibulopathy of this type, found that a significant proportion (9 of 22 cases) had a prior history of prolonged episodes of vertigo consistent with the diagnosis of bilateral sequential vestibular neuritis (see below).

Vestibular Neuritis (Neuronitis)

This was the term applied originally by Dix and Hallpike to a distinctive disturbance of vestibular function, characterized clinically by a paroxysmal and usually a prolonged single attack of vertigo and by a conspicuous absence of tinnitus and deafness. The entity is, however, more nebulous than most discussions indicate.

This disorder occurs mainly in young to middle-aged adults (children and older individuals also may be affected), without preference for either sex. The patient frequently gives a history of an antecedent upper respiratory infection of nonspecific type, but it is not clear whether this is requisite for the diagnosis. Usually, the onset of vertigo is fairly abrupt, although some patients describe a prodromal period of several hours or days in which they felt "top-heavy" or "off balance." Persistence of the symptoms for a day or more differentiates the process from Ménière disease. The vertigo is severe as a rule and is associated with nausea, vomiting, and the need to remain immobile.

Nystagmus (quick component) and a sense of body motion are to the opposite side, whereas falling and past pointing are to the side of the affected labyrinth. In some patients, the caloric responses are abnormal bilaterally, and in some, the vertigo may recur, affecting the same or the other ear. Auditory function is normal. Examination discloses vestibular paresis on one side, that is, an absent or diminished response to caloric stimulation of the horizontal semicircular canal. If the patient will tolerate small head movements, the previously described rapid-head-impulse test of Halmagyi and Cremer is one of the best means of demonstrating absent function of one lateral semicircular canal.

Although the symptoms can be quite disabling for a short period, vestibular neuritis is an ostensibly benign disorder. The severe vertigo and associated symptoms subside in a matter of several days, but lesser degrees of these symptoms, made worse by rapid movements of the head, may persist for months. The caloric responses are gradually restored to normal as well. In some patients, there has been a recurrence months or years later, as already mentioned.

The portion of the vestibular pathway that is primarily affected in this disease is thought to be the superior part of the vestibular nerve trunk, which was observed to show degenerative changes by Schuknecht and Kitamura. Earlier, Dix and Hallpike had reasoned that the lesion was located central to the labyrinth, as hearing is spared and vestibular function usually returns to normal. They used the term *vestibular neuritis* because of the uncertainty of more precise localization within the peripheral vestibular pathway. The cause of vestibular neuritis is still uncertain, but many authorities have attributed it to a viral infection of the vestibular nerve, analogous to Bell palsy, and from time to time, enhancement of the eighth nerve or the membranous labyrinth is seen after gadolinium administration on MRI. For want of more specific etiologic or pathologic data, many neurologists prefer the term *vestibular neuropathy* or *neuritis* or *acute unilateral peripheral vestibulopathy*. It is likely that the conditions described under the terms *epidemic vertigo, epidemic labyrinthitis*, and *acute labyrinthitis* or *neurolabyrinthitis* refer to the same process. Certainly, herpes zoster oticus causes this syndrome (as well as affecting the seventh nerve); this characterizes the Ramsay Hunt syndrome described in Chaps. 9 and 44.

During the acute stage, antihistamine drugs, promethazine, clonazepam, and scopolamine may be helpful in reducing the symptoms. Vestibular exercises have been

recommended (Baloh 2003) in his review of the subject. One clinical trial has demonstrated a more rapid recovery with the use of methylprednisolone, 100 mg orally, tapered over 3 weeks; valacyclovir did not have this effect (Strupp et al).

Other Causes of Vertigo of Vestibular Nerve Origin

Vertigo may occur with diseases that involve the eighth nerve in the petrous bone or at the cerebellopontine angle. Aside from vestibular neuritis, discussed above, the two most common causes of vertigo of eighth nerve origin are probably an acoustic or vestibular schwannoma and vascular irritation or compression by a small branch of the basilar artery. The frequency of the vascular compression syndrome as a cause of otherwise undifferentiated vertigo is not known (see earlier).

Regarding vestibular schwannoma, vertigo is rarely the initial symptom; the usual sequence is deafness affecting the high-frequency tones initially, followed some months or years later by mild chronic imbalance rather than vertigo and by impaired caloric responses, and then, if untreated, by additional cranial nerve palsies (the seventh, fifth, and tenth nerves), ipsilateral ataxia of limbs, and headache. Variations in the sequence of development of symptoms are frequent, and probably many vestibular schwannomas discovered in the process of an evaluation for vertigo are incidental; that is, almost 1 percent of the general population harbors small tumors. In the diagnosis of vestibular and acoustic schwannoma, MRI and BAEP are the most important ancillary examinations. Bilateral vestibular/acoustic Schwannomas are almost always a manifestation of neurofibromatosis type 2.

Labyrinthine infarction can be a component of the stroke syndrome from occlusion of the anterior inferior cerebellar artery (AICA). In the complete syndrome, there is hearing loss, cerebellar ataxia, and sometimes "screaming tinnitus" or lesser degrees of tonal tinnitus. Also reported is a clinical syndrome of unknown nature consisting of a single abrupt attack of severe vertigo, nausea, and vomiting without tinnitus or hearing loss but with permanent ablation of labyrinthine function on one side. It has been suggested that this syndrome is a result of occlusion of the labyrinthine division of the internal auditory artery, but so far, anatomic confirmation has not been obtained. Labyrinthine hemorrhage has been demonstrated by MRI in some of these patients; others are attributed, speculatively, to viral infection.

A particular form of paroxysmal vertigo that occurs in childhood has been described (Basser). The attacks occur in a setting of good health and are of sudden onset and brief duration. Pallor, sweating, and immobility are prominent manifestations; occasionally, vomiting and nystagmus occur. No relation to posture or movement has been observed. The attacks are recurrent but tend to cease spontaneously after a period of several months or years. The outstanding abnormality is demonstrated by caloric testing, which shows impairment or loss of vestibular function, bilaterally or unilaterally, frequently persisting after the attacks have ceased. Cochlear function is unimpaired. The basis of this disorder has not been determined, and a suggested connection with migraine is tenuous. The special case of basilar artery migraine is discussed below.

Cogan described an infrequent syndrome in young adults in which a *nonsyphilitic interstitial keratitis* is associated with vertigo, tinnitus, nystagmus, and rapidly progressive deafness. The prognosis for vision is good, but the deafness and loss of vestibular function are usually permanent. The cause and pathogenesis of this syndrome are unknown, although approximately half of the patients later develop aortic insufficiency or a systemic vasculitis that resembles polyarteritis nodosa. These vascular complications proved fatal in 7 of 78 cases in one reveiw (Vollertsen and colleagues).

There are many other causes of aural vertigo, such as purulent labyrinthitis complicating mastoiditis or meningitis; serous labyrinthitis caused by infection of the middle ear; "toxic labyrinthitis" caused by intoxication with alcohol, quinine, or salicylates; motion sickness; and hemorrhage into the inner ear. Bárány (1911) was the first to draw attention to the nystagmus and positional vertigo, worse on closing the eyes that occurs at a certain level of intoxication with alcohol and lasts a few hours. Such an episode of alcohol-induced vertigo tends to last longer than a vertiginous attack of Ménière disease, but in other respects, the symptoms (excepting tinnitus) are similar.

Vertigo with varying degrees of spontaneous or positional nystagmus and reduced vestibular responses is a frequent complication of *cranial trauma*. Vertigo, often of the nonrotatory, to-and-fro type, may follow cerebral concussion or whiplash injury, in which the head has not been impacted. Brandt has attributed this syndrome to a loosening or dislodgement of the otoconia in the otoliths. The vertigo in these circumstances usually improves in a few days or weeks and is rarely accompanied by impairment of hearing—in distinction to the vertigo that follows fractures of the temporal bones (as described earlier in this chapter in the discussion of deafness). Dizziness is also a prominent complaint as part of the syndrome of a postconcussion syndrome as described in Chap. 35, but usually this proves to be ill-defined giddiness rather than true vertigo.

There is, nonetheless, a type of vestibular concussion accompanying closed head trauma that may leave the patient with imbalance or positional vertigo. Otolaryngologists are familiar with a syndrome resulting from a perilymph fistula after traumatic injury. The trauma may be minor, even forceful coughing, sneezing, or lifting; some cases are a result of chronic ear infection or cholesteatoma. Disruption of the oval or round windows causes a leak of perilymph into the middle ear. Vertigo and nystagmus can be induced by pressure in the external ear canal (the fistula test). If enough perilymph migrates to the middle ear, a conductive hearing loss may also be detected. Superior canal dehiscence, in which loud sounds induce brief vertigo, nystagmus or eye movements (Tullio phenomenon) is another result of perilymphatic fistula, as discussed earlier. A perilymph fistula may be pronounced enough to also cause low pressure of the spinal fluid with the characteristic enhancement of the dura on MRI.

Vertigo of Brain Stem Origin

Reference was made earlier to the occurrence of vertigo and nystagmus with lower and upper brain stem lesions. In these cases, vestibular nuclei and their connections are implicated. Auditory function is nearly always spared, because the vestibular and cochlear fibers diverge upon entering the brain stem at the junction of the medulla and pons. The vertigo of brain stem origin, as well as the accompanying nausea, vomiting, nystagmus, and disequilibrium, is generally more protracted but less severe than with labyrinthine lesions, but one can think of exceptions to this statement. Nevertheless, with brain stem lesions, one often observes marked nystagmus without the slightest degree of vertigo—which does not happen with labyrinthine disease. The nystagmus of brain stem origin may be uni- or bidirectional, purely horizontal, vertical, or rotary, and is characteristically worsened by attempted visual fixation. In contrast, nystagmus of labyrinthine origin is unidirectional when the head is in a single position, usually with a rotary component, and past pointing and falling are in the direction of the slow phase; purely vertical nystagmus does not occur, and a purely horizontal nystagmus without a rotary component is unusual. Furthermore, labyrinthine nystagmus is inhibited by visual fixation and reverses direction with changes in the position of the head; nystagmus of brain stem origin generally displays none of these features. Either may have a positional- or movement-induced worsening, but this finding is more prominent in labyrinthine disease. Table 14-2 summarizes these findings.

Table 14-2

DIFFERENTIATION OF PERIPHERAL FROM CENTRAL NYSTAGMUS (SEE TEXT)

	PERIPHERAL	CENTRAL
Vertigo and nausea	Pronounced	Mild
Direction of nystagmus	• Mixed torsional-vertical • Mixed torsional-horizontal • May be pure - horizontal	• Pure horizontal • Pure vertical • Pure torsional
Influence of gaze	Does not change direction with gaze	Direction changes with gaze
Visual fixation	Inhibits nystagmus	Does not affect nystagmus
Latency following repositioning maneuver	Up to 20 s	Brief
Direction changing with reversal of head position	Present and characteristic	Absent
Hearing loss/ tinnitus	Variably present	Absent
Signs of brainstem or cerebellar disease	Absent	Generally present

The central localization of vertigo is confirmed mainly by finding signs of involvement of other structures within the brain stem (cranial nerves, sensory and motor tracts, etc.). The mode of onset, duration, and other features of the clinical picture depend on the nature of the causative disease, which may be vascular, demyelinative, or neoplastic.

Vertigo is a prominent symptom of ischemic attacks and of brain stem infarction occurring in the territory of the vertebrobasilar arteries, particularly the Wallenberg syndrome of lateral medullary infarction.

On the other hand, our colleague C.M. Fisher had pointed out that vertigo as the *sole* manifestation of brain stem ischemia from basilar arterial disease is rare. Unless other symptoms and signs of a brain stem disorder appear contemporaneously or soon after the vertigo, one can usually postulate an aural origin and nearly always exclude vascular disease of the brain stem. However, we have encountered rare patients with repeated brief attacks of vertigo that later proved to be caused by basilar artery stenosis, but in whom only a few episodes were associated with signs of brain stem disease such as dysarthria, facial numbness, or diplopia. In other words, frequent and sudden episodes of vertigo lasting a minute or so may infrequently be related to transient brain stem ischemia.

Vertigo of cerebellar origin is exceptional in this respect in that it may rarely be the sole manifestation of cerebellar infarction or hemorrhage, as described earlier in the introductory sections of the chapter and in Chaps. 5 and 33. It follows that isolated vertigo may be the result of occlusion of the posterior inferior cerebellar artery or its parent vertebral artery although most often, there are additional features related to damage to the lateral medulla. In instances of isolated vertigo, one seeks confirmation that there are no features pointing to a central origin or conversely, if there are signs such as nystagmus in more than one direction of gaze with a single position of the head, or vertical nystagmus, there is concern for ischemia of the brain stem. The nystagmus and ataxia of gait (more of a propelling, or pulsion, to one side) that accompany acute cerebellar lesions are toward the same side (the side of the lesion), while in acute vestibulopathies, nystagmus beats away from the side of the lesion and pulsion is still toward the affected side.

Multiple sclerosis may be the explanation of persistent vertigo in an adolescent or young adult, sometimes with little or no nystagmus. In most cases, there are other characteristic features of multiple sclerosis (e.g., internuclear ophthalmoplegia) but rarely, a demyelinating plaque in the vicinity of the vestibular nuclei simulates a peripheral vestibular disorder.

The relationship of migraine to vertigo was mentioned earlier. This refers to otherwise mundane migraine in which the vertigo is perhaps an aura, or to episodes of paroxysmal vertigo in adults that are considered to be migraine equivalents. In addition, attacks of vertigo followed by an intense unilateral and often suboccipital headache and vomiting are the characteristic features of *basilar artery migraine*. The prodromal visual symptoms take the form of blindness or of photopsia that occupies all of the visual fields. Between headaches, tests of cochlear and vestibular function in these patients are normal. Some authorities have stated that most cases of recurrent vertigo without hearing

Table 14-3

VERTIGINOUS SYNDROMES WITH LESIONS OF DIFFERENT PARTS OF THE VESTIBULAR SYSTEM

SYNDROME	NEUROLOGIC FINDINGS	DISORDERS OF EQUILIBRIUM	TYPE OF NYSTAGMUS[a]	HEARING	LABORATORY EXAM
Labyrinths (postural vertigo, trauma, Ménière disease, aminoglycoside toxicity, labyrinthitis)	None	Ipsilateral past pointing and lateral propulsion to side of lesion	Horizontal or rotary to side opposite lesion, positional and position changing, fatigable	Normal or conduction or neurosensory deafness with recruitment	Vestibular paresis by caloric testing, directional preponderance
Vestibular nerve and ganglia (vestibular neuronitis, herpes zoster)	Auditory eighth and seventh cranial nerve abnormalities; abnormal head impulse test to affected side	Ipsilateral past pointing and lateral propulsion to side of lesion	Unidirectional positional	Sometimes sensorineural deafness, without recruitment (vestibulolabyrinthitis)	Imaging may be normal or abnormal Vestibular paresis on caloric testing Directional preponderance
Cerebellopontine angle (acoustic neuroma, glomus, and other tumors)	Ipsilateral fifth, seventh, ninth, tenth cranial nerves, cerebellar ataxia Increased intracranial pressure (late)	Ataxia and falling ipsilaterally	Gaze-paretic, positional, coarser to side of lesion	Sensorineural deafness without recruitment	Imaging abnormal Vestibular paresis on caloric testing BAEPs abnormal Increased CSF protein
Brainstem and cerebellum (infarcts, tumors, viral infections)	Multiple cranial nerves, brainstem tract signs, cerebellar ataxia	Ataxia present with eyes open	Coarse horizontal and vertical, gaze-paretic	Usually normal	Hyperactive labyrinths or directional preponderance on caloric testing Imaging, and BAEPs abnormal in most cases
Higher (cerebral) connections	Aphasia, visual field, hemimotor, hemisensory, and other cerebral abnormalities, seizures	No change	Usually absent	Normal	No change in caloric responses Imaging and electroencephalogram may be abnormal

[a]See text and Chap. 13 for description of types of nystagmus. BAEPs, brainstem auditory evoked potentials.

loss over many years can be attributed to migraine and not to Ménière disease. An instructive series of such cases has been published (Dieterich and Brandt).

Finally, mention should be made of a *familial vestibulocerebellar syndrome*, beginning in childhood or early adult life and characterized by recurrent episodes of vertigo and imbalance. Diplopia and dysarthria complicate some attacks, which seem to be precipitated by extreme exertion and emotion. Repeated attacks are followed by a mild, persistent ataxia, mainly of the trunk. This disorder was first described by Farmer and Mustian and more recently by Baloh and Winder, who have pointed out that both the episodic vertigo and ataxia are markedly reduced or abolished by the administration of acetazolamide. This process is most likely related to the inherited acetazolamide-responsive ataxic channelopathy syndrome described in Chap. 5. A form that is kinesigenic, that is, brought on by activity, has a similar appearance.

In summary, the nature of the nystagmus, instability of the eyes during the head impulse test, and the other features of the neurologic examination allow a distinction to be made between central and peripheral cases of vertigo. Associated hearing loss favors a vestibular cause of vertigo. Tables 14-2 and 14-3 summarize the features of the various vertiginous syndromes.

Epilepsy and Other Seizure Disorders

The prevalence and importance of epilepsy, recurrent unprovoked seizures, can hardly be overstated. From the epidemiologic studies of Hauser and colleagues, one may extrapolate an incidence of approximately 2 million individuals in the United States who have epilepsy and predict about 44 new cases per 100,000 persons each year. These figures are exclusive of patients in whom seizures transiently complicate febrile and other illnesses or injuries. It has also been estimated that slightly less than 1 percent of persons in the United States will have epilepsy by the age of 20 years (Hauser and Annegers, 1992). Over two-thirds of all epileptic seizures begin in childhood (most in the first year of life), and this is the period when seizures assume the widest array of forms. In the practice of pediatric neurology, epilepsy is one of the most common disorders, and the chronicity of childhood forms adds to their importance. The incidence increases again after age 60 years. For all these reasons, physicians should know something of the nature of seizure disorders and their treatment. It is notable that, in striking contrast to the various treatments available for epilepsy, many persons with epilepsy in the developing world never receive medical attention.

The word *epilepsy* is derived from Greek words meaning "to seize upon" or "taking hold of." Our predecessors referred to it as the "falling sickness" or the "falling evil." Although a useful medical term to denote recurrent seizures, the words *epilepsy* and *epileptic* may still have unpleasant connotations and should be used advisedly in dealing with patients. In 1870, Hughlings Jackson, the eminent British neurologist, postulated that seizures were due to "an excessive and disorderly discharge of cerebral nervous tissue on muscles." The discharge may result in an almost instantaneous loss of consciousness, alteration of perception or impairment of psychic function, convulsive movements, disturbance of sensation, or some combination thereof.

Terminologic difficulty arises from the diversity of the clinical manifestations of seizures. The term *convulsion*, referring as it does to an intense paroxysm of involuntary repetitive muscular contractions, does not fully capture the range of disorders resulting from abnormal electrical discharges, or seizures, that may consist only of an alteration of sensation or consciousness. *Seizure* is preferable as a generic term because it embraces all paroxysmal electrical discharges of the brain, and also because it lends itself to qualification. The term *motor* or *convulsive seizure*, therefore, is not tautologic, and one may likewise speak of a *sensory seizure* or *cognitive seizure*. There is also an entity of "nonconvulsive seizure" that may impair consciousness, but not manifest any abnormal convulsive movement. This represents an important and potentially treatable form of an acute encephalopathy or confusional state.

A first solitary seizure or brief outburst of seizures may occur during the course of many medical illnesses. It indicates that the cerebral cortex has been affected by disease, either primarily or secondarily. If prolonged or repeated every few minutes, the condition termed *status epilepticus*, it may threaten life. Equally important, a seizure or a series of seizures may be the manifestation of an ongoing neurologic disease that requires special diagnostic and therapeutic measures. Status epilepticus may be of the nonconvulsive type, continuously impair consciousness, and is difficult to detect clinically because of the absence of characteristic movements.

A more common and less-grave circumstance is for a seizure to be but one in an extensive series recurring over a long period of time, with most of the attacks being more or less similar in type. In this instance, they may be the result of an inactive lesion that remains as a scar in the cerebral cortex. The original disease may have passed unnoticed, or perhaps had occurred in utero, at birth, in infancy, or in parts of the brain inaccessible for examination or too immature to manifest signs. The increasingly refined techniques of MRI now also reveal focal zones of cortical dysplasia and hippocampal sclerosis, both of which tend to be epileptogenic. Patients with such long-standing but subtle lesions probably make up a large portion of those with recurrent seizures. If there is no underlying lesion, the condition is classified as idiopathic or primary, but in the modern era, this is come to be almost synonymous with a genetic cause. In this category, there are a large number of important types of epilepsy for which no pathologic basis has been established, and for which there is no apparent underlying cause except a genetic disorder of ion channel function. Included here are hereditary forms such as generalized tonic-clonic (grand mal), and "absence" seizure states as suggested in classifications many years ago by Lennox and Forster. Persistent seizures, regardless of cause, can secondarily damage cortical tissue by several mechanisms that include excitotoxicity and, in the setting of prolonged tonic seizures, systemic hypoxia.

CLASSIFICATION OF SEIZURES AND EPILEPSIES

Seizures have been grouped in several ways: according to their presumed etiology, that is, idiopathic (primary) or symptomatic (secondary); their site of origin; their clinical form (generalized or focal); their frequency (isolated, cyclic, or repetitive, or the closely spaced sequence of status epilepticus); or by particular electroencephalographic (EEG) patterns. A distinction must be made between the classification of *seizures*: generalized tonic clonic (grand mal), absence (petit mal), myoclonic, partial, and others, and the classification of the *epilepsies*, or *epileptic syndromes*, which are specific diseases, many of which may manifest several seizure types. These are discussed later in the chapter. A further distinction is made by clinical and EEG features. This approach allows for the reasonable predictability of response to specific medications and to some extent, in prognosis.

Basically, this classification divides seizures into two types—*focal onset* (*formerly termed partial*), in which a focal or localized onset can be discerned clinically or by EEG, or *generalized onset*, in which the seizures appear to begin bilaterally. *Generalized seizures* are of two types—*convulsive* and *nonconvulsive*. The common convulsive type is the *tonic-clonic* (*grand mal*) *seizure*. Less common is a purely tonic, purely clonic, atonic, and myoclonic. The typical nonconvulsive generalized seizure is the brief lapse of consciousness or absence (petit mal); included also under this heading are minor motor phenomena. Focal seizures can also be convulsive or uncommonly, nonconvulsive. Furthermore, focal seizures can secondarily generalize into any of the types listed above.

The classification followed here was first proposed by Gastaut et al in 1970 and has been refined repeatedly by the Commission on Classification and Terminology of the International League against Epilepsy, most recently in 2017 (Fisher and colleagues). This nomenclature, based mainly on the clinical form of the seizure and its EEG features, has been adopted worldwide and is generally referred to as the "International Classification" (Table 15-1).

Focal seizures are further classified according to their additional features such as a specific subjective experience (*aura*), motor, autonomic, and most importantly, whether awareness or consciousness is disturbed; the latter was formerly called *partial complex seizure*. In reality, an aura represents the initial phase of a focal seizure; in some instances, it may constitute the entire epileptic attack.

A complementary classification is provided by considering the *epilepsy syndromes,* a group of somewhat diverse, age-dependent, and usually genetically determined entities that arise without underlying structural abnormalities. The syndromes are characterized by the age of onset, type of seizure, and often, by a particular EEG pattern. By contrast, epilepsies manifesting as seizures that begin locally and may evolve into generalized tonic-clonic seizures, termed *secondarily generalized tonic-clonic seizures*, generally have no such genetic component and are usually the result of underlying brain disease, either acquired or a result of congenital malformations or metabolic defects. Quite often, the initial focal phase is not appreciated, leading to misdiagnosis. An increasing frequency and severity of this group of disorders with age reflects the accumulation of focal cerebral damage from trauma, strokes, and other causes.

We begin our discussion with a practical approximation of the classification shown in Table 15-1, followed by consideration of a number of well-defined epilepsies and epileptic syndromes.

A classification of epileptic syndromes based on the age of onset of the seizure disorder is as follows: onset of the electroclinical syndrome in the *neonatal period* (benign neonatal seizures, benign familial neonatal epilepsy, Ohtahara syndrome, early myoclonic encephalopathy), during *infancy* (febrile seizures, febrile seizures +, benign infantile epilepsy, benign familial infantile epilepsy, West syndrome, Dravet syndrome, myoclonic epilepsy in infancy, myoclonic encephalopathy in nonprogressive disorders, epilespy of infancy with migrating focal seizures),

Table 15-1

CLASSIFICATION OF EPILEPTIC SEIZURES

I. Generalized Onset (bilaterally symmetrical and without focal onset)
  A. Motor
    1. Tonic-clonic (*grand mal*)
    2. Clonic
    3. Tonic
    4. Myoclonic
    5. Myoclonic-tonic-clonic
    6. Myoclonic-atonic
    7. Atonic
    8. Epileptic spasms
  B. Non-motor, Absence (*petit mal*)
    1. Typical
    2. Atypical
    3. Myoclonic
    4. Eyelid myotonia
II. Focal Onset (formerly "partial") with awareness maintained (formerly "simple") or impaired (formerly "complex")
  A. Motor Onset
    1. Automatisms
    2. Atonic
    3. Clonic
    4. Epileptic spasms
    5. Hyperkinetic
    6. Myoclonic
    7. Tonic
  B. Non-motor Onset
    1. Autonomic
    2. Behavior arrest
    3. Cognitive
    4. Emotional
    5. Sensory
III. Unknown Onset
  A. Motor
    1. Tonic-clonic
    2. Epileptic spasms
  B. Non-motor
    1. Behavior arrest
  C. Unclassified

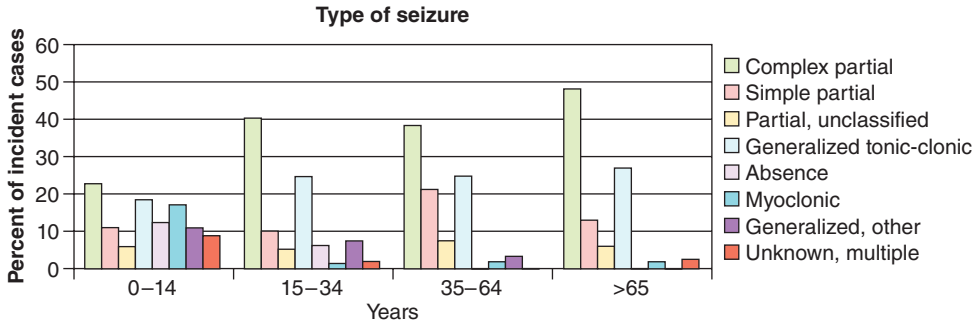

Figure 15-1. The distribution of the main types of epilepsy by age. The overrepresentation of absence and myoclonic seizures in childhood and of complex partial seizures in older individuals is evident. Complex partial = focal with dyscognitive features; simple partial = focal without dyscognitive features. (Adapted from Hauser and Annegers and the texts of Engel and of Pedley.)

during *childhood* (febrile seizures, febrile seizures +, Panayiotopoulos syndrome, epilepsy with myoclonic atonic seizures, absence epilepsy, benign epilepsy with centrotemporal spikes, autosomal dominant nocturnal frontal lobe epilepsy, late onset childhood occipital epilepsy, epilepsy with myoclonic absences, Lennox-Gastaut syndrome, epileptic encephalopathy with continuous spike-and-wave during sleep, Landau-Kleffner syndrome), in *adolescence and adulthood* (juvenile absence epilepsy, juvenile myoclonic epilepsy, epilepsy with generalized tonic-clonic seizures alone, autosomal dominant epilepsy with auditory features, other familial temporal lobe epilepsies), and at *variable age* (familial focal epilepsy with variable foci, progressive myoclonic epilepsies, and reflex epilepsies). The distribution of the seizure types for each age epoch obtained and aggregated from several sources is shown in Fig. 15-1. There continues to be progress in defining the molecular basis of familial and hereditary epilepsies and it is likely that these insights will lead to modification of both the clinical classifications and management of epilepsies.

GENERALIZED ONSET SEIZURES

Generalized Onset Motor Seizures (Tonic-Clonic, Grand Mal)

In the common primary type of seizure, most often a convulsion starts with little or no warning. Sometimes the patient senses the approach of a seizure by several subjective phenomena (*prodrome*) even prior to an epileptic aura, which represents a focal seizure. For some hours, the patient may feel apathetic, depressed, irritable, or, rarely, the opposite—ecstatic. In a patient with generalized epilepsy (juvenile myoclonic epilepsy being one typical type), one or more myoclonic jerks of the trunk or limbs on awakening may herald a seizure later in the day. Abdominal pains or cramps, a sinking, rising, or gripping feeling in the epigastrium, pallor or redness of the face, throbbing headache, constipation, or diarrhea have been given prodromal status, but they do not occur consistently enough to be predictive of an oncoming seizure.

Most often, generalized seizures strike without warning, beginning with a sudden loss of consciousness and a fall to the ground that may lead to facial and other injuries. In some cases of generalized seizure there may be momentary movement of one part of the body before consciousness is lost (turning of the head and eyes or whole body or intermittent jerking of a limb), although the patient often fails to form a memory of this, and such information is obtained only from an observer. At times, this movement represents a focal onset of a seizure and, as has already been pointed out, it is useful to distinguish between a primary (generalized) type of seizure with widespread EEG abnormalities at the onset, and a secondarily generalized type. The secondary generalized type implicates a focal brain lesion.

The initial motor signs are typically a brief flexion of the trunk, an opening of the mouth and eyelids, and upward deviation of the eyes. The arms are elevated and abducted, the elbows semiflexed, and the hands pronated. These are followed by a more protracted extension (*tonic*) phase, involving first the back and neck, then the arms and legs. There may be a piercing cry as the whole musculature is seized in a spasm with biting of the lateral margin of the tongue, and air is forcibly emitted through the closed vocal cords. Because the respiratory muscles are caught up in the tonic spasm, breathing is suspended and after some seconds the skin and lips may become cyanotic. The pupils are dilated and unreactive to light. The bladder may empty at this stage or later, during the postictal period. This is the tonic phase of the seizure and lasts for 10 to 20 s.

There then occurs a transition from the tonic to the *clonic phase* of the convulsion. At first, there is a mild generalized tremor, which is, in effect, a repetitive relaxation of the tonic contraction. It begins at a rate of approximately 8 per second and coarsens to 4 per second; then it rapidly gives way to brief, violent flexor spasms that come in rhythmic salvos and agitate the entire body. If prolonged, the face becomes violaceous and contorted by a series of grimaces. Autonomic signs are prominent: the pulse is rapid, blood pressure is elevated, pupils are dilated, and salivation and sweating are prominent; bladder pressure may increase sixfold during this phase. The clonic jerks decrease in amplitude and frequency over a period of about 30 s. The patient remains apneic until the end of the clonic phase, which is often marked by a deep inspiration. Instead of the whole dramatic sequence described

above, the seizures may be abbreviated or limited in scope by medications.

In the terminal phase of the seizure, all movements end and the patient is motionless and limp in a deep coma. The pupils begin to contract to light. Breathing may be quiet or stertorous. This state persists for several minutes, after which the patient opens his eyes, begins to look about, appears bewildered and confused, and may be quite agitated. The patient may speak and later not remember anything that has been said and undisturbed becomes drowsy and falls asleep, sometimes for several hours, then often awakens with a pulsatile headache. When fully recovered, such a patient has no memory of any part of the spell but knows that something has happened because of the strange surroundings (in ambulance or hospital), the obvious concern of those around him, and often, a sore, bitten tongue and aching muscles from the violent movements. The convulsive contractions, if violent enough, may crush a vertebral body or result in a serious injury; a fracture, periorbital hemorrhages, subdural hematoma, posterior shoulder dislocation, or burn may have been sustained in the fall.

Each of the phases of the generalized tonic-clonic seizure has characteristic EEG accompaniments. Initially, movement artifacts obscure the EEG tracing; sometimes there are repetitive spikes or spike-wave discharges lasting a few seconds, followed by an approximately 10-s period of 10-Hz spikes. As the clonic phase asserts itself, the spikes become mixed with slow waves and then the EEG slowly assumes a polyspike-and-wave pattern. When all movements have ceased, the EEG tracing is nearly isoelectric for a variable time, and then the brain waves gradually resume their pre-seizure pattern.

Severe seizures may be accompanied by a systemic lactic acidosis with a fall in arterial pH, reduction in arterial oxygen saturation, and rise in PCO_2. These effects are secondary to the respiratory arrest and excessive muscular activity. If prolonged, they may cause hypoxic damage to areas in the cerebrum, basal ganglia, and cerebellum. In paralyzed and artificially ventilated subjects receiving electroconvulsive therapy (ECT), these changes are less marked and the oxygen tension in cerebral venous blood may actually rise. Heart rate, blood pressure, and particularly CSF pressure rise briskly during an ECT-induced seizure. The rise in blood pressure evoked by a seizure usually causes a sufficient increase in cerebral blood flow to meet the increased metabolic needs of the brain (Plum and colleagues).

Convulsions of this type ordinarily come singly or in groups of two or three and may occur when the patient is awake and active or during sleep, or when falling asleep or awakening. It is useful to know that seizures on awakening usually signify a generalized type, whereas those occurring during the period of sleep are more often focal in nature. Some 5 to 8 percent of such patients will at some time have a prolonged series of such seizures without resumption of consciousness between them; this is *status epilepticus* and demands urgent treatment. The first outburst of seizures in an individual may take the form of status epilepticus.

Aside from psychogenic episodes that imitate seizures, few clinical states simulate a generalized tonic-clonic seizure, but several are worthy of mention. One is a clonic jerking of the extended limbs (usually less severe than those of a grand mal seizure) that occurs with vasodepressor syncope or a Stokes-Adams hypotensive attack. In contrast to an epileptic type of EEG, the brain waves are slow in frequency and low in amplitude during the jerking movements. A rarer phenomenon that may be indistinguishable from a generalized convulsion occurs as part of the syndrome of basilar artery occlusion. This presumably has its basis in ischemia of the corticospinal tracts in the pons (Ropper); a similar ischemic mechanism in the cortex has been invoked for "limb-shaking TIAs" (transient ischemic attacks), in which there are clonic movements of one limb or one side of the body during an episode of cerebral ischemia. Clonic limb movements occur immediately after a traumatic concussion and an observer who arrives at this moment will be unable to determine if the inciting event was a seizure causing a fall with head injury, or a collision causing a concussion and convulsive movements. In infants, a breath-holding spell may closely simulate the tonic phase of a generalized seizure. Another disorder that simulates a seizure, albeit self-induced, is the *fainting lark* (or in the British, the "mess trick"). By hyperventilating in a squatting position and standing rapidly combined with a Valsalva maneuver, a syncopal episode is induced that ends with generalized convulsive movements (see Lempert et al).

Generalized Onset Non-motor Seizures (Absence, Petit Mal)

In contrast to generalized motor seizures, absence seizures (formerly referred to as *petit mal* or *pyknoepilepsy*) are notable for their brevity, rapid onset and cessation, and frequency and the paucity of motor activity. Indeed, they may be so brief that the patients themselves are sometimes not aware of them; to an onlooker, they resemble a moment of absentmindedness or daydreaming. The attack, coming without warning, consists of a sudden interruption of consciousness, for which the French word *absence* ("not present," "not in attendance") has been retained. The patient stares and briefly stops talking or ceases to respond. Only about 10 percent of such patients are completely motionless during the attack; in the remainder, one observes a brief burst of fine clonic (myoclonic) movements of the eyelids, facial muscles, or fingers or small synchronous movements of both arms, all at a rate of 3 per second as shown many years ago by Penry and colleagues. This rate corresponds to that of the EEG abnormality, which takes the form of a generalized 3-per-second spike-and-wave pattern (see Fig. 2-7I). Absence seizures are said to be "typical" if they have a rapid onset and offset, a 3-per-second spike and wave, and complete loss of awareness.

Minor automatisms—in the form of lip-smacking, chewing, and fumbling movements of the fingers—are common during an attack but may be subtle. Postural tone may be slightly decreased or increased, and occasionally there is a mild vasomotor disorder. As a rule, such patients

do not fall; they may even continue complex acts such as walking or riding a bicycle. After 2 to 10 s, occasionally longer, the patient reestablishes full contact with the environment and resumes preseizure activities. Only a loss of the thread of conversation or the place in reading betrays the occurrence of the momentary "blank" period (the absence). In many such patients, voluntary hyperventilation for 2 to 3 min is an effective way of inducing absence attacks.

Typical absence seizures constitute the most characteristic epilepsy of childhood ("childhood absence"); rarely do the seizures begin before 4 years of age or after puberty. Another attribute is their great frequency (hence, the old term *pykno*, meaning "compact" or "dense"). As many as several hundred may occur in a single day, sometimes in bursts at certain consistent times of the day. They produce periods of inattention and may appear in the classroom when the child is sitting quietly rather than participating actively in his lessons. If frequent, they disturb attention and thinking to the point that the child's performance in school is impaired. Less frequently, such attacks may last for hours with no interval of normal mental activity between them—this would constitute a generalized onset non-motor status epilepticus. Absence epilepsy of adolescent onset ("juvenile absence") does not have the very high seizure frequency of the childhood type. Cases of absence status have also been described in adults with frontal lobe epilepsy (see in the following text). In contrast to childhood absence seizures, the disorder may last well into adulthood and be punctuated by generalized onset motor seizures or a burst of seizures.

The typical absence seizure, with or without myoclonic jerks, rarely causes the patient to fall. Absence should be considered a separate entity because of its relative benignity. The attacks tend to diminish in frequency in adolescence and then often disappear, only to be replaced in some instances by generalized onset motor seizures. About one-third of children with absence attacks will, in addition, display symmetrical or asymmetrical myoclonic jerks without loss of consciousness, and about half will at some time have tonic-clonic convulsions.

Absence Variants

Distinguished from typical absence seizures are variants in which the loss of consciousness is less complete or in which myoclonus is prominent, and others in which the EEG abnormalities are less regularly of a 3-per-second spike-and-wave type (they may occur at the rate of 2–2.5 per second or take the form of irregular 4- to 6-Hz polyspike-and-wave complexes). *Atypical absence* is a term that was introduced to describe long runs of slow spike-and-wave activity, usually with no apparent loss of consciousness. External stimuli, such as asking the patient to answer a question or to count, interrupt the run of abnormal EEG activity. The current classification (see Table 15-1) separates the absence seizures into groups that are identified as typical, atypical, and having special features, namely, myoclonic jerks or eyelid myotonia.

Lennox-Gastaut Syndrome

In sharp contrast to the typical absence epilepsies is a form that has its onset between 2 and 6 years of age and is characterized by atonic, or astatic, seizures (i.e., falling attacks), often succeeded by various combinations of minor motor, tonic-clonic, and partial seizures and by progressive intellectual impairment in association with a distinctive, slow (1- to 2-Hz) spike-and-wave EEG pattern. This is the *Lennox-Gastaut syndrome*. Often it is preceded in earlier life by infantile spasms, a characteristic high amplitude chaotic EEG picture (*hypsarrhythmia*), and an arrest in mental development, a triad sometimes referred to as the *West syndrome* (see further on). The early onset of atonic seizures with abrupt falls, injuries, and associated abnormalities nearly always has a grave implication—namely, the presence of serious neurologic disease. Prematurity, perinatal injury and metabolic diseases of infancy are the most common underlying conditions. This is essentially a form of symptomatic generalized epilepsy, in contrast to the foregoing idiopathic types such as typical absence epilepsy. The Lennox-Gastaut syndrome may persist into adult life and is one of the most difficult forms of epilepsy to treat.

Myoclonic Seizures

The phenomenon of myoclonus was discussed in Chap. 4, where the relationship to seizures was emphasized. Characterized by a brusque, brief, muscular contraction, some myoclonic jerks may be so small as to involve only one muscle or part of a muscle; others are so large as to displace a limb on one or both sides of the body or the entire trunk musculature. Many are brief, lasting 50 to 100 ms; they may occur intermittently and unpredictably or present as a single jerk or a brief salvo.

As mentioned earlier, a series of several small, rhythmic myoclonic jerks may appear with varying frequency as part of atypical absence seizures, and as isolated events in patients with generalized tonic, clonic, or tonic-clonic seizures. As a rule, seizure-associated myoclonus, when occurring in isolation, is relatively common, signifies nothing more than the seizure disorder, and usually responds well to antiepileptic medication. In contrast, there are diseases in which myoclonus is progressive in severity or very frequent. These disorders have their onset in childhood and raise the suspicion of entities such as the myoclonus-opsoclonus-ataxia syndrome, lithium or other drug toxicity or, if lasting a few weeks, subacute sclerosing panencephalitis. Chronic progressive polymyoclonus with dementia characterizes the group of juvenile lipidosis (see Chap. 36), Lafora-type familial myoclonic epilepsy, certain mitochondrial disorders, and other chronic familial degenerative diseases of undefined type (paramyoclonus multiplex of Friedreich) as noted further on in Table 15-3. A large number of adult diseases causative of myoclonus and seizure disorders are discussed in later chapters.

Juvenile Myoclonic Epilepsy

This is the most common form of idiopathic generalized epilepsy in older children and young adults. It begins in adolescence, typically around age 15 years, with a range

that essentially spans all of the teenage years. The patient comes to attention because of a generalized tonic-clonic seizure, often on awakening or because of myoclonic jerks in the morning that involve the entire body; sometimes absence seizures are prominent. The family reports that the patient has occasional myoclonic jerks of the arm and upper trunk that is brought out with fatigue, early stages of sleep, or alcohol ingestion. A few patients in our experience have had only the myoclonic phenomena and rare absence or tonic-clonic seizures that persisted unnoticed for years. The EEG shows characteristic bursts of 4- to 6-Hz irregular polyspike activity. A linkage has been established to several loci, mainly of ion channels and of GABA-related receptors.

The disorder does not impair intelligence and tends not to be progressive, for which reason it has been called "benign," but a proclivity to infrequent seizures usually continues throughout life. A report by Baykan and colleagues has indicated that, over an average of two decades, the majority of patients have long seizure-free periods and a large reduction in myoclonic seizures by the fourth decade but only one-fifth become virtually seizure free. Valproic acid in particular and some other antiepileptic drugs are highly effective in eliminating the seizures and myoclonus, but they should be continued indefinitely as discontinuation of medication is associated with a high rate of relapse. Owing to the potential teratogenicity of valproate, women of childbearing age are often given levetiracetam or lamotrigine, acknowledging that they may not be as effective as the first choice of drug. It has been observed that carbamazepine and phenytoin may exaggerate the seizures.

Table 15-2

COMMON FOCAL SEIZURE PATTERNS

CLINICAL TYPE	LOCALIZATION
Somatic Motor	
Jacksonian (focal motor)	Prerolandic gyrus
Masticatory, salivation, speech arrest	Amygdaloid nuclei, opercular
Simple contraversive	Frontal
Head and eye turning associated with arm movement or athetoid-dystonic postures	Supplementary motor cortex
Somatic and Special Sensory (Auras)	
Somatosensory	Contralateral posterior rolandic
Unformed images, lights, patterns	Occipital
Auditory	Heschl gyri
Vertiginous	Superior temporal
Olfactory	Mesial temporal
Gustatory	Insula
Visceral: autonomic	Insular-orbital-frontal cortex
Focal Seizure with Altered Consciousness	
Formed hallucinations	Temporal neocortex or amygdaloid–hippocampal complex
Illusions	Temporal
Dyscognitive experiences (déjà vu, dreamy states, depersonalization)	Temporal
Affective states (fear, depression, or elation)	Temporal
Automatism (ictal and postictal)	Temporal and frontal
Staring	Frontal cortex, amygdaloid–hippocampal complex, reticular– cortical system

Source: Modified from Penfield and Jasper.

FOCAL ONSET SEIZURES

As indicated earlier, the International Classification divides all seizures into two types—generalized, in which the clinical and EEG manifestations indicate bilateral and diffuse cerebral cortical involvement from the onset, and focal, in which the seizure is often the product of a demonstrable focal lesion or EEG abnormality in some part of the cerebral cortex. The manifestations of focal seizures reflect the locale of the lesion. In the past focal seizures were classified by whether consciousness was retained (partial) or impaired (complex) but are now subsumed under the term "impaired awareness" if awareness is altered. Focal seizures with sensory or motor features at the onset most often arise from foci in the sensorimotor cortex. Those with impairment of consciousness, which occurs in many forms, most often have their focus in the limbic and autonomic areas or in the temporal lobe, but a frontal localization is also known. Table 15-2 lists the common sites of lesions and the corresponding types of seizures.

Relatively few focal seizures can be localized precisely from clinical data alone. However, when combined with scalp and intracranial EEG recording and brain MRI as well as other imaging modalities, the localization is considerably more accurate.

Frontal Lobe Seizures (Focal Motor and Jacksonian Seizures)

Focal onset motor seizures are attributable to a discharging lesion of the frontal lobe. A common type, originating in the supplementary motor area, takes the form of a turning movement of the head and eyes to the side opposite the irritative focus, often associated with a tonic extension of limbs, also on the side contralateral to the affected hemisphere. This may constitute the entire seizure, or it may be followed by generalized clonic movements. The extension of the limbs may occur just before or simultaneously with loss of consciousness but a lesion in one frontal lobe may give rise to a generalized convulsion without an initial turning of the head and eyes. It has been postulated that, if there is loss of consciousness, it is the result of a rapid spread of the discharge from the frontal lobe to integrating centers in the thalamic or high midbrain reticular formation.

One form of focal frontal convulsion is the *Jacksonian motor seizure*, which begins with tonic and then clonic contraction of the fingers of one hand, the face on one side, or the muscles of one foot. Sometimes a series of clonic movements of increasing frequency build up to a tonic contraction. The characteristic feature is that the movements spread (march) from the part first affected to

other contiguous muscles on the same side of the body. In its typical form, the seizure spreads from the hand, up the arm, to the face, and down the leg; or if the first movement is in the foot, the seizure marches up the leg, down the arm, and to the face, usually in a matter of 20 to 30 s. Rarely, the first muscular contraction is in the abdomen, thorax, or neck. In some cases, the one-sided seizure activity is followed by turning of the head and eyes to the convulsing side, occasionally to the opposite side, and then by a generalized seizure with loss of consciousness. Consciousness is not lost if the sensorimotor symptoms remain confined to one side.

The frontal lobe, being so large, can give rise to numerous forms of seizure including the typical Jacksonian type described above, but also adversive (contralateral turning of the body or of a body part), speech arrest, frontal, absence types, and a number of unusual disorders related to discharges from the supplementary motor area including hyperkinetic and postural tonic varieties. In practice, it is often difficult to distinguish such seizures from parasomnic (sleep related) events (see Chap. 18).

Focal motor seizures may begin with forceful, sustained deviation of the head and eyes, and sometimes of the entire body, and are referred to as *versive* or *adversive*. The turning movements are usually to the side opposite the electrical focus but sometimes to the same side. The same is true for the head and eye turning that occurs at the end of the generalized tonic-clonic phase of seizures (Wylie et al). In seizures of temporal lobe origin, early in the seizure, there may be head turning ipsilaterally followed by forceful, contraversive head (and body) turning. These head and body movements, if they occur, may be preceded by quiet staring or automatisms. Nonforceful, unsustained, or seemingly random lateral head movements during the ictus do not have localizing value and suggest that the phenomena are epileptic.

Following convulsions that have a prominent focal motor signature, there is often a transient paralysis of the affected limbs. This *Todd paralysis* persists for minutes or at times for hours after the seizure, usually in proportion to the duration of the convulsion. Continued focal paralysis beyond this time usually indicates the presence of a focal brain lesion as the underlying cause of the seizure or persisting seizures in a nonconvulsive form. A similar Todd phenomenon is found in cases of focal epilepsy that involve the language, somesthetic, or visual areas; here the persistent deficit corresponds to the region of the brain affected.

The high incidence of focal motor epilepsy that originates with movements in the face, hands, and toes is probably related to the disproportionately large cortical representations of these body parts. Contraversive deviation of only the head and eyes can be induced most consistently by electrical stimulation of the superolateral frontal region (area 8), just anterior to area 6 (see Figs. 21-1 and 21-2). The disease process or focus of excitation is usually in or near the rolandic (motor) cortex, that is, area 4 of Brodmann (see Figs. 3-3 and 22-2); in some cases, and especially if there is a sensory accompaniment, it has been found in the post-rolandic convolution.

Lesions confined to the motor cortex are reported to assume the form of clonic contractions, and those confined to the premotor cortex (area 6), tonic contractions of the contralateral arm, face, neck, or all of one side of the body. Tonic elevation and extension of the contralateral arm and flexion of the ipsilateral arm (fencing posture) and choreoathetotic and dystonic postures have been associated with high medial frontal lesions (area 8 and supplementary motor cortex), as have complex, bizarre, and flailing movements of a contralateral limb, but this always raises the suspicion of a nonepileptic phenomenon. Perspiration and piloerection occur occasionally in parts of the body involved in a focal motor seizure, suggesting that these autonomic functions have a cortical representation in or adjacent to the rolandic area. Focal motor and Jacksonian seizures have essentially the same localizing significance.

Seizure discharges arising from the cortical language areas may give rise to a brief aphasic disturbance (*ictal aphasia*) and utterance of a word or loud sound or, more frequently, a vocal arrest. Ictal aphasia is usually succeeded by other focal or generalized seizure activity but may occur in isolation, without loss of consciousness, in which case it can later be described by the patient. Postictal aphasia is more common than ictal aphasia. Verbalization at the onset of a seizure has no consistent lateralizing significance and, paradoxically, is usually associated with an origin in the nondominant hemisphere. These disturbances should be distinguished from the stereotyped repetition of words or phrases or the garbled speech that characterizes some complex partial seizures or the postictal confusional state and, of course, Wernicke aphasia.

Somatosensory, Visual, and Other Types of Sensory Seizures

Somatosensory seizures, either focal or "marching" to other parts of the body on one side, are nearly always indicative of a focus in or near the post-rolandic convolution of the opposite cerebral hemisphere. The sensory disorder is usually described as numbness, tingling, or a "pins-and-needles" feeling and occasionally as a sensation of crawling (formication), electricity, or movement of the body part. Pain and thermal sensations may occur but are exceedingly rare. In the majority of cases, the onset of the sensory seizure is in the lips, fingers, or toes, and the spread to adjacent parts of the body follows a pattern determined by sensory arrangements in the postcentral (post-rolandic) convolution of the parietal lobe (Salanova and colleagues). If the sensory symptoms are localized to the head, the focus is in or adjacent to the most lateral part of the convolution, near the sylvian fissure; if the symptoms are in the leg or foot, the upper part of the convolution, near the superior sagittal sinus or on the medial surface of the hemisphere, is involved.

Olfactory hallucinations, perhaps the most important of the sensory seizures because they signify a particular localization, are associated with disease of the inferior and medial parts of the temporal lobe, usually in the region of the parahippocampal convolution or the uncus (hence Jackson's term *uncinate seizures* [see also Chap. 11]).

Usually, the perceived odor is exteriorized, that is, projected to someplace in the environment, and is described as disagreeable or foul, though otherwise unidentifiable. *Gustatory hallucinations* also have been recorded in proven cases of temporal lobe disease and less often with lesions of the insula and parietal operculum; salivation and a sensation of thirst may be associated. Electrical stimulation in the depths of the sylvian fissure, extending into the insular region, has produced peculiar sensations of taste.

Visual seizures are relatively rare but also have localizing significance. Lesions in or near the striate cortex of the occipital lobe usually produce elemental visual sensations of darkness or sparks and flashes of light, which may be stationary or moving and colorless or colored. Red is the most frequently reported color, followed by blue, green, and yellow (Gowers). These images may be referred to as the visual field on the side opposite of the lesion or may appear straight ahead. If they occur on one side of the visual field, patients perceive that only one eye is affected (the one opposite the lesion), probably because most persons are aware of only the temporal half of a homonymous field defect. Curiously, a seizure arising in one occipital lobe may cause momentary blindness in both fields. It has been noted that lesions on the lateral surface of the occipital lobe (Brodmann areas 18 and 19) are likely to cause a sensation of twinkling or pulsating lights. More complex or formed visual hallucinations are usually caused by a focus in the posterior part of the temporal lobe, near its junction with the occipital lobe, and may be associated with auditory hallucinations. The localizing value of visual auras was confirmed in a group of 20 surgically treated patients with intractable seizures due to occipital lobe epilepsy who experienced elementary visual hallucinations and visual loss, though similar visual phenomena also occurred with seizure foci in the anteromedial temporal and occipitotemporal regions (Bien and colleagues, 2000). Reference is made here to the childhood occipital seizure disorder described by Panayiotopoulos, discussed further on. These patients experience rudimentary visual hallucinations. One interesting feature that we have observed is of extreme turning of the head and eyes toward the visual images.

Auditory hallucinations are infrequent as an initial manifestation of a seizure and usually represent a psychotic disorder or one of several more benign conditions. Occasionally, a patient with a focus in one superior temporal convolution will report a buzzing or roaring in the ears. A human voice, sometimes repeating unrecognizable words, or the sound of music has been noted a few times with lesions in the more posterior part of one temporal lobe. Some people with epilepsy and a strong family history of seizures with auditory auras, may have normal imaging but turn out to have mutations in the *LGI1* gene.

Vertiginous sensations of a type suggesting a vestibular origin may on rare occasions be the first symptom of a seizure. The lesion is usually located in the posterior superior temporal region or the junction between parietal and temporal lobes. In one of the cases reported by Penfield and Jasper, a sensation of vertigo was evoked by stimulating the cortex at the junction of the parietal and occipital lobes. Occasionally with a temporal focus, the vertigo is followed by an auditory sensation. Giddiness, or light-headedness, is a frequent prelude to a seizure, but this symptom, as discussed in Chap. 14, has so many different connotations that it is of little diagnostic value.

Vague and often indefinable *visceral sensations* arising in the thorax, epigastrium, and abdomen are among the most frequent of auras, as already indicated. Most often they have a temporal lobe origin, although in several such cases the seizure discharge has been localized to the upper bank of the sylvian fissure, in the upper or middle frontal gyrus, or in the medial frontal area near the cingulate gyrus. Palpitation and acceleration of the heart rate at the beginning of the attack have also been related mainly to a temporal lobe focus.

Temporal Lobe Seizures

These differ from the major generalized and absence seizures discussed above in that (1) they signify a focal onset in the temporal lobe as reflected by an aura that may be a hallucination or perceptual illusion, or (2) a period of altered behavior and incomplete impairment of consciousness, a dyscognitive state, in contrast to the loss of connection to the environment typical of absence epilepsy.

Although it is difficult to enumerate all the psychic experiences that may occur during these types of seizures, they may be categorized as illusions, hallucinations, depersonalization states, and affective experiences. Among the altered psychic states are a feeling of intense perception of familiarity in an unfamiliar circumstance or place (déjà vu) or, conversely, of strangeness or unfamiliarity (jamais vu) in a previously known place or circumstance. There may be the experience of autoscopy, a type of depersonalization, or a dream-like state in which the patient views himself as an external observer. Fragments of certain old memories or scenes may insert themselves into the patient's mind and recur with striking clarity, or there may be an abrupt interruption of memory (Gloor). Sensory illusions, or distortions of ongoing perceptions, are the most common. Objects or persons in the environment may shrink or recede into the distance, or they may enlarge (micropsia and macropsia), or perseverate as the eyes are moved (palinopsia). A perceived tilting of the visual environment has been reported as well. Hallucinations are most often visual or auditory, consisting of formed or unformed visual images, sounds, and voices; less frequently, they may be olfactory (usually unpleasant, unidentifiable sensations of smell), gustatory, or vertiginous. Associated epigastric and abdominal sensations have been alluded to above and likely have their origin in autonomic and limbic structures.

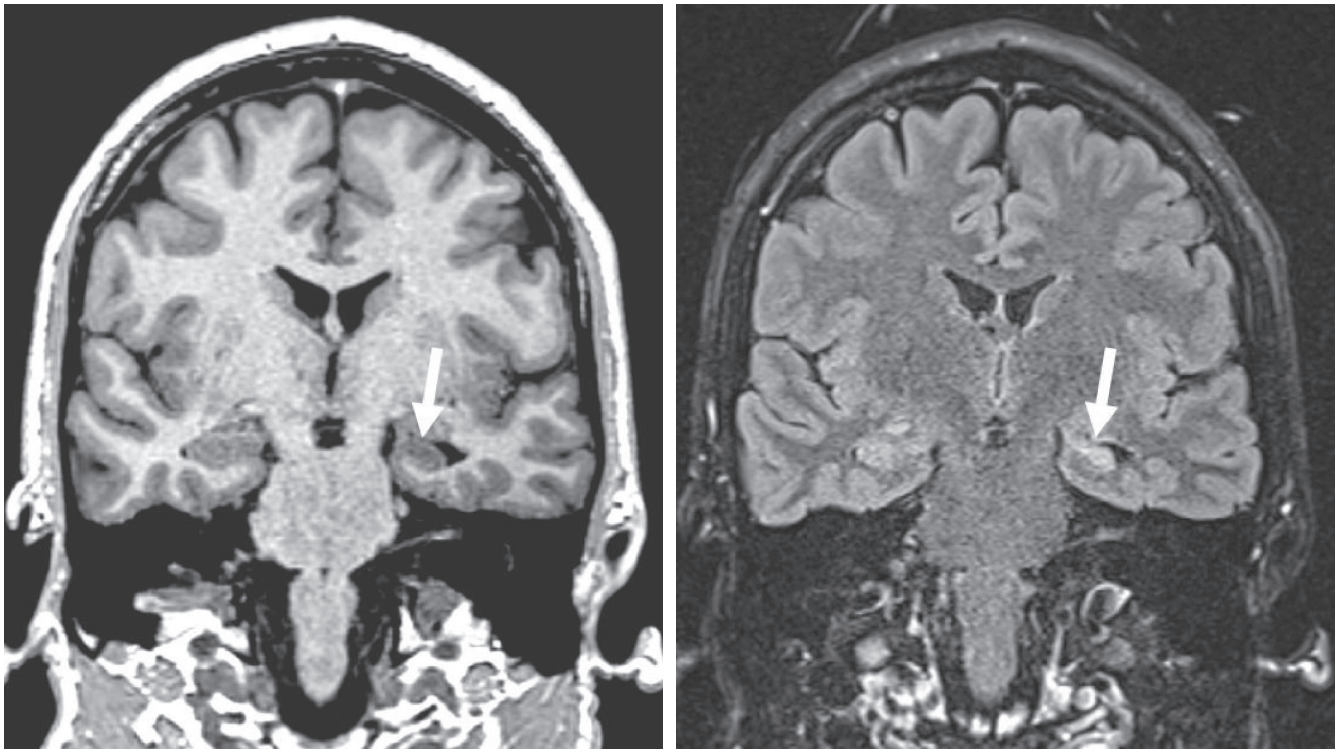
Emotional experiences as a result of seizure, while less common, may be dramatic—fear, anxiety, sadness, anger, happiness, ecstasy, and sexual excitement have all been recorded. Fear and anxiety are the most common affective experiences, while occasionally the patient describes a feeling of rage or intense anger as part of a temporal lobe seizure.

Each of these subjective psychic states may constitute the entire seizure or some combination may occur and immediately precedes a period of altered awareness. These "auras" represent electrical seizures as already mentioned and have the same localizing significance as motor convulsions do for the frontal cortex. All the temporal lobe ictal experiences have no apparent connection to objective circumstances and are generally not related to the situation in which the patient finds himself during the seizure.

The motor components of a focal temporal lobe or limbic seizure, if they occur, arise during the later phase of the seizure and take the form of *automatisms* such as lip smacking, chewing or swallowing movements, salivation, fumbling of the hands, or shuffling of the feet. Patients may walk around in a daze or act inappropriately. Complex acts that were initiated before the loss of consciousness—such as walking, chewing food, turning the pages of a book, or even driving—may continue. However, when asked a specific question or given a command, the patients are obviously out of contact with their surroundings. There may be no response at all, or the patient may look toward the examiner in a perplexed way or utter a few stereotyped phrases. The patient may walk repetitively in small circles (*volvular epilepsy*), run (*epilepsia procursiva*), or simply wander aimlessly, either as an ictal or postictal phenomenon (*poriomania*). These forms of seizure, according to some epileptologists, are actually more common with frontal lobe than with temporal lobe foci of origin. Dystonic stiffness of the arm and leg contralateral to the seizure focus is found to be an accompaniment of temporal lobe seizures (more often this is from the supplementary motor of the frontal than the temporal lobes).

In a small number of patients with temporal lobe seizures, some degree of responsiveness to simple questions and motor commands is preserved in the presence of prominent automatisms such as lip-smacking and swallowing (Ebner and colleagues). Interestingly, the seizures originate in the right temporal lobe. That consciousness should be altered with temporal lobe epilepsy is not at all self-evident. Several mechanisms have been studied, particularly by Blumenfeld's group, and converge on the effects of temporal lobe discharge on deep structures such as the medial thalamus and the septal nuclei (Englot and colleagues). Amnesia is an important component of the alteration in the state of consciousness in temporal lobe epilepsy but does not explain the entire syndrome.

The patient, in a confused and irritable state, may resist or strike out at the examiner. These types of behaviors, which occur in a limited number of patients with temporal lobe or frontal seizures, usually take the form of nondirected oppositional resistance to restraint. These behaviors manifest during a period of automatic behavior (so-called because the patient presumably acts like an automaton) or, more often, in the postictal period. Unprovoked assault or outbursts of intense rage or blind fury are very unusual; for example, in only 16 of 666 patients (2.4 percent) with temporal lobe epilepsy (Currie and colleagues). Penfield once commented that he had never observed a rage state as a result of temporal lobe stimulation. It is thus exceedingly unlikely that an organized violent act requiring several sequential steps in its performance, such as obtaining a weapon and using it in a directed manner, could represent a temporal lobe seizure.



Rarely, laughter may be the most striking feature of a seizure (*gelastic epilepsy*). A particular combination of gelastic seizures and precocious puberty has been traced to a hamartoma of the hypothalamus. Crying, or *dacrystic epilepsy*, on the other hand, while demonstrated in children, is very infrequent and more often indicates a psychogenically induced episode.

The patient with temporal lobe seizures may exhibit only one of the foregoing manifestations of seizure activity or various combinations. In a series of 414 patients, 43 percent displayed some of the motor changes; 32 percent, automatic behavior; and 25 percent, alterations in psychic function (Lennox, 1960). Because of the frequent concurrence of these symptom complexes, Lennox referred to them as the *psycho-motor triad*. Probably the clinical pattern varies with the precise locality of the lesion and the direction and extent of spread of the electrical discharge.

After the attack, the patient usually has no memory or only fragments of recall for what was said or done. Any type of complex partial seizures may proceed to other forms of secondary generalized seizures. Indeed the tendency to secondarily generalize holds true for all types of focal epilepsy.

Temporal lobe seizures are not peculiar to any period of life, but they do show an increased incidence in adolescence and the adult years and have an uncertain relationship to childhood febrile seizures. The topic of febrile seizures is broader than this association suggests; it is taken up in a later section of the chapter. Neonatal convulsions, head trauma, and various other nonprogressive perinatal neurologic disorders are other antecedents that place a child at risk of developing complex partial seizures (Rocca and colleagues). Two-thirds of patients with temporal lobe seizures also have generalized motor seizures or have had them in early childhood, and it has been theorized that the generalized seizures may have led to secondary excitotoxic damage to the hippocampal portions of the temporal lobes. In the latter cases, carefully performed and quantitated MRI in the coronal plane (ideally, perpendicular to the long axis of each hippocampal body) may disclose a loss of volume, gliosis, and other morphologic changes in the hippocampi and adjacent gyri on one or both sides—that is, *medial (or mesial) temporal sclerosis*, discussed later in the chapter (Fig. 15-2).

Temporal lobe seizures are highly variable in duration. Behavioral automatisms rarely last longer than a minute or two, although postictal confusion and amnesia may persist for a considerably longer time. Some consist only of a momentary change in facial expression and a blank spell, resembling an absence. Almost always, however, temporal lobe events are characterized by distinct ictal and postictal phases, whereas patients with absence attacks usually have an instantaneous return of full consciousness following the ictus.

A B

Figure 15-2. Medial temporal sclerosis. *A*. T1-weighted MRI in the coronal plane, showing reduced volume of the left hippocampus (*shown by arrow*) and secondary enlargement of the adjacent temporal horn of the lateral ventricle. *B*. Coronal T2-FLAIR image showing abnormal hyperintense signal within the left hippocampus (*shown by arrow*).

Postictal behavior after temporal lobe seizures is often accompanied by a widespread or focal slowing in the EEG. Prolonged disorientation for time and place suggests a right-sided source. Automatisms in the postictal period have no lateralizing connotation (Devinsky and colleagues, 1994). However, postictal posturing and paresis of an arm (*Todd paralysis*) or an aphasic difficulty are helpful in determining the side of the lesion (Cascino). Postictal nose wiping, which is reported to occur in half of patients with temporal lobe seizures, is carried out by the hand ipsilateral to the seizure focus (Leutzmezer and colleagues).

Amnesic Seizures (Transient Epileptic Amnesia)

Rarely, recurrent attacks of transient amnesia are the only manifestations of temporal lobe epilepsy, although it is unclear whether the amnesia in such patients represents an ictal or postictal phenomenon. These attacks of pure amnesia have been referred to as *transient epileptic amnesia* (Palmini and colleagues; Zeman and colleagues). If the patient functions at a fairly high level during the attack, as may happen, there is a resemblance to transient global amnesia (described in Chap. 20). However, in contrast to transient global amnesia, the relative brevity and frequency of the amnesic spells, their tendency to occur on awakening, the impaired performance on complex cognitive tasks, and the absence of repetitive stereotyped questions help to make the distinction.

MEDICAL AND PSYCHIATRIC ASPECTS OF EPILEPSY

Behavioral and Psychiatric Disorders With Epilepsy

Some comments are in order concerning the issues of *behavioral* and *psychiatric disorders* in patients who have seizures. Data as to prevalence of these disorders have been derived mainly from studies of selected groups of patients attending specialty clinics that tend to treat the most difficult and complicated cases. In such studies, approximately one-third of patients with epilepsy had a history of major depressive illness, and an equal number had symptoms of anxiety disorder; fewer had psychotic symptoms. It must be emphasized that these remarkably high rates of psychiatric morbidity do not reflect the prevalence in the entire population of patients with epilepsy. Epidemiologic studies provide only limited evidence of an association with psychosis in the overall population of epileptics (Trimble). Furthermore, it should be borne in mind that many chronic medical conditions are associated with psychiatric reactions and the unpredictability and stigma of the epileptic disorders may contribute to depression and anxiety.

The postictal state in patients with temporal lobe epilepsy rarely incorporates a protracted *paranoid delusional*

or *amnesic psychosis* lasting for days or weeks. The EEG during this period may show no seizure discharge, although this does not exclude repeated seizures in temporal lobe structures that are remote from the recording electrodes. This disorder, virtually indistinguishable from psychosis, may also present in the interictal period.

It had been observed that some patients with temporal lobe seizures may exhibit a number of personal peculiarities. It was stated that they are slow and rigid in their thinking, verbose, circumstantial and tedious in conversation, inclined to mysticism, and preoccupied with rather naive religious and philosophical ideas. Obsessionalism, humorless sobriety, emotionality (mood swings, sadness, and anger), and a tendency to paranoia are other frequently described traits. Diminished sexual interest and potency in men and menstrual problems in women, not readily attributable to antiepileptic drugs, are common among patients with complex partial seizures of temporal lobe origin. Waxman and Geschwind proposed that a triad of behavioral abnormalities—hyposexuality, hypergraphia, and hyperreligiosity—constitutes a characteristic syndrome but this has been disputed. It has been suggested that certain personality traits are more common with *right* temporal lesions, and that anger, paranoia, and cosmologic or religious conceptualizing are more characteristic of *left* temporal lesions (Bear and Fedio). However, others have found no features that would distinguish foci on either side and no behavioral changes that would distinguish patients with temporal lobe epilepsy from other groups of epileptics (Rodin and Schmaltz). The problem of personality disturbances in epilepsy has not been clarified and many modern clinicians no longer identify these traits as parts of the epileptic syndrome, having in the past been imputed to these patients by societal and medical biases but even this is open to other interpretation.

Sudden Unexplained Death in Epilepsy

In the past few decades, sudden death has been emphasized as an underappreciated problem in the epileptic population. Certainly, the mortality in individuals with epilepsy is increased ostensibly from accidents, suicide, and the underlying cause of seizures. However, the main contributor to the increased mortality rate in otherwise healthy people with epilepsy is unexpected death outside of circumstances such as drowning, trauma from a fall, myocardial infarction, and automobile accidents during the seizure. It is to this group that the acronym "*SUDEP*," or *sudden unexplained death in epilepsy*, has been applied. Surprisingly, unexpected death is predominantly an issue of adulthood more than of childhood. The rate of unexpected death increases with the duration and severity of epilepsy and several population studies suggest that the rate may be as high as several-fold higher than in age-matched individuals in the general population. The rate of this entity is generally given as approximately 0.35 cases per 1,000 person years but with severe epilepsy, and as high as 3 to 9 per 1,000 person years (Leestma and colleagues). Most patients affected have a history of generalized tonic-clonic seizures and die in bed. In children, those with treatment-resistant epilepsy, developmental delay, and several syndromes such as tuberous sclerosis are at particular risk.

Several factors have emerged as risks from population-based and cohort case-controlled studies; the postictal period immediately after a tonic-clonic seizure, increasing seizure frequency (including three generalized seizures in the preceding year), lack of successful treatment (i.e., patients not in remission as documented in a 40-year follow-up study of childhood epilepsy by Sillanpää and Shinnar) or subtherapeutic levels of antiepileptic drugs, the period of early adulthood, long-standing epilepsy, and mental retardation.

Most instances of SUDEP occur when the patient is unattended or during sleep. Although respiratory difficulty and cardiac changes including asystole and ventricular arrhythmias are known to occur during and immediately after seizures, none of these has been a consistent factor and usually, the precise mechanism of death has been difficult to determine. A postictal "shutdown" of brainstem activity resulting in hypercapnia or hypoxemia has been suggested but there may be various causes operative in different cases.

One approach to preventing sudden death is adequate treatment with antiepileptic drugs. The risk of sudden death is as high as 20 times greater for untreated patients. Specialists in the field of epilepsy suggest that the practitioner should consider having an open conversation about the problem of SUDEP with patients and their families (Devinsky; and Devinsky and colleagues, 2016). A retrospective cohort study of patients with epilepsy showed that those who were under the care of an epilepsy specialist or neurologist had a reduced risk of premature mortality, and those who received care at a comprehensive epilepsy center had the greatest benefit (Lowerison and colleagues).

OTHER EPILEPTIC SYNDROMES

There remain to be considered several epileptic syndromes and other seizure states that cannot be readily classified with the usual types of generalized or focal onset seizures. Many of these, particularly the first four entities discussed below, have been found to have a genetic basis, typically involving a disorder of ion channel function.

Benign Epilepsy of Childhood With Centrotemporal Spikes (Rolandic Epilepsy, Sylvian Epilepsy)

This common focal onset motor epilepsy is unique among the focal epilepsies of childhood in that it is self-limiting despite a very abnormal EEG pattern. It is usually transmitted in families as an autosomal dominant trait and begins between 5 and 9 years of age. It typically announces itself by a nocturnal tonic-clonic seizure with focal onset. Thereafter, the seizures take the form of clonic contractions of one side of the face, less often of one arm or leg, and the interictal EEG shows high-voltage spikes in the

contralateral lower rolandic or centrotemporal area. Seizures are readily controlled by a single anticonvulsant drug and gradually disappear during adolescence. The relation of this syndrome to developmental dyslexia is unsettled.

Epilepsy With Occipital Spikes (Panayiotopoulos Syndrome)

A similar type of epilepsy, usually benign in the sense that there is no cognitive deterioration and the seizures often cease in adolescence, has been associated with spike activity over the occipital lobes (Panayiotopoulos). Visual hallucinations, while not invariable, are the most common clinical feature (Taylor and colleagues); sensations of movements of the eyes, tinnitus, or vertigo are also reported in cases of occipital epilepsy, and autonomic overactivity in association with the seizures is prominent in some children. In both of these types of childhood epilepsy, the observation that spikes are greatly accentuated by sleep is a useful diagnostic feature.

Infantile Spasms (West Syndrome)

This term is applied to a particularly dramatic form of epilepsy of infancy and early childhood. William West, in the mid-nineteenth century, described the condition in his son in great detail (West). This disorder, which in most cases appears during the first year of life, is characterized by recurrent, single or brief episodes of gross flexion movements of the trunk and limbs and, less frequently, by extension movements (hence the alternative terms *infantile spasms* or *salaam* or *jackknife seizures*). Most but not all patients with this disorder show major EEG abnormalities consisting of continuous multifocal spikes and slow waves of large amplitude. However, this pattern, named by Gibbs and Gibbs in 1952 as *hypsarrhythmia* ("mountainous" dysrhythmia), is not specific for infantile spasms, being frequently associated with other developmental or acquired abnormalities of the brain. As the child matures, the seizures diminish and usually disappear by the fourth to fifth year. If MRI and CT scans are more or less normal, the usual pathologic findings are cortical dysgeneses (Jellinger). Both the seizures and the EEG abnormalities may respond dramatically to treatment with adrenocorticotropic hormone (ACTH), corticosteroids, or the benzodiazepine drugs, of which clonazepam is probably the most widely used. A type of West syndrome that is caused by tuberous sclerosis also responds dramatically to gamma-aminobutyric acid (GABA)-inhibiting drugs. However, most patients, even those who were apparently normal when the seizures appeared, are left with some degree of developmental delay. Infantile spasms may later progress to the *Lennox-Gastaut syndrome*, a seizure disorder of early childhood of graver prognosis as discussed in a previous section.

Febrile Seizures

The well-known uncomplicated *febrile seizure*, specific to infants and children between 6 months and 5 years of age (peak incidence ages 9–20 months) and with an inherited tendency, is generally regarded as a benign condition. It is the most common neurologic disorder observed in the pediatric age group. The frequency has been estimated to be approximately 4 percent of children under the age of 5 and reportedly twice as high in Japanese children. It usually takes the form of a single, generalized motor seizure occurring as the patient's core temperature rises or reaches its peak. Seldom does the seizure last longer than a few minutes and by the time an EEG can be obtained, there is no abnormality and recovery is complete. The seizures do not recur during the same episode of fever. The temperature is usually above 38°C (100.4°F).

Any viral or bacterial illness, or, rarely, an immunization, may be the precipitant of the fever; herpesvirus 6 is one of the common precipitants, probably because of its tendency to cause high fever. Prophylactic antiepileptic drugs have not been found to be helpful in preventing febrile seizures. Except for a presumed genetic relationship with benign epilepsy of childhood, which in itself is transient in nature, these patients' risk of developing epilepsy in later life is only slightly greater than that of the general population. In some families, febrile seizures alone, without generalized epilepsy, have been associated with a particular gene by linkage analysis (Nabbout and colleagues). Presumably, when the gene products are identified, some insight into the nature of defects that lower the seizure threshold will be forthcoming.

This benign type of febrile seizure should not be confused with more serious illnesses in which a febrile acute encephalitic or encephalopathic state causes focal or prolonged seizures, generalized or focal EEG abnormalities, and repeated episodes of febrile convulsions during a febrile illness (*complex febrile seizures*). In these cases, these seizures may recur not only with infections but also at other times. When patients with both types are combined together under the rubric of febrile convulsions, it is not surprising that a high percentage are complicated by later atypical petit mal, atonic, and astatic spells followed by focal motor and non-motor epilepsy with impaired awareness, and developmental delay. In a study of 67 patients with medial temporal lobe epilepsy, 70 percent had a history of complex febrile seizures during the first 5 years of life, although many did not again develop seizures until their teens (French and colleagues). Bacterial meningitis was an important risk factor; head and birth trauma were less-common factors. Epidemiologic studies have substantiated this clinical point of view. A cohort of 687 children were followed for an average of 18 years after their initial febrile convulsion, and overall, these children had a fivefold excess of unprovoked seizures in later life (Annegers and colleagues) Among the children with simple febrile convulsions, the risk was only 2.4 percent. By contrast, children with complex febrile convulsions (focal, prolonged, or repeated episodes of febrile seizures) had a greatly increased risk—8, 17, or 49 percent, depending on the association of one, two, or three of the complicating features.

Reflex Epilepsies

It has been appreciated for a long time that seizures can be evoked in certain individuals by a discrete physiologic or psychologic stimulus. The term *reflex epilepsy* is reserved for this small subgroup. These seizures have been classified in accordance with their evocative stimuli into five types: (1) *visual*—flickering light, visual patterns, and specific colors (especially red), leading to rapid blinking or eye closure; (2) *auditory*—sudden unexpected noise (startle), specific sounds, musical themes, and voices; (3) *somatosensory*—either a brisk unexpected tap or sudden movement after sitting or lying still, or a prolonged tactile or thermal stimulus to a certain part of the body; (4) *writing* or *reading* of words or numbers; and (5) *eating* (Forster).

Visually induced seizures are by far the most common type. The seizures are usually myoclonic but may be generalized and triggered by the photic stimulation of television or an EEG examination or by the photic or pattern stimulation of video games. In other types of reflex epilepsy, the evoked seizure may be focal (beginning often in the part of the body that was stimulated) or generalized and may take the form of one or a series of myoclonic jerks or of an absence or tonic-clonic seizure. Seizures induced by reading, voices, or eating are most often of the complex partial type; seizures induced by music are usually myoclonic, simple, or complex partial. A few such instances of reflex epilepsy have been caused by focal cerebral disease, particularly occipital lesions.

Many of the antiepileptic drugs are effective in controlling individual instances of reflex epilepsy. Some patients learn to avert the seizure by undertaking a mental task, for example, thinking about some distracting subject, counting, or by initiating some type of physical activity. In certain types of reflex epilepsy, the repeated presentation of the stimulus may eventually render the trigger innocuous, but this requires a great deal of time and reinforcement, which limits its therapeutic value (Forster).

Epilepsia Partialis Continua

This is a type of focal motor epilepsy without impaired awareness characterized by persistent rhythmic clonic movements of one muscle group—usually of the face, arm, or leg—which are repeated at fairly regular intervals every few seconds and continue for hours, days, weeks, or months without spreading to other parts of the body. Thus, epilepsia partialis continua is, in effect, a highly restricted and very persistent focal motor status epilepticus. The distal muscles of the leg and arm, especially the flexors of the hand and fingers, are affected more frequently than the proximal ones. In the face, the recurrent contractions involve either the corner of the mouth or one or both eyelids. Occasionally, isolated muscles of the neck or trunk are affected on one side. The clonic activity may be accentuated by active or passive movement of the involved muscles and may be reduced in severity but not abolished during sleep.

First described by Kozhevnikov in patients with Russian spring-summer encephalitis, these ongoing partial seizures may be induced by a variety of acute or chronic cerebral lesions. In some cases, the underlying disease is not apparent, and the clonic movements may be mistaken for some type of slow tremor or extrapyramidal movement disorder. Most patients with epilepsia partialis continua show focal EEG abnormalities, either repetitive slow-wave abnormalities or sharp waves or spikes over the central areas of the contralateral hemisphere. In some cases, the spike activity can be related precisely in location and time to the clonic movements (Thomas and colleagues).

As would be expected, a wide range of causative lesions has been implicated—developmental anomalies, encephalitis, demyelinative diseases, tumors, metabolic abnormalities, particularly hyperosmolarity, and degenerative diseases. Epilepsia partialis continua is particularly common in patients with the rare condition, Rasmussen encephalitis (see further on).

Whether cortical or subcortical mechanisms are responsible for epilepsia partialis continua is an unresolved question. The electrophysiologic evidence favors a cortical origin; the pathologic evidence is less definite (Thomas and colleagues). In each of eight cases in which the brain was examined postmortem, some degree of involvement of the motor cortex or adjacent cortical area contralateral to the affected limbs was found. However, all but one of these patients also had some involvement of deeper structures on the same side as the cortical lesion, on the opposite side, or on both sides.

It is characteristic of the disorder to be resistant to treatment, often leading to the use of several antiepileptic drugs and either still finding them to be ineffectual or intolerable due to side effects including somnolence. At times, it is preferable to reduce the medications and their number in favor of producing fewer side effects. These judgments must be made in view of the disruption of daily life. Although exceptional cases may persist for a year or more, most resolve, leaving variable neurologic defects.

Rasmussen Syndrome

In 1958, Rasmussen and colleagues described three children in whom the clinical problem consisted of intractable focal epilepsy (the epilepsia partialis continua described above) in association with a progressive hemiparesis. The cerebral cortex disclosed a mild meningeal infiltration of inflammatory cells and an encephalitic process marked by neuronal destruction, gliosis, neuronophagia, some degree of tissue necrosis, and perivascular cuffing. Many additional cases were soon uncovered and Rasmussen was able to summarize the natural history of 48 personally observed patients (Bien and colleagues, 2005). Adult cases are known, and they tend to have a milder and more protracted course (Villani and colleagues). Some have focal cortical myoclonus.

An expanded view of the syndrome has added several interesting features. The affected children are typically aged 3 to 15 years, more girls than boys. Half of them have

epilepsia partialis continua. The progression of the disease leads to hemiplegia or other lateralized deficits and focal brain atrophy, and even total hemi-atrophy, in most cases. The neuropathology of five cases revealed extensive destruction of the cortex and white matter with intense gliosis and lingering inflammatory reactions.

The CSF shows a pleocytosis and occasional oligoclonal bands but neither of these are uniform findings. Focal cortical and subcortical lesions are usually visualized on MRI and are bilateral in some cases. The finding of antibodies to glutamate receptors (GluR3) in a proportion of patients with Rasmussen encephalitis has raised interest in an immune causation (Antel and Rasmussen). The autoimmune hypothesis has been supported by the finding that these antibodies cause seizures in rabbits and lead to the release of the neurotoxin kainate in cell cultures (Twyman and colleagues). However, others have found these antibodies and many others in various types of focal epilepsy and have questioned their specificity (Wendl and colleagues). In general though, the initial damage to the brain seems to be inflammatory in nature and mediated by T cells and microglia (Varadkar and colleagues).

The unrelenting course of the disease had in the past defied medical therapy. In some patients the process eventually burns out, but in those with continuous focal epilepsy, the seizures continued despite all antiepileptic drugs. High doses of corticosteroids, when started within the first year of the disease, proved beneficial in 5 of 8 patients (Chinchilla and colleagues). Repeated plasma exchanges and immune globulin have also been tried, but the results are difficult to interpret. When the disease is extensive and unilateral, neurosurgeons have resorted to partial hemispherectomy, and though this remains the only durable cure for seizures, functional compromises must be considered.

PSYCHOGENIC NONEPILEPTIC SEIZURES

These common episodes, which simulate convulsive or nonconvulsive seizures, are not the result of a paroxysmal neuronal discharge. They are termed *psychogenic nonepileptic seizures* (PNES) and comprise a heterogeneous group of disorders that are easily mistaken for epileptic spells. Moreover, they comprise a large proportion of treatment-resistant epilepsy and often are treated with multiple antiepileptic drugs, to which they are unresponsive. It has been estimated that 70 percent of people diagnosed with PNES have been previously diagnosed and treated for epilepsy. In large series, nonepileptic seizures comprise 4 percent of cases of transient loss of consciousness, 20 percent of referrals to specialist epilepsy services, and 50 percent of apparent status epilepticus. It should be emphasized that patients with epileptic seizures can exhibit PNES as well, making the distinction between the two particularly difficult. It is this population that proves most vexing (and common) in specialty epilepsy practice.

Our current conceptualization is that the condition arises as a behavioral response to underlying emotional or psychological distress and is categorized in DSM-5 as a form of functional neurologic disorder. Episodes may be derived from traumatic experiences in early life, particularly physical, sexual, and psychological abuse during childhood but such is not always the case. In the past, many experts considered this condition to be allied with hysteria (*Briquet disease, conversion disorder*, as discussed in Chap. 47) or malingering. Recent studies suggest that a conversion disorder accounts for most cases, and that malingering is rare, but this is difficult to prove.

Three broad categories of psychogenic states seem to generate pseudoseizures: (1) panic disorder that is itself common in people with epilepsy; (2) dissociative disorders, in which convulsions are typically prolonged, resembling generalized tonic-clonic seizures, or alternatively, swooning as in a faint or presyncopal spell, or blank spells that closely simulate absence seizure; and (3) malingering, the deliberate feigning of seizures to avoid certain situations, for example, imprisonment.

Often, the unconventional motor display in the course of a nonepileptic seizure is sufficient to identify it as such: completely asynchronous thrashing of the limbs and repeated side-to-side movements of the head; striking out at a person who is trying to restrain the patient; hand biting, kicking, trembling, and quivering; pelvic thrusting and opisthotonic arching postures; and screaming or talking during the ictus. It is helpful to observe that the eyes are kept quietly or forcefully closed during a psychogenic nonepileptic seizure whereas the lids are open or show clonic movement in epilepsy. Psychogenic spells are more likely if attacks are prolonged (many minutes, even hours), if there is rapid breathing (whereas apnea is typical during and after a seizure), or if there is tearfulness after an episode. Psychogenic seizures tend to occur in the presence of observers and to be precipitated by emotional factors. With few exceptions, tongue-biting, incontinence, hurtful falls, or postictal confusion are lacking but if the tongue is bitten in one of these spells it is usually the front of the tongue, compared to the lateral tongue injury that is more characteristic of an epileptic attack. Incontinence does not assist in making a clear distinction from epileptic seizures.

Another clue to nonepileptic seizures has been highly resistant epilepsy in an individual with normal cognitive function and normal brain imaging. Sometimes there has been a background of unexplained medical problems, previous psychological problems (depression, panic disorder, overdose, self harm, addiction), and a life story that includes intense emotional trauma. Prolonged fugue states usually prove to be manifestations of hysteria or a psychopathy, that is, a dissociative state, even in a known epileptic.

The serum creatine kinase levels are normal after nonepileptic seizures; this may be helpful in distinguishing them from epilepsy. Where doubt remains, a recording of the ictal or postictal EEG or prolonged combined video and EEG recording of an attack may settle the issue.

The treatment of these patients requires a patient, nonjudgmental, and multidisciplinary approach with the goal of reducing disability and hospital admission and eliminating unnecessary medications.

THE NATURE OF THE ELECTRICAL DISCHARGE IN EPILEPSY

Physiologically, the epileptic seizure has been defined as a sudden alteration of central nervous system (CNS) function resulting from a paroxysmal high-frequency or synchronous low-frequency, high-voltage electrical discharge. This discharge arises from an assemblage of excitable neurons in any part of the cerebral cortex and possibly in secondarily involved subcortical structures as well. In the proper circumstances, a seizure discharge can be initiated in an entirely normal cerebral cortex, as when the cortex is activated by ingestion of drugs, or by withdrawal from alcohol or other sedative drugs. A mechanism that ostensibly creates a secondary seizure focus, "kindling," is the result of repeated stimulation with subconvulsive electrical pulses from an established focus elsewhere; it is known to occur in animal models but is a controversial entity in humans.

Viewed from a larger physiologic perspective, seizures require three conditions: (1) a population of pathologically excitable neurons; (2) an increase in excitatory, mainly glutaminergic, activity through recurrent connections to spread the discharge; and (3) a reduction in the activity of the normally inhibitory GABAergic projections. Each of these has been challenged but is supported by considerable data and together they serve as a reasonable model, as noted below. Understanding of the initial discharges and their spread has been advanced by the identification of several rare forms of familial epilepsy that are the result of mutations in sodium, potassium, acetylcholine receptor, or GABA channels on neurons. These are discussed further on under "Role of Genetics."

Just why the neurons in or near a focal cortical lesion discharge spontaneously and synchronously is not fully understood. Some of the electrical properties of a cortical epileptogenic focus suggest that its neurons have been deafferented. Neurons in these circumstances are hyperexcitable, and they may chronically remain in a state of partial depolarization, able to fire irregularly at rates as high as 700 to 1,000 per second. The cytoplasmic membranes of such cells have an increased ionic permeability, which renders them susceptible to activation by hyperthermia, hypoxia, hypoglycemia, hypocalcemia, and hyponatremia, as well as by repeated sensory (e.g., photic) stimulation and during certain phases of sleep (where *hypersynchrony* of neurons occurs).

As a model of spontaneous discharges, epileptic foci induced in the animal cortex by the application of penicillin are characterized by spontaneous interictal discharges, during which the neurons of the discharging focus exhibit large, calcium-mediated paroxysmal depolarizations (depolarizing shifts), followed by prolonged after-hyperpolarizations. The latter are caused in part by calcium-dependent potassium currents, but enhanced synaptic inhibition also plays a role. The depolarizing shifts occur synchronously in the penicillin focus and summate to produce surface-recorded interictal EEG spikes; the after-polarizations correspond to the slow wave of the EEG spike-and-wave complex. The neurons surrounding an experimental epileptogenic focus are hyperpolarized and release inhibitory GABA. The spread of seizures depends on factors that activate neurons in the focus or inhibit those surrounding it. Beyond this, the precise mechanism that governs the transition from a circumscribed interictal discharge to a widespread seizure state is not understood.

Biochemical studies of neurons from a seizure focus have not greatly clarified the problem. Levels of extracellular potassium are elevated in glial scars near epileptic foci, and a defect in voltage-sensitive calcium channels has also been postulated. Epileptic foci are known to be sensitive to acetylcholine and to be slow in binding and removal of the neurotransmitter. A deficiency of the inhibitory neurotransmitter GABA, increased glycine, decreased taurine, and either decreased or increased glutamic acid have been variously reported in excised human epileptogenic tissue, but whether these changes are the cause or result of seizure activity has not been determined. The interpretation of reported abnormalities of GABA, biogenic amines, and acetylcholine in the cerebrospinal fluid (CSF) of epileptic patients poses similarly great difficulties.

Concurrent EEG recordings from an epileptogenic cortical focus and subcortical, thalamic, and brainstem centers in the animal model have enabled investigators to construct a sequence of electrical and clinical events that characterize an evolving focal seizure. Firing of the involved neurons in the cortical focus is reflected in the EEG as a series of periodic spike discharges, which increase progressively in amplitude and frequency. Once the intensity of the seizure discharge exceeds a certain point, it overcomes the inhibitory influence of surrounding neurons and spreads to neighboring cortical regions via short corticocortical synaptic connections.

A provocative finding, based on sophisticated mathematical analysis of EEG tracings, indicates that subtle electrographic changes arise several minutes before the ictal discharge (Le Van Quyen and colleagues). This suggests that seizures could be triggered either by a change in central thalamic rhythm generators or a subtle alteration in the electrical activity in the region of a focal lesion. Also of interest is the finding that there can be prolonged bursts of seizure-like activity even days before the onset of temporal lobe seizures (Litt and colleagues); these events may cause a cascade of electrophysiologic changes that very gradually culminate in a seizure.

If unchecked, cortical excitation spreads to the adjacent cortex and to the contralateral cortex via interhemispheric pathways, and also to anatomically and functionally related pathways in subcortical nuclei (basal ganglionic, thalamic, and brainstem reticular nuclei). It is at this time that the clinical manifestations of the

seizure begin. The excitatory activity from the subcortical nuclei is conceived to feed back to the original focus and to other parts of the cerebrum, a mechanism that serves to amplify their excitatory activity and to give rise to the characteristic high-voltage polyspike discharge seen on the EEG. The spread of excitation to subcortical, thalamic, and brainstem centers corresponds to the tonic phase of the seizure and to loss of consciousness as well as to the signs of autonomic nervous system overactivity (mydriasis, tachycardia, hypertension) and to arrest of respiration. The development of unconsciousness and the generalized tonic contraction of muscles are reflected in the EEG by a diffuse high-voltage discharge pattern appearing simultaneously over the entire cortex. There is little evidence to support the conjecture made by Penfield that seizure activity originates in the thalamus; thus his term *centrencephalic seizure* is no longer used.

Soon after the spread of excitation, a diencephalic inhibition begins and intermittently interrupts the seizure discharge, changing it from the persistent tonic phase to the intermittent bursts of the clonic phase. In the surface EEG, a transition occurs from a continuous polyspike to a spike-and-wave pattern. The intermittent clonic bursts become decreasingly frequent and finally cease altogether, leaving in their wake an "exhaustion" (paralysis) of the neurons of the epileptogenic focus and a regional increase in permeability of the blood–brain barrier and edema. An excess of these inhibitory mechanisms and metabolic exhaustion are thought to be the basis of *Todd paralysis* and of postictal stupor, sensory loss, aphasia, hemianopia, headache, and diffuse slow waves on the EEG. A two- to threefold increase in cerebral glucose utilization during seizure discharges has been observed, and it has been suggested that the paralysis that follows a seizure might be a result of neuronal depletion of glucose and an increase in lactic acid (Plum and colleagues). The exact roles played by each of these factors in postictal paralysis of function are not settled.

Insights into absence seizures have been obtained from animal models of bilaterally synchronous 3-per-second high-voltage spike-and-wave discharges. The spike-and-wave complex, which represents brief excitation followed by slow-wave inhibition, is the type of EEG pattern that characterizes the clonic (inhibitory) phase of the focal or generalized onset convulsive seizure. By contrast, this strong element of inhibition is present diffusely throughout an "absence" attack, a feature that perhaps accounts for the failure of excitation to spread to lower brainstem and spinal structures (tonic-clonic movements do not occur). Earlier mentioned is work by Blumenfeld's group, suggesting that the interruption of consciousness in this syndrome can be linked with electrophysiologic changes in the thalamus, comparable to what is described for types of generalized seizure (Guo and colleagues).

Of theoretical importance is the observation that a seizure focus may establish, via commissural connections, a persistent secondary focus in the corresponding cortical area of the opposite hemisphere (*mirror focus*). The nature of this phenomenon is obscure; it may be similar to the "kindling" phenomenon mentioned earlier in animals, where a repeated nonconvulsive electrical stimulation of normal cortex induces a permanent epileptic focus. No morphologic change is visible in the mirror focus, at least by light microscopy. The mirror focus may be a source of confusion when trying to identify the side of the primary discharging lesion by EEG, and there is only limited evidence that mirror foci related to the kindling phenomenon produce seizures in humans (Goldensohn).

EEG AND LABORATORY TESTING IN EPILEPSY

The origins of EEG activity of an epileptic focus and the generalization of seizures are discussed in Chap. 2 and earlier in this chapter. The EEG provides confirmation of Hughlings Jackson's concept of epilepsy—that it represents a recurrent, sudden, excessive discharge of cortical neurons. The EEG is the most sensitive, indeed indispensable, tool for the diagnosis of epilepsy; but like other ancillary tests, it must be used in conjunction with clinical data. In patients with idiopathic generalized seizures, and in a high proportion of their relatives, interictal spike- and-wave abnormalities without any clinical seizure activity are common, especially if the EEG is repeated several times or taken over long periods. By contrast, a proportion of persons with epilepsy have a completely normal interictal EEG. Using standard methods of scalp recording, the EEG may even be normal during the experiential aura of a focal seizure. Furthermore, interpretation of EEG abnormalities must take into account that a small number of healthy persons (approximately 2 to 3 percent) show paroxysmal EEG abnormalities.

A single EEG tracing obtained during the interictal state is abnormal to some degree in 30 to 50 percent of epileptic patients; this figure rises to 60 to 70 percent if patients are subjected to several recordings or a single prolonged recording. Many EEG patterns are possible in seizures. One consistent observation, however, has been that the region of earliest spike activity corresponds best to the epileptogenic focus, a rule that has come to guide epilepsy surgery. The postseizure or postictal state also has an EEG correlate, taking the form of random generalized slow waves after generalized onset seizures and focal slowing following focal onset seizures. With clinical recovery, the EEG returns to normal or to the preseizure state.

A higher yield of abnormalities and a more precise definition of seizure types can be obtained by the use of several special EEG procedures, as described in Chap. 2. Activating procedures such as hyperventilation, photic stroboscopic stimulation, and sleep increase the yield of EEG recordings. EEG recording during sleep is particularly helpful because focal abnormalities, particularly in the temporal lobes, may become prominent in slow-wave and stage 2 sleep. Sphenoidal leads have been used to detect inferomedial temporal seizure activity, but they are uncomfortable and probably add little more information than can be obtained by the placement of additional

subtemporal scalp electrodes. Nasopharyngeal electrode recordings are too contaminated by artifact to be clinically useful.

Beyond dependably identifying artifacts in the EEG recording, one of the main challenges for the electroencephalographer is to differentiate between normal patterns that simulate seizures and true epileptic or interictal discharges. These paroxysmal but ostensibly normal patterns appear mostly during sleep, each with a highly characteristic morphology. These include small sharp spikes, "14 and 6" polyspike activity, lambda and posterior occipital mu rhythm, and occipital sharp transients (see Chap 2).

Several methods of *long-term EEG monitoring* are now in common use and are of particular value in the investigation of patients with surgically removable epileptogenic foci and of PNES. The most common of these makes use of telemetry systems, in which the patient is attached to the EEG machine by cable or radio transmitter without unduly limiting freedom of movement. The telemetry system is joined to an audiovisual recording system, making it possible to record seizure phenomena (even at night, under dim or infrared light) and to synchronize them with the EEG abnormalities. An alternative is the use of a small digital recording device that is attached to a miniature EEG machine worn by the patient at home and at work ("ambulatory EEG"). The patient is instructed to push a button if an "event" is experienced, which can later be correlated with EEG activity.

Imaging and Laboratory Abnormalities Associated With Seizures

Cerebral imaging has come to play a major role in the diagnosis of seizures. CT is able to demonstrate many of the typical underlying causes of seizures, but MRI is much more sensitive for the detection of small structural abnormalities underlying epilepsy including tumor, stroke, and traumatic lesions. Furthermore, more subtle abnormalities such as medial temporal sclerosis, heterotopias and other disorders of neuronal migration, and small glial scars can be clearly visualized with MRI. Advances in MRI field strength and techniques such as thin slice acquisition continue to expose structural lesions in what were previously called cryptogenic cases of epilepsy, and importantly, some of these lesions may be surgically remediable. These lesions are often subtle, and it may be that interpretation by specialists can improve their detection, particularly when correlated with clinical and electrophysiologic data.

After a seizure, particularly one with a focal component, MRI sometimes discloses subtle focal cortical swelling and signal change on T2-weighted sequences and on diffusion-weighted sequences, or, if a contrast agent is administered, an ill-defined cortical blush may be visible. Similar signal change can be seen in the thalami. These changes are transient and are the effect of, rather than cause of, seizure and are thought to reflect disruption of the blood–brain barrier and metabolic changes in the cortex. There is an approximate relationship between the duration of seizure activity and the intensity and extent of these changes, but they rarely persist for more than a day or two and clinical improvement often precedes radiographic improvement. Likewise, angiography or perfusion imaging performed soon after a seizure may show a focal area of enhanced blood flow or elevated blood volume. There are also imaging changes in the white matter, particularly the splenium of the corpus callosum, that may occur soon after the withdrawal of certain antiepileptic medications as discussed in the later section on the use of these drugs and by Gürtler and colleagues, though a similar appearing splenial lesion can occur in several non-seizure settings too (Garcia-Monco and colleagues).

The CSF after a seizure occasionally contains a small number of white blood cells (most often in the range of $10/mm^3$) in about 5 percent of patients. In a series of 309 individuals, up to 24 white blood cells were found but the median was far lower (Tumani and colleagues). A slight increase in protein is also possible. Like the imaging abnormalities these findings may lead to spurious conclusions about the presence of an active intracranial lesion, particularly if polymorphonuclear leukocytes predominate; a larger pleocytosis should always be construed as a sign of inflammatory or infectious disease.

Systemic (lactic) acidosis is a common result of convulsive seizures, and it is not unusual for the serum pH to reach levels near or below 7 if taken immediately after a convulsion. Of more practical value is the fact that almost all generalized convulsions produce a rise in serum creatine kinase activity that persists for hours, a finding that could be used to greater advantage in emergency departments to assist in distinguishing seizures from fainting. Of course, extensive muscle injury from a fall or prolonged compression during a period of unconsciousness can produce the same abnormality.

Concentrations of serum prolactin, like those of other hypothalamic hormones, rise for 10 to 20 min after all types of generalized seizures, including complex partial types, but not in absence or myoclonic types. An elevation may help differentiate a psychogenic seizure from a genuine one; however, serum prolactin may also be slightly elevated after a syncopal episode (Fisher and colleagues). There is also a postictal rise in ACTH and serum cortisol, but these changes have a longer latency and briefer duration. If elevations in these hormonal levels are used as diagnostic tests, one must have information about normal baseline levels, diurnal variations, and the effects of concurrent medications. Changes in body temperature, which are said to sometimes precede a seizure, may reflect hypothalamic changes but are far less consistent and difficult to use in clinical work.

PATHOLOGY OF EPILEPSY

In most autopsied cases of primary generalized epilepsy of the genetic variety, the CNS is grossly and microscopically normal. Not surprisingly, there are also no visible lesions in the seizure states complicating drug intoxication

and withdrawal, transient hyper- and hyponatremia, and hyper- and hypoglycemia, which presumably represent derangements at the cellular level.

In contrast, symptomatic epilepsies have definable lesions. MRI, particularly at higher magnetic field strengths, has exposed cortical heterotopias that had been previously difficult to detect, and has also highlighted the frequency of gliosis in the medial temporal lobes. Other lesions include zones of neuronal loss and gliosis, heterotopias, dysgenic cortex, hamartoma, vascular malformations, porencephaly, and tumor. Vascular malformations, hamartomas, ganglioneuromas and related dysembryoplastic neuroectodermal tumors (DNET), which are important causes of drug-resistant epilepsy, and low-grade astrocytomas were less frequent; again, in a small number, no abnormalities could be found. Certainly, the focal epilepsies are associated with the highest incidence of structural abnormalities, although in certain cases no morphologic change is visible.

It has not been possible to determine which component of the lesion is responsible for the seizures. Gliosis, fibrosis, vascularization, and meningocerebral cicatrix have all been incriminated, but they are found in nonepileptic foci as well.

Medial (Mesial) Temporal Sclerosis

In several series of cases of temporal lobe excisions in prior decades, a specific pattern of neuronal loss with gliosis (sclerosis) in the hippocampal and amygdaloid region was found in the majority (Falconer), and this abnormality has been likewise recognized with MRI (*medial temporal sclerosis*; see Fig. 15-2). The most common associated histologic finding is loss of neurons in the CA1 segment (Sommer sector) of the pyramidal cell layer of the hippocampus, often unilateral, extending into contiguous regions of both the pyramidal layer and the underlying dentate gyrus. It is still undetermined whether this neuronal loss is primary or secondary and, if the latter, whether it was incurred at birth or happened later as the consequence of recurrent seizures. The loss of hippocampal neurons can sometimes be accompanied by atrophy of the ipsilateral fornix and mammillary body, which carry and receive output from the hippocampus, respectively. Perhaps more worrisome was the MRI finding of diffuse and accelerated cortical thinning reported in a cohort of patients with focal epilepsy (Galovic and colleagues). Such a neurodegenerative component of focal epilepsy would place an even greater priority on its early diagnosis and treatment (including evaluation for surgery).

Early life head trauma, infections, and a variety of less-common perturbations may also cause the combination of neuron loss and mild gliosis of medial temporal sclerosis. The cessation of seizures in many patients following surgical resection of the medial temporal lobe favors the first interpretation that the pathologic change is primary in most cases (see further on under "Surgical Treatment of Epilepsy"). Attesting to the uncertainty of cause or effect are numerous surgical series that favor one view or the other (Sutula and Pitkänen).

Role of Genetics

Most primary epilepsies have a genetic basis and, as in many other diseases such as diabetes and atherosclerosis, the mode of inheritance is complex, that is, some are likely to be polygenic but increasingly, single mutations are being found. That a genetic factor is operative in the primary generalized epilepsies is suggested by a familial incidence in 5 to 10 percent of such patients and, in certain families, the inheritance of a seizure disorder through specific genes (Afawi and colleagues). The importance of genetic factors in the primary epilepsies is also underscored by evidence from twin registries; the overall concordance rate has been up to 70 percent for monozygotic twins and 30 percent for dizygotic pairs (Vadlamudi and colleagues).

Of course, epilepsy is a component of many genetic syndromes that are defined by their dysmorphic appearance, neurocutaneous features, or maldevelopment of the cerebra with or without developmental delay. What we consider first are the few idiopathic seizure disorders that are inherited by a simple (mendelian) pattern. These include a subgroup of benign neonatal familial convulsions inherited as an autosomal dominant trait, and a similar disorder of infantile onset and a benign myoclonic epilepsy of childhood (autosomal recessive). Particularly informative are a group of epileptic disorders in which monogenic genetic defects are related to abnormalities of ion channels or neurotransmitter receptors (Table 15-3). These were mentioned earlier in the discussion of the physiology of seizures and despite their rarity they suggest that idiopathic epilepsy may be caused by a disruption in the function of these same channels.

The consequences of almost all of these mutations are to enhance overall neuronal excitability. Examples include autosomal dominant nocturnal frontal lobe epilepsy, which may present as a focal seizure (in which the offending mutations are in subunits of the nicotinic acetylcholine receptor subunit); *generalized epilepsy with febrile seizures plus* (GEFS+; subunits of a neuronal sodium channel associated with various combinations of uncomplicated febrile seizures, febrile seizures persisting beyond childhood, generalized, absence, myoclonic, atonic, and complex partial seizures); benign familial neonatal convulsions (two different potassium channels); and forms of juvenile myoclonic epilepsy and childhood absence epilepsy (subunits of the brain $GABA_A$ receptor).

Some of these are summarized in Table 15-3, and their number will almost certainly expand. As with numerous other genetic neurologic disorders, a single mutation may produce different epilepsy and seizure types, and a single type may be the result of one of several different mutations. Also notable is the low penetrance of some monogenic epileptic disorders, particularly the autosomal dominant one associated with nocturnal frontal seizures.

Another group of epilepsies with mendelian inheritance has been ascribed to genetic defects that do not implicate ion channels. Most of these are primarily myoclonic disorders in which the epilepsy is one component. Two forms of progressive myoclonic epilepsy, Unverricht Lundborg disease and Lafora body disease, are the result, respectively, of mutations in genes encoding cystatin B and

Table 15-3

MONOGENIC EPILEPTIC DISORDERS

	GENE	PROTEIN INVOLVED
Channelopathies		
Sodium channels		
Familial generalized epilepsy with febrile seizures "plus" (GEFS+); see text	SCN1A,B ($GABA_A$)	Sodium channel subunits; less often, GABA receptor
Benign familial neonatal convulsions	SCN2A	Sodium channel subunits
Dravet syndrome (severe myoclonic epilepsy of infancy)	SCN1A	Sodium channel α-subunit
Potassium channels		
Benign infantile epilepsy	KCNQ2,3	Potassium channel subunits
Episodic ataxia type 1 with partial epilepsy	KCNA1	
Ligand-gated channels		
Autosomal dominant nocturnal frontal seizures	CHRNA 2,4	Nicotinic acetylcholine receptor subunits
Familial generalized and febrile seizures	GABRG2	$GABA_A$ receptor subunit
Juvenile myoclonic epilepsy	GABRA1 (CACNB4)	$GABA_A$ receptor subunit; less often, calcium channel subunit
Glucose transporter-1 deficiency	SLC2A1	GLUT1 (responsive to ketogenic diet)
Calcium channels		
Episodic ataxia type 2 with spike-wave seizures	CACNA1A	Calcium channel subunit
Malformations of Cortical Development		
Holoprosencephaly, generalized epilepsy	SHH, PTCH, ZIC2, SIX3, TGIF	Sonic hedgehog, SHH receptor, transcription factors
Schizencephaly, generalized epilepsy	EMX2	Homeodomain protein
Tuberous sclerosis, generalized epilepsy	TSC1, 2	Hamartin, tuberin
Lissencephaly, generalized epilepsy	LIS1	Platelet-activating factor acid hydrolase
Double-cortex syndrome, generalized epilepsy	DCX	Doublecortin
Heterotopia, focal epilepsy	FLN1	Filamin1
Fukuyama muscular dystrophy, lissencephaly, generalized epilepsy	FCMD	Fukutin
Walker-Warburg syndrome, generalized epilepsy	POMT1	*O*-mannosyl transferase
Muscle-eye-brain disease, generalized epilepsy	MEB	Glycosyltransferase, PMGnT1
Angelman syndrome: myoclonic, tonic-clonic, atonic seizures	UBE3A	Ubiquitin-protein ligase
Progressive Myoclonic Epilepsies (PME)		
Unverricht-Lundborg disease with PME	EPM1	Cystatin B
Lafora body disease with PME	EPM2A	Laforin, protein tyrosine phosphatase
Myoclonic epilepsy with ragged red fibers	tRNAlys	Mitochondrial lysine tRNA
Dentatorubro-pallidoluysian atrophy with PME	DRPLA	Atrophin-1
Gaucher disease	PSAP	β-Glucocerebrosidase
Sialidosis type I	NEU1	Sialidase
Ceroid lipofuscinosis (CLN) and PME	CLN	CLN2, CLN3, CLN5, CLN6 also cause generalized, atonic and atypical absence seizures
Mixed Seizure Types		
Lipoid proteinosis and temporal lobe epilepsy	ECM1	Extracellular matrix protein 1
Autosomal dominant lateral temporal lobe epilepsy	LGI1	Leucine-rich glioma inactivated protein
CLN8; progressive nonmyoclonic epilepsy with retardation	CLN8	Membrane protein in endoplasmic reticulum
Pyridoxine deficiency	ALDH7A1	Antiquitin (ATQ-1)

tyrosine phosphatase. To these inherited forms of epilepsy may be added diseases such as tuberous sclerosis and ceroid lipofuscinosis (see Chap. 36), which have a strong proclivity to cause seizures and genetically determined heterotopias such as FLN1 (this and other developmental aberrations are discussed in Chap. 37).

More complex genetic elements are identified in several childhood seizure disorders—absence epilepsy with 3-per-second spike-and-wave discharges and benign epilepsy of childhood with centrotemporal spikes—both of which are transmitted as autosomal dominant traits with incomplete penetrance or perhaps in a more complicated manner. In the partial, or focal, epilepsies the role of heredity is not nearly so clear. Yet in numerous studies there has been a greater-than-expected incidence of seizures, EEG abnormalities, or both among first-degree relatives. Among the familial cortical epilepsies, both a temporal and frontal lobe type, are inherited in a polygenic fashion or in an autosomal dominant pattern. Undoubtedly also inherited, is the tendency to develop simple febrile convulsions, though the mode of inheritance is uncertain. Finally, copy number variations probably play a role in approximately 5 percent of cases (Olsen and colleagues).

CLINICAL APPROACH TO EPILEPSY

The physician faced with a patient who seeks advice about an episodic disorder of nervous system function must determine first, whether the episode in question is a seizure. In the diagnosis of epilepsy, history is the key; in many adult cases the physical examination is unrevealing. The examination in infants and children is of greater value, as the finding of dysmorphic and cutaneous abnormalities allow the diagnosis of a number of highly characteristic cerebral diseases that give rise to epilepsy.

Paramount in establishing that there has been a seizure is a description from a witness. A detailed account of the event is required and in particular, the type and duration of bodily movements, level of alertness and responsiveness during and immediately after the episode, skin color and breathing, and incontinence. If a witness is not available, then a telephone call to observers and family may give more information than does sophisticated laboratory testing. From the patient, information can be obtained regarding tongue biting, incontinence, and recollection of the event of the immediately preceding epoch. If the patient is able to provide information, previous events that may have been misinterpreted as other than a seizure, for example, brief losses of consciousness, myoclonic jerks, rumpled bedsheets with incontinence, unexplained falls with injury and so forth, may hint at preceding seizures. The family history, developmental milestones, neonatal events, and the circumstances of birth are useful additional aspects of the evaluation of epilepsy.

In the category of genuine seizures, the diagnosis of temporal lobe epilepsy may be difficult to distinguish from imitators of epilepsy. These attacks are so variable and so often induce disturbances of behavior and psychic function—rather than overt interruptions or loss of consciousness—that they may be mistaken for temper tantrums in children, drug ingestion, hysteria, panic attacks, or acute psychosis. These seizures may include verbalizations that cannot be remembered, walking aimlessly, repetitive olfactory and gustatory hallucinations, stereotyped hand movements or automatisms such as lip smacking. The nature of the patient's report of a psychic experience is often helpful in distinguishing seizures from psychogenic events. In the former, patients attempt to focus with great effort on the description of the experience, although the term "indescribable" is often included in the report, whereas vague and imprecise descriptions of "something being wrong" or resorting to a friend or family member to describe the event may more strongly implicate a psychogenic etiology. We place emphasis on amnesia for the events of at least part of the seizure as an important criterion for the diagnosis of temporal lobe epilepsy. Hysterical fugues can cause substantial difficulty in diagnosis. They may be recognized by the loss of personal identity and by episodes that are longer than typical of seizures, sometimes up to a few days.

Absence attacks may be similarly difficult to distinguish from other brief disorders of consciousness. Helpful maneuvers are to have the patient hyperventilate to evoke an attack or to observe the patient counting aloud for several minutes. Those with frequent absence attacks will pause or skip one or two numbers.

The conditions most likely to simulate an epileptic seizure are PNES and other paroxysmal events such as panic attack and syncope but also, unexplained falls (drop attacks), transient ischemic attacks, particularly those associated with limb shaking, rapid eye movement (REM) sleep behavior disorder, subarachnoid hemorrhage, migraine, hypoglycemia, cataplexy, paroxysmal ataxia and choreoathetosis, and transient global amnesia. In emergency departments it is often difficult to differentiate the postictal effects of an unwitnessed seizure from the confusion and amnesia following cerebral concussion.

The clinical differences between a seizure and a *syncopal attack* are considered in Chap. 17; there it was emphasized that no single criterion stands inviolate. Particularly emphasized because of their potential gravity are episodes of cardiac syncope from a serious arrhythmia, especially ventricular tachycardia. Cardiac arrhythmias may present as episodes of unheralded loss of consciousness, sometimes with associated convulsive movements that simulate epileptic disorders, and the failure to pursue the diagnosis of arrhythmia may have important consequences. Palpitations, previous myocardial infarction, ECG abnormalities, valvular disease, and thoracic trauma may direct attention to the proper diagnosis.

Migraine may too be mistaken for a seizure. One feature of the focal neurologic disorder of typical migraine is particularly helpful—namely, the pace of the sequence of cerebral malfunction over a period of minutes rather than seconds, as in focal epilepsy. Even this criterion may fail occasionally, especially if both migraine and partial seizures are joined, for example, as expressions of a vascular malformation of the brain.

Identification of a TIA and its separation from focal epilepsy are aided by considering that most paroxysmal vascular disorders are characterized by loss of function that can be attributed to one area of the cortex such as paralysis, blindness, diplopia, or aphasia, or to the structures within one cerebral arterial territory. If the ischemic attack is marked by an evolution of symptoms, they tend to develop more slowly than those of a seizure. The patient's age and presence of vascular risk factors, evidence of disease of the heart and carotid arteries, and the lack of disorder of consciousness or amnesia may be supportive of the diagnosis of vascular disease. However, a "limb-shaking" TIA and convulsive phenomena at the outset of basilar artery occlusion may be nearly impossible to distinguish from epilepsy.

Regarding the distinction of seizures from disorders such as cataplexy, paroxysmal ataxia or choreoathetosis, and transient global amnesia, it is sufficient to be aware of the diagnostic features for each of these conditions. REM sleep behavior disorder tends to occur later in the sleep cycle, as they enter REM, whereas frontal epileptic seizures with violent motions or acts that might be mistaken for REM sleep behavior disorder can occur at any time of the night and tend to be briefer than the sleep disorder. *Drop attacks* (falling to the ground without loss of consciousness, as discussed in Chap. 6) remain an enigma. In most cases,

it has not been possible to substantiate an association with circulatory disturbances of the vertebrobasilar system and seldom have we observed drop attacks to be an expression of atonic or myoclonic epilepsy.

Several laboratory studies are usually included in the initial diagnostic evaluation—complete blood count (CBC), blood chemistries, ECG, EEG, and imaging of the brain, preferably MRI. If blood is tested after the episode in question, elevation in creatine kinase (persistent for hours) and elevation of prolactin (for up to 10 min) may occur after an unwitnessed convulsive seizure but the test is not specific enough to be useful in general practice. Other forms of testing—for example, cardiac stress tests, Holter monitor, tilt-table testing, long-term cardiac rhythm monitors, and sleep studies—are sometimes indicated to exclude some of the nonepileptic disorders listed earlier. Some patients may need prolonged EEG monitoring, either in the hospital or with portable equipment at home. In all forms of epilepsy, prolonged EEG and video monitoring in a hospital unit may prove diagnostic.

Seizures in Each Age Period (Table 15-4 and Fig. 15-3)

Having concluded that the neurologic disturbance under consideration is one of seizure, the next issue is to identify its type. Indeed, in most cases this determines the nature of treatment. Because there are so many seizure types, especially in childhood and adolescence, each one tending to predominate in a certain age period, a clinical advantage accrues to considering seizures from just this point of view. A broader approach includes consideration of the neurologic and EEG findings, the response to drugs, etiology, and prognosis.

Figure 15-3 displays the frequency of each seizure type and the main causes of seizures by age group. These data are assembled from various sources and are approximate, but they highlight several points of clinical importance.

Table 15-4

CAUSES OF RECURRENT SEIZURES IN DIFFERENT AGE GROUPS

AGE OF ONSET	PROBABLE CAUSE[a]
Neonatal	Congenital maldevelopment, birth injury, anoxia, metabolic disorders (hypocalcemia, hypoglycemia, vitamin B_6 deficiency, biotinidase deficiency, phenylketonuria, and others)
Infancy (1–6 months)	As above; infantile spasms (West syndrome)
Early childhood (6 months–3 years)	Infantile spasms, febrile convulsions, birth injury and anoxia, infections, trauma, metabolic disorders, cortical dysgenesis, accidental drug poisoning
Childhood (3–10 years)	Perinatal anoxia, injury at birth or later, infections, thrombosis of cerebral arteries or veins, metabolic disorders, cortical malformations, Lennox-Gastaut syndrome, "idiopathic," probably inherited, epilepsy (Rolandic epilepsy)
Adolescence (10–18 years)	Idiopathic epilepsy, including genetically transmitted types, juvenile myoclonic epilepsy, trauma, drugs
Early adulthood (18–25 years)	Idiopathic epilepsy, trauma, neoplasm, withdrawal from alcohol or other sedative drugs
Middle age (35–60 years)	Trauma, neoplasm, vascular disease, alcohol or other drug withdrawal
Late life (older than 60 years)	Vascular disease (usually postinfarction), neoplasm, abscess, degenerative disease, trauma

[a]Meningitis or encephalitis and their complications may be a cause of seizures at any age. This is true also of severe metabolic disturbances. In tropical and subtropical countries, parasitic infection of the CNS is a common cause. (See also Fig. 15-4.)

Neonatal Seizures

The neonatologist is often confronted by an infant who begins to convulse in the first days of life. In most instances, the seizures are fragmentary—an abrupt movement or posturing of a limb, stiffening of the body, rolling up of the eyes, a pause in respirations, lip-smacking, chewing, or bicycling movements of the legs. Even the experienced observer may have difficulty at times in distinguishing seizure activity from the normal movements of the neonate. If manifest seizures are frequent and stereotyped, the diagnosis is less difficult. The seizures correlate with focal or multifocal cortical discharges; however, as is the case with most EEG changes in neonates, these are poorly formed and less distinct than seizure discharges in later life. Presumably the immaturity of the cerebrum prevents the development of a fully organized seizure pattern, and the incomplete corticocortical myelination prevents bihemispheric spread. The EEG is nonetheless helpful in diagnosis. For example, periods of EEG suppression may alternate with sharp or slow waves, or there may be discontinuous theta activity that represents electrographic seizure activity. Conversely, electrical seizure activity in the neonate may be unattended by clinical manifestations.

An early onset of myoclonic jerks, either fragmentary or massive, with an EEG pattern of alternating suppression and complex bursts of activity is particularly ominous. Another unfavorable form of neonatal seizure evolving in infancy into infantile spasms (West syndrome) and Lennox-Gastaut syndrome and leaving in its wake severe brain damage has been described (Ohtahara). Most reported patients have been left developmentally delayed.

Neonatal seizures occurring within 24 to 48 h of a difficult birth are usually indicative of severe cerebral damage, typically anoxic, either antenatal or parturitional. Such infants often succumb, and about half of the survivors are severely disabled. Seizures having their onset several days or weeks after birth are more often an expression of acquired or hereditary metabolic disease. In the latter group, hypoglycemia is the most frequent cause; another, hypocalcemia with tetany, has become infrequent. A hereditary form of pyridoxine deficiency is a rare but treatable cause, sometimes also inducing seizures in utero and characteristically responding promptly to massive doses (100 mg) of vitamin B_6 given intravenously. Biotinidase deficiency is another rare but correctable cause. Nonketotic hyperglycemia, maple syrup urine disease, as well as other metabolic disorders may lead to seizures in the first week or two of life and are expressive of a more diffuse encephalopathy.

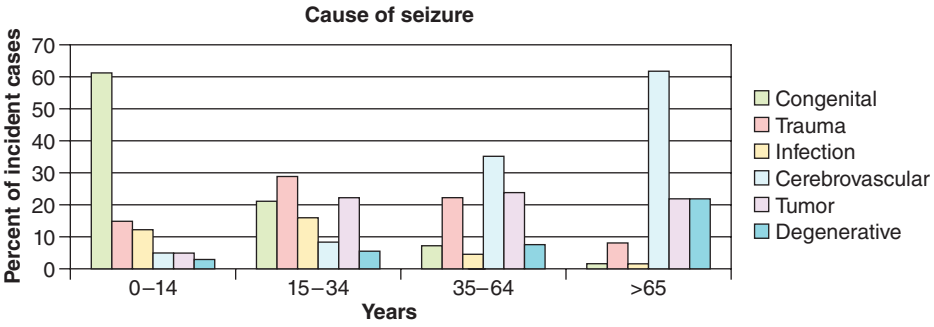


Figure 15-3. Distribution of the main causes of epilepsy at different ages. Evident is the prevalence of congenital causes in childhood and the emergence of cerebrovascular disease in older patients. (Adapted from several sources including Hauser and Annegers and the texts of Engel and Pedley.)

In contrast, benign forms of neonatal seizures have also been identified. For example, a form of benign neonatal clonic convulsions beginning on days 2 and 3, up to day 7, ("fifth-day seizures") in which there were no specific EEG changes, has been described (Plouin). The seizures then remit and have a good prognosis. The inheritance is autosomal dominant. There are other nonfamilial cases with onset on days 4 to 6, wherein the partial seizures may even increase to status epilepticus; the EEG consists of discontinuous theta activity. In both these groups, the outlook for normal development is good and seizures seldom recur later in life. There are also benign forms of polymyoclonus without seizures or EEG abnormality in this age period. Some occur only with slow-wave sleep or feeding. They disappear after a few months and require no treatment. A form of benign nocturnal myoclonus in the neonate is also well known.

Infantile Epilepsies

Neonatal seizures may continue into the infantile period, or seizures may begin in an infant who seemed to be normal up to the time of the first convulsive attack. While the most common type of convulsion is the febrile seizure, not strictly a type of epilepsy, the most characteristic epilepsy at this age is the massive sudden myoclonic jerk of head and arms leading to flexion or, less often, to extension of the body (*infantile spasms*, *salaam spasms*). This form, which characterizes the West syndrome as described earlier, has many underlying causes. The same seizure type occurs in infants with tuberous sclerosis (diagnosed in infancy by the presence of hypopigmentated macules, or "ash-leaf spots"), phenylketonuria, or Sturge-Weber angiomatosis, but most often it is associated with other diseases beginning in this age period. Infantile spasms cease by the end of the second year and are replaced by focal and secondarily generalized seizures. They do not respond well to the usual antiepileptic medications. Some instances of infantile spasms may be due to a metabolic encephalopathy of unknown type or, a cortical dysgenesis (Jellinger). West syndrome is characterized by an EEG picture of large bilateral slow waves and multifocal spikes (*hypsarrhythmia*), described earlier.

The Dravet syndrome, which includes myoclonic and focal seizures, occurs in this age group but is also relevant to adult practice as patients are recognized with persistence of resistant epilepsy of several types. In the past this form of epilepsy and developmental delay were attributed to a febrile illness or vaccination in infancy, but it has become clear that the syndrome is the result of a loss of function mutation in a sodium channel gene (*SCN1A* in most cases). The initial seizures in these cases have been brought forward by a febrile episode or other neonatal event but they are subsequently characterized by unprovoked and treatment-resistant episodes.

Febrile seizures represent a challenging problem in this age period. When febrile seizures are prolonged, focal, or accompanied by a neurologic deficit, they are referred to as *complicated febrile seizures*. These are distinguished from the benign familial febrile seizure syndrome discussed earlier in the chapter. While myoclonic activity with seizures in this age group raises concern of a serious condition, there is a common benign form with a heritable component and does not lead to developmental delay.

Seizures Presenting in Early Childhood

A number of focal epilepsies may appear for the first time during this age period and carry a good prognosis, that is, the neurologic and intellectual capacities remain relatively unimpaired and seizures may cease in adolescence. These disorders begin between 3 and 13 years of age and there is often a familial predisposition. Most are marked by distinctive focal spike activity that is accentuated by sleep (see earlier, in reference to benign childhood epilepsy with centrotemporal or occipital spikes). Several of these have been discussed earlier under the "Other Epileptic Syndromes." In one form, benign childhood epilepsy with centrotemporal spikes, unilateral tonic or clonic contractions of the face and limbs recur repeatedly with or without paresthesia; anarthria may follow the seizure. There are central and temporal spikes in the EEG interictally. Less commonly, the focus originates in an occipital lobe with EEG spiking on eye closure. An acquired aphasia characterizes the onset of another disorder in which there are partial or generalized motor seizures and multifocal spike or spike-and-wave discharges in the EEG and deterioration of language function (Landau and Kleffner).

As in any age group, there are structural causes of seizures that include medial temporal sclerosis, described in several places in this chapter, tumor, and arteriovenous malformation. Rasmussen encephalitis and intractable seizures have already been discussed under the "Other Epileptic Syndromes."

Among the generalized idiopathic epilepsies, the typical absence disorder, with its regularly recurring 3-per-second spike-and-wave EEG abnormality, begins

in this age period (rarely before age 4 years) and carries a good prognosis. This seizure disorder responds well to medications, as indicated further on. Its features are fully described in "Absence Variants."

Convulsions in this age group may present around the age of 4 years as focal myoclonus with or without astatic seizures, atypical absence, or generalized tonic-clonic seizures. The EEG, repeated if initially normal, is most helpful in diagnosis; it reveals a paroxysmal 2- to 2.5-per-second spike-and-wave pattern on a background of predominant 4- to 7-Hz slow waves. Many of these cases qualify as the Lennox-Gastaut syndrome, are difficult to treat, and are likely to be associated with developmental delay. At this age, perhaps more than any other, the first burst of seizures may take the form of status epilepticus and, if not successfully controlled, may end fatally.

Seizures in Later Childhood and Adolescence

These represent a common problem in practice but present a difficulty because this is the age at which syncope and psychogenic seizures begin to occur and alcohol and drug abuse may too begin. In this age period in particular, as the adolescent strives for independence, the social disruption caused by seizures are likely to take a toll on the relationships and educational progress of the emerging adult. Here, we also face the frequent issue relating to the nature and management of the first seizure in an otherwise normal young person. As in other age groups, the history often discloses the likely provocation of seizures, as for example, a young person has been sleep deprived or imbibing alcohol or a recreational drug and has a first seizure. A search for a cause of the first seizure in this age group is necessary by MRI, ECG, and EEG but these tests less frequently disclose an underlying lesion than in other age groups. Often, there has only been a single event and no clinical or EEG features to define the nature of the seizure disorder. However, the type of seizure that first brings the child or adolescent to medical attention is most likely to be a generalized tonic-clonic convulsion and may mark the beginning of idiopathic generalized epilepsy or juvenile myoclonic epilepsy, as described in earlier sections.

A few patients have had a history of absence in which the EEG shows a characteristic polyspike pattern, about one-third with a photomyoclonic response. When the seizures are an expression of a congenital epileptic focus that is associated with developmental delay or scholastic failure, the diagnostic and therapeutic problem becomes demanding. In the group of younger individuals with *longstanding seizures*, nearly half have temporal lobe epilepsy. A study that followed 145 infants and children with intractable epilepsy found that the majority had developmental delay (Huttenlocher and Hapke).

Opinion is divided on whether treatment is required for the older child or adolescent who comes to medical attention because of a first seizure that appears to be idiopathic. Age, sex, and the circumstances of the seizure (withdrawal from drugs or alcohol, myoclonic episodes, family history) all figure into the risk of subsequent seizures. What is apparent is that the early use of antiepileptic drugs has little effect on the occurrence of later seizures, though may reduce seizure frequency in the short term (Krumholz and colleagues; Marson and colleagues). When such cases have been observed without treatment, the risk of another seizure over 10 years was 13 percent unless the first episode was status epilepticus, in which case the risk was 41 percent (Hesdorfer and colleagues). Attention is given to regularizing sleep and minimizing alcohol and stimulants.

Seizures in Late Adult Life

There is an increase in the incidence of seizures as the population ages—from 11.9 per 100,000 in the 40- to 60-year-old age group to 82 per 100,000 in those 60 years of age or older (Hauser and Kurland). Older individuals may live alone so there is no witness to the event, they often have multiple medical problems, they may have cognitive difficulty that impedes an accurate history, they likely take multiple medications, and cerebral imaging is likely to show abnormalities that may not be referable to the problem at hand.

An older person who begins to have seizures of either focal or generalized type may harbor a primary or secondary tumor, a past cerebral infarct, or a traumatic cortical scar that had not declared itself clinically. For example, previous infarcts are by far the most common lesions underlying status epilepticus in late adult life (Sung and Chu). Probably the nature of the population in a given clinic determines the relative frequency of underlying causes. In any case, cerebral imaging usually settles the issue.

However, many seizure-like events in this age group are the result of a cardiac arrhythmia, particularly ventricular tachycardia but also cardiac disorders not related to rhythm such as aortic stenosis. Therefore, ECG and long-term monitoring of heart rhythm are useful ancillary tests if the episode remains unexplained.

Cortical and subcortical lesions, the result of previous traumatic contusions, are a particularly important cause of seizures; the lesions are revealed by brain imaging and are typically located in the anterior frontal and temporal lobes. Brain abscess and other inflammatory and infectious illnesses remain common causes of adult seizures in tropical regions. In the elderly, seizures as a result of advanced Alzheimer and other degenerative diseases occur in up to 10 percent of cases; moreover, these patients are subject to falls, subdural hematoma, and all other illnesses of old age, such as cancer, that secondarily affect the brain. In individuals with cancer, cerebral metastasis is certainly a common cause of a first seizure.

In the common case of an adult with a first unexplained seizure, it has been our practice not to administer an antiepileptic medication unless there is an underlying structural lesion or an abnormality on a single EEG or with prolonged monitoring and to reevaluate the situation in 6 to 12 months. The decision regarding starting treatment in an older adult is informed by a number of factors including occupation, need for driving, safety of home environment, use of alcohol and other sedatives, anticipated compliance, and drug interactions. Usually, a second MRI and EEG are performed to exclude focal abnormalities that were not appreciated during the initial evaluation, but often these studies are again unrevealing. This approach has been prompted by data showing that about one-third of patients

with a single unprovoked seizure will have another seizure within 5 years; the risk is even greater if there is a history of seizures in a sibling, a complex febrile convulsion in childhood, or a spike-and-wave abnormality in the EEG. Moreover, the risk of recurrence is greatest in the first 24 months. In patients with two or three unexplained seizures, a far higher proportion, about 75 percent, have further seizures in the subsequent 4 years.

Seizures due to Underlying Medical Disease

Several diseases announce themselves by an acute convulsion. Here we focus on generalized medical disorders as causes of single and episodic seizures, in contrast to structural lesions of the brain that cause focal or generalized epilepsy.

Withdrawal Seizures

The possibility of withdrawal seizures in patients who abuse alcohol or use benzodiazepine and related sedative drugs, must be considered when seizures occur for the first time in adult life or in adolescence. Suspicion is raised by the stigmata of alcohol abuse or a history of prolonged anxiety requiring sedative drugs. Also, sleep disturbance, tremulousness, disorientation, illusions, and hallucinations can be associated with the convulsive phase of the withdrawal syndrome. Seizures in this setting may occur singly, but as often, in a brief flurry, the entire convulsive period lasting for several hours and rarely for a day or longer, during which time the patient may display twitchiness or myoclonus and be unduly sensitive to photic stimulation. Chapter 41 discusses alcohol and other drug-related seizures in detail.

Infections and Inflammatory-Immune Conditions

An outburst of seizures is also a prominent feature of all varieties of *bacterial meningitis*, more so in children than in adults. Fever, headache, and stiff neck provide the clues to diagnosis, and lumbar puncture yields the salient data. In endemic areas and in individuals who have traveled from these areas, cysticercosis and tuberculous granulomas of the brain are very common causes of epilepsy. Myoclonic jerking and seizures may appear early in acute *herpes simplex encephalitis* and other forms of viral, treponemal, and parasitic encephalitis, including those derived from HIV infection, toxoplasmosis, and in subacute sclerosing panencephalitis. Seizures without fever or stiff neck may be the initial manifestation of syphilitic meningitis, a fact worth noting as this process has reemerged in immunocompromised individuals.

A variety of autoimmune encephalitides, particularly those affecting limbic structures, may cause seizures as, for example, with the anti-NMDA receptor antibody that is associated with ovarian and other teratomas and other paraneoplastic conditions such as the antibody syndrome directed at the voltage-gated potassium channel complex (see Chap. 30).

Seizures in Metabolic Encephalopathy

Uremia has a strong tendency to produce convulsions. Of interest is the relation of seizures to the development of acute anuric renal failure, generally from acute tubular necrosis but occasionally due to glomerular disease. Total anuria may be tolerated for several days without the appearance of neurologic signs, and then there is an abrupt onset of twitching, trembling, myoclonic jerks, and brief generalized motor seizures; acute hypertension probably plays a role. The entire motor constellation, one of the most dramatic in medicine, lasts several days until the patient sinks into terminal coma or recovers by dialysis. When this *twitch-convulsive syndrome* accompanies lupus erythematosus, seizures of undetermined cause, or generalized neoplasia, one should suspect its basis in renal failure.

Other *acute metabolic illnesses and electrolytic disorders* complicated by generalized and multifocal motor seizures are hyponatremia and its opposite, the hypernatremic, hyperglycemic and other hyperosmolar states, hypoglycemia, thyrotoxicity, porphyria, hypomagnesemia, and hypocalcemia. In all these cases, rapidly evolving electrolyte abnormalities are more likely to cause seizures than those occurring gradually. For this reason it is not possible to assign absolute levels of sodium, blood urea nitrogen (BUN), osmolarity, or glucose concentrations above or below which seizures are likely to occur. Lead (in children) and mercury (in children and adults) are the most frequent of the metallic poisons, still rare as a group, that cause convulsions. The presence of these heavy metals in homeopathic treatments should not be overlooked.

Generalized seizures, with or without twitching, occur in the advanced stages of many other illnesses, such as hypertensive encephalopathy, the posterior reversible encephalopathy syndrome from various drugs (PRES, as discussed in Chap. 33), sepsis—especially gram-negative septicemia with shock—and hepatic coma. Usually, seizures in these circumstances can be traced to an associated metabolic abnormality and are revealed by appropriate studies of the blood. Seizures are a central feature of the eclamptic syndrome as discussed in a separate section below.

In most cases of seizures caused by metabolic and withdrawal states, treatment with antiepileptic drugs is not necessary as long as the underlying disturbance is rectified. Indeed, antiepileptic drugs are usually ineffective in halting the seizures if the metabolic disorder persists.

Medications and Other Drugs as Causes of Seizures

In addition to the withdrawal states, a large number of medications are themselves capable of causing seizures, usually when toxic blood levels are attained. The antibiotic imipenem and excessive doses of other penicillin congeners as well as linezolid may be responsible, particularly if renal failure leads to drug accumulation. Cefepime, a fourth-generation cephalosporin, widely used for the treatment of gram-negative sepsis, can result in status epilepticus, if given in excessive dosage (Dixit and colleagues). Renal dysfunction, preexisting brain lesions and previous epilepsy have been emphasized as features associated with antibiotic-induced seizures (Sutter and colleagues, 2015), and they emphasize that the associations between seizures and specific antibiotics are often based on limited evidence.

The tricyclic antidepressants, bupropion, and lithium may cause seizures, particularly in the presence of a structural brain lesion. Lidocaine and aminophylline are known to induce an unheralded single convulsion if administered too quickly or in excessive doses. The use of the analgesic tramadol has also been associated with seizures. Curiously, the anesthetic propofol, which is discussed further on as a potent anticonvulsant in the treatment of status epilepticus, has caused marked myoclonic phenomena in some patients and, rarely, seizures. These may occur during induction or emergence from anesthesia or as a delayed effect (Walder and colleagues).

The list of medications that at one time or another have been associated with a convulsion is long and, if no other explanation for a single seizure is evident, the physician is advised to look up in standard references the side effects of the drugs being administered to the patient. In a few of our otherwise healthy adult patients, extreme sleep deprivation coupled with ingestion of large doses of antibiotics or adrenergic medications or other remedies that are used indiscriminately for the symptomatic relief of colds has been the only plausible explanation for a single or doublet seizure.

Furthermore, many illicit drugs of several varieties may cause seizures. Among the most prominent are cocaine, high-potency synthetic cannabinoids, amphetamines, phencyclidine, psilocybin, and lysergic acid. Some of these cause convulsions through an intermediate of extreme hypertension of vasculopathy but others seem to have a direct neurotoxic effect.

Circulatory or Respiratory Arrest

Cardiac arrest, suffocation or respiratory failure, carbon monoxide poisoning, or other causes of *hypoxemic* or *hypoxemic-ischemic encephalopathy* tend to induce diffuse myoclonic jerking and generalized seizures as cardiac function resumes. The myoclonic-convulsive phase of this condition may last only a few hours or days, in association with coma, stupor, and confusion; or it may persist indefinitely as an intention myoclonus state (*Lance-Adams syndrome*). These movements are to be distinguished from the convulsive movements of syncope discussed earlier in the chapter and in Chap. 17.

Cerebrovascular Diseases

Convulsive seizures are quite uncommon in the acute or evolving phases of an arterial stroke. The ischemic convulsive phenomena of a *limb-shaking TIA* and a burst of generalized clonic motor activity during basilar artery occlusion have been mentioned earlier but are uncommon and are not truly epileptic phenomena. Embolic infarcts involving the cortex become epileptogenic in fewer than 10 percent of cases and only after an interval of several months or longer. Thrombotic infarcts involving the cortex are almost never convulsive at their onset. Lacunar infarctions, being deep and not involving the cortical surface, do not produce convulsions.

In contrast, *cortical venous thrombosis* with underlying edema, ischemia, and infarction acts as a highly epileptogenic lesion (see Chap. 33). The same is true for hypertensive encephalopathy (including the above mentioned posterior reversible encephalopathy [PRES] and eclampsia) and thrombotic thrombocytopenic purpura (TTP), which has a strong tendency to cause nonconvulsive status epilepticus. The rupture of a saccular aneurysm is sometimes marked by one or two generalized convulsions that are not epileptic in nature and are probably predicated on the arrest of cerebral circulation. Cerebral hemorrhages, spontaneous or traumatic, that extend near the cortex, also may present with seizures acutely or become sources of recurrent focal seizures as a delayed consequence.

The use of anticonvulsants as prophylaxis for seizures after a typical cortical stroke of embolic or thrombotic type or nontraumatic cerebral hemorrhage is not necessary. The rate of such seizures has been estimated to be 3 percent or less in the first year. This subject is addressed further in Chap. 33.

Seizures With Acute Head Injury

It is not uncommon for severe concussion to be attended by brief convulsive movements (see Chap. 34). The appearance is in most cases of clonic twitching but may include a momentary tonic phase. Rarely, a prolonged clonic convulsion occurs. The nature of this event, whether originating in the reticular formation as a component of concussion, or from some disruption of cortical activity, is not clear. Almost invariably in our experience, the EEG recorded hours or a day later is normal, and imaging studies are likewise normal or show a small contusion. There is little to guide one in treatment of these patients; we tend to give a course of antiepileptic medications for several weeks, but it is not established if this is the correct approach. Aside from penetrating brain trauma, the risk of delayed seizures is low. Further details on this subject, particularly seizures that occur as a late effect of traumatic brain injury can be found in Chap. 34.

Seizures During Pregnancy

Here one contends with two scenarios: the woman with epilepsy who becomes pregnant and the woman who has her first seizure during pregnancy. In the EURAP study, about two-thirds of women with epilepsy who become pregnant were found to have no change in seizure frequency or severity; the majority remained seizure free and the remainder were evenly split between those in whom the frequency either increased or decreased. A more recent multicenter prospective study examined the frequency of seizures in women with epilepsy through pregnancy and the post-partum period compared to age-matched non-pregnant women with epilepsy (Pennell and colleagues). No differences in seizure frequency during any trimester of pregnancy or in the post-partum period were found compared to the non-pregnant cohort, though there was a higher frequency of antiseizure medication dose increases in the pregnant group.

Many antiepileptic medications also seem to be safe for the baby during breast-feeding in that only small amounts are excreted in lactated milk (Birnbaum and colleagues). The degree of penetration into breast milk is dependent on the extent of protein binding. Highly bound drugs do not

appear in substantial concentrations and the converse is true. Relatively safe agents include carbamazepine, which is found to be 40 percent of the mother's serum concentration, resulting in a neonatal blood level that is below the conventionally detectable amount. Phenytoin is excreted at 15 percent of maternal serum concentration, and valproate, being highly protein bound, is virtually absent in breast milk. No adverse effects have been attributed to these small amounts of these drugs. Those that appear in intermediate concentrations include levetiracetam, oxcarbazepine, tiagabine, vigabatrin, gabapentin, and topiramate. Drugs considered risky for the infant because of high concentrations in breast milk include phenobarbital, primidone, ethosuximide, zonisamide, and benzodiazepines. The risks of using this last group of drugs in the postpartum period must be weighed against the sedating effects of the medication on the neonate.

In the past, issues regarding coagulopathy in the fetus exposed to phenobarbital (now infrequently used for adult seizure disorders) and certain other drugs are well known to obstetricians and pediatric specialists and are treated with the oral administration of vitamin K during the eighth month or intravenously before birth and then intramuscularly to the neonate.

Teratogenic Effects of Antiepileptic Medications

Because it is important to prevent major convulsions in the pregnant epileptic woman, antiepileptic medication should not be discontinued or arbitrarily reduced, particularly if there have been recent convulsions. The conventional drugs (phenytoin, carbamazepine, levetiracetam, lamotrigine) are all tolerated in pregnancy comparably to their use before pregnancy. Plasma levels of most of these drugs, both the free and protein-bound fractions, fall slightly in pregnancy in part because they are cleared more rapidly from the blood but there is considerable inter-individual variability. It is important to monitor the drug levels so that adjustments can be made. The main issue, however, pertains to the potential teratogenicity of most of the drugs with valproate having more risk than the others, and a slight reduction in verbal IQ in children born of mothers who had been exposed to valproate during pregnancy.

The most common teratogenic effects have been cleft lip and cleft palate, but infrequently also a subtle facial dysmorphism ("fetal anticonvulsant syndrome"), similar to the fetal alcohol syndrome. In general, the risk of major congenital defects is low; it increases to 4 to 5 percent in women taking antiepileptic drugs during pregnancy, in comparison to 2 to 3 percent in the overall population of pregnant women. These statistics have been essentially confirmed in a large study conducted among several Boston hospitals (Holmes and colleagues). When all types of malformations were included, both major and minor, 20 percent of infants born to mothers who took antiepileptics during pregnancy showed abnormalities, compared to 9 percent of mothers who had not taken medications. These authors identified "midface hypoplasia" (shortened nose, philtrum, or inner canthal distance) and finger hypoplasia as characteristic of anticonvulsant exposure; these changes were found in 13 and 8 percent of exposed infants, respectively. However, it should be emphasized that in large surveys, major malformations have occurred in only 5 percent of infants exposed to antiepileptic drugs. The infants born of a group of women with epilepsy who had not taken anticonvulsants during pregnancy showed an overall rate of dysmorphic features comparable to that in control infants, but there was still a 2 to 3 percent rate of facial and finger hypoplasia. This risk is shared more or less equally by all the major antiepileptics again, with valproate associated with a higher rate. Aggregating eight databases, a number of malformations of the nervous and somatic systems were found to be increased in comparison to other antiepileptic drugs (Jetnik and colleagues).

Of equal or greater concern has been the finding that in utero exposure to valproate was associated with lower IQs (by 9 points) compared to lamotrigine in children at the age of 4 (Meador and colleagues). It is not clear if the effect persists after this age. Children who had been exposed to phenytoin or to carbamazepine also had slightly lower IQs, but this difference was ostensibly accounted for by lower maternal IQ. Some studies suggest that folate may have an ameliorating effect on this detrimental effect at age 3, whereas there is an uncertain benefit of folate in preventing fetal malformations due to the drugs.

The risk of neural tube defects is also slightly increased by anticonvulsants during pregnancy, and greatest for the use of valproate. It had been considered to be reduced by giving folate before pregnancy has begun (it is not clear if this is true for valproate), but epilepsy experts avoid the use of valproate during pregnancy altogether. These risks are greater in women taking more than one anticonvulsant, so that monotherapy is a desirable goal. Furthermore, the risk is disproportionately increased in families with a history of these defects. Some of the newer anticonvulsants should probably be used cautiously until greater experience has been obtained. As each new drug has been introduced over the years, there has usually been a tentative claim of reduced teratogenic effects, often proven later to be incorrect. Claims have been made of safety in this regard for lamotrigine, causing many specialists to change from the more conventional drugs to this one in women who anticipate becoming pregnant, but lamotrigine levels tend to fall precipitously during pregnancy. A report by Cunnington and colleagues using registry information suggests that the incidence of major birth defects in the fetuses exposed to lamotrigine during the first trimester is just under 3 percent, similar to risk estimates for the general population but also close to the 3 to 4 percent risk derived from most registries of women on anticonvulsants. Polytherapy with lamotrigine and valproate raised the estimate of risk to 12 percent. For all the drugs, polytherapy has the highest risk and there is a significant dose effect for an individual drug on the likelihood of fetal malformation.

If a woman with epilepsy has not required medications for a time before getting pregnant and has a seizure during pregnancy, the best choice of medication may be phenytoin for its advantage in rapid seizure control, or levetiracetam. Exposure of the fetus late in gestation poses few teratogenic risks. If a woman discovers she is pregnant while on an antiepileptic drug, changing medications is

unlikely to reduce the chances of birth defects, even for valproate, but this drug retains the risk of lower IQ in the child. The special case of eclamptic seizures is managed by infusion of magnesium as noted below.

Epileptic women of childbearing age who are on an antiepileptic medication, particularly those which induce cytochrome P450, should be advised that higher doses of the estradiol component of birth control agents are required or they may be exposed to the issues of becoming pregnant while antiepileptic medications. Phenytoin, carbamazepine, and topiramate induce hepatic enzymes and most other medications do not have this effect.

Seizures in Eclampsia (See Also Chap. 33)

This syndrome appears during the last trimester of pregnancy or soon after delivery and may announce itself by hypertension and convulsions; the latter are generalized and tend to occur in clusters. The standard practice is to induce labor or perform a cesarean section and manage the seizures as one would manage those of hypertensive encephalopathy (of which this is one type). The administration of magnesium sulfate continues to be the favored treatment by obstetricians for the prevention of eclamptic seizures; two randomized trials have reestablished its value in preventing seizures in preeclamptic women (Lucas and colleagues) and in avoiding a second convulsion once one had occurred (Eclampsia Trial Collaborative Group). Magnesium sulfate, 10 g IM, followed by 5 g every 4 h, proved comparable to standard doses of phenytoin as prophylaxis for seizures. Our colleagues use a regimen of 4 g IV given over 5 to 10 min followed by a maintenance dose of 5 g every 4 h IM or 1 to 2 g/h IV. In nontoxic gestational epilepsy, approximately 25 percent of patients are found to have some disease (neoplastic, vascular, or traumatic) that will persist.

TREATMENT OF EPILEPSY

The treatment of epilepsy of all types can be divided into four parts: the use of antiepileptic drugs, the surgical excision of epileptic foci and other surgical measures, the removal of causative and precipitating factors, and the regulation of physical and mental activity.

Antiepileptic Drugs—General Principles

The goal of drug treatment is to create a seizure-free state if possible and with the fewest side effects. In the past, a few seizures a year had been considered adequate control but with numerous newer medications it is reasonable to try to eliminate seizures. On the other hand, it is equivalently deleterious to render a patient so impaired by the sedating or cognitive dulling effects of the medications as to interfere with function at work or school. The choice and dose of medication depends on many factors including sex, age, other medications, and renal or hepatic dysfunction or other medical conditions and psychiatric conditions that might be favorably influenced by a particular agent. As a general rule, starting in the lower dose range and attempting to provide twice daily or daily administration are favored.

In approximately 70 percent of all patients with epilepsy, the seizures are controlled completely or almost completely by medications; in an additional 20 to 25 percent, the attacks are significantly reduced in number and severity. Almost half of the patients with a new seizure disorder can be controlled with a first medication, another approximately 15 percent respond to a second as monotherapy, and a third medication choice controls very few additional instances—the remaining cases are considered treatment-resistant (Kwan and Brodie). In more modern series, the response to a first agent of a newer class was similar, but subsequent agent cumulatively was somewhat more successful, achieving 75 percent control (Bonnett and colleagues). More importantly, the simultaneous use of medications presents special problems and the rates of suppression of seizures with each additional drug are low and generally not additive. This approach, however, may not apply to combinations of some of the newer drugs.

An additional question regards whether to start treatment immediately in an adult with a first unprovoked seizure. The Multicentre trial for Early Epilepsy and Single Seizures (MESS) trial, which randomized large groups of patients after a first unprovoked seizure to either immediate treatment or none, concluded that the treated group had fewer subsequent seizures at 6 months (18 vs 26 percent), 2 years (32 vs 39 percent), and 5 years (42 vs 51 percent) and the differences were larger for those who had multiple seizures before randomization and the time to the next seizure was delayed (Marson and colleagues). However, the differences became less significant over time and the side effects of the medications, as judged by practical factors such as keeping a job, were no different between groups. The death rates were comparable as well. A 30-year longitudinal analysis of patients with newly diagnosed and treated epilepsy showed, perhaps surprisingly, that the tolerability of the newer AEDs was no better than the older AEDs (Alsfouk and colleagues). Factors such as tolerance of the medications, patient preferences, and nature of work must be taken into account when making decisions regarding antiepileptic medicines. Guidelines from the American Academy of Neurology generally accord with these views (Krumholz and colleagues).

Table 15-5 lists the most commonly used drugs along with their mechanisms of action, their principal indications, and their major limitations. Table 15-6 lists the drugs along with their dosages, effective blood levels, and serum half-lives. Because of the long half-lives of phenytoin, phenobarbital, and ethosuximide, these drugs need to be taken only once daily, preferably at bedtime. Valproate and carbamazepine have shorter half-lives, and their administration should be spaced during the day. It is useful to be familiar with the serum protein-binding characteristics of antiepileptic drugs and the interactions among these drugs, and between antiepileptic and other drugs.

Certain drugs are somewhat more effective in one type of seizure than in another, and it is necessary to use the proper drugs in optimum dosages for different circumstances. Initially, only one drug should be used, and the

Table 15-5

MECHANISMS AND USES OF THE MAIN ANTIEPILEPTIC DRUGS

GENERIC NAME	MECHANISM OF ACTION	PRINCIPAL INDICATIONS	MAJOR LIMITATIONS
Major Antiepileptic Used as Monotherapy			
Valproic acid	Multiple, including GABA potentiation, NMDA inhibition, sodium channel inhibition, T-type calcium channel inhibition	Focal and generalized seizures, absence seizures	Hepatic enzyme inhibitor, teratogenicity, weight gain
Phenytoin	Sodium channel inhibitor	Focal and generalized seizures	Hepatic enzyme inducer, nonlinear pharmacokinetics, skin hypersensitivity
Carbamazepine	Sodium channel inhibitor	Focal and generalized seizures	Hepatic enzyme inducer, skin hypersensitivity, hyponatremia
Oxcarbazepine	Sodium channel inhibitor	Focal seizures	Hepatic enzyme inducer, hyponatremia
Eslicarbazepine	Sodium channel inhibitor	Focal seizures, adjunctive use only	Hepatic enzyme inducer, hyponatremia
Phenobarbital	GABA potentiation	Focal and generalized seizures	Hepatic enzyme inducer, skin sensitivity
Lamotrigine	Sodium channel inhibitor	Focal and generalized seizures	Hepatic enzyme inducer, skin hypersensitivity
Levetiracetam	SV2A modulation	Focal and generalized seizures	Mood disturbance, psychosis
Brivaracetam	SV2A modulation	Focal and generalized seizures	Less mood disturbance and psychosis than levetiracetam
Topiramate	Multiple, including GABA potentiation, AMPA inhibition, sodium channel inhibition, calcium channel inhibition	Focal and generalized seizures	Nephrolithiasis, cognitive impairment, weight loss
Lacosamide	Sodium channel inhibition	Focal and generalized seizures	
Zonisamide	Sodium channel inhibition	Focal and generalized seizures	Nephrolithiasis, cognitive impairment, weight loss
Ethosuximide	T-type calcium channel inhibition	Absence seizures	Insomnia
Clobazam	GABA potentiation	Focal and generalized seizures, adjunctive use only	Tolerance, sedation
Gabapentin	Calcium channel inhibition	Focal and generalized, adjunctive use only	
Pregabalin	Calcium channel inhibition	Focal and generalized, adjunctive use only	Weight gain
Perampanel	Glutamate (AMPA) inhibition	Focal and generalized seizures, adjunctive use only	
Vigabatrin	GABA potentiation	Infantile spasms, focal and generalized seizures	Retinal toxicity
Clonazepam	GABA potentiation	Adjunctive use only	Tolerance, sedation
Diazepam	GABA potentiation	Adjunctive use only	Tolerance, sedation
Lorazepam	GABA potentiation	Adjunctive use only	Tolerance, sedation
Fosphenytoin	Sodium channel inhibitor	Focal and generalized seizures	Skin hypersensitivity
Propofol	Multiple, including GABA potentiation and NMDA inhibition	Adjunctive use only (for refractory status epilepticus)	Sedation, hypertriglyceridemia, hypotension

dosage increased until sustained therapeutic levels have been attained. If the first drug does not control seizures, a different one should be tried, but frequent shifting of drugs is not advisable; each should be given an adequate trial before another is substituted. A general approach to the choice of drug in certain common forms of epilepsy is given in Table 15-5 for adults and Table 15-7 for children, but it must be noted that there are a number of drugs that may be appropriate in each circumstance. Furthermore, the antiepileptic drugs have approved purposes as assigned by the Federal Drug Administration (FDA) and the European Medicines Agency (EMA). These are more restrictive than are found in general use but it is worthwhile being familiar with the standing of various medications. A tabular summary of these approvals, main uses, and their dates of inception that divide the agents into three generations can be found in a review that is current as of 2016 (Schmidt).

It is difficult to give definitive guidance on combining medications for refractory seizures. Several general principles are worth noting. First, it may seem sensible to avoid drug combinations with similar putative mechanisms because their side effects may be additive, for example, the addition of lamotrigine to carbamazepine or of phenytoin to carbamazepine may not be ideal but at the same time, it should be mentioned that the mechanism of action has little influence on clinical effectiveness and drugs of a similar class are often combined. Second, the clinician should be aware of known interactions through metabolic pathways such as valproate combined with either lamotrigine or phenobarbital as they share the cytochrome P450 degradation pathway. Third, although it is appropriate to use drugs that are known to be effective for the class of seizures under treatment, it is often necessary to extend the choices beyond these restrictions.

Table 15-6

PHARMACOLOGIC ASPECTS OF ANTIEPILEPTIC DRUGS

		USUAL DOSAGE			
GENERIC NAME	TRADE NAME	CHILDREN, mg/kg	ADULTS, mg/d	SERUM HALF-LIFE, h	EFFECTIVE BLOOD LEVEL, μg/mL
Valproic acid	Depakote	30–60	1,000–3,000	6–15	50–100
Phenytoin	Dilantin	4–7	300–400	12–36	10–20
Carbamazepine	Tegretol	20–30	600–1,200	14–25	4–12
Oxcarbazepine	Trileptal	10–40	900–2,400	1–5	
Eslicarbazepine	Aptiom		400–1200	13–20	
Phenobarbital	Luminal	3–5 (8 for infants)	90–200	40–120	15–40
Lamotrigine	Lamictal	0.5	300–500	15–60	2–7
Levetiracetam	Keppra	20–60	500–3,000	6–8	
Brivaracetam	Briviact		50–200	9	
Topiramate	Topamax		400	20–30	
Lacosamide	Vimpat	6–8 mg/kg	300–400 mg/d	13 hours	
Zonisamide	Zonegran	100–600 mg/d		63 hours	
Ethosuximide	Zarontin	20–40	750–1,500	20–60	50–100
Clobazam	Onfi		5–40	16–42	
Gabapentin	Neurontin		900–3,600	5–7	
Pregabalin	Lyrica		150–600	6	
Perampanel	Fycompa		2–12	105	
Vigabatrin	Sabril	100–300	1,000–3,000	5–11	
Clonazepam	Klonopin	0.01–0.2	2–10	18–50	0.01–0.07
Diazepam	Valium		2–40	60–72	
Lorazepam	Ativan	0.15–2	2–20	12	
Fosphenytoin	Cerebyx	5–20	10–20 mg/kg	8–30 min	
Propofol	Diprivan	1.2–12 mg/kg/h	1.2–12 mg/kg/h	40 minutes	

The therapeutic dose for any given patient must be determined, to some extent by clinical effect, guided by measurement of serum levels, as described below. Inquiry regarding seizure control and drug side effects is more valuable than adjustment of medication based solely on drug concentrations. Blood for serum levels is ideally drawn in the morning before the first dose of antiepileptic medication ("trough levels"), a practice that introduces consistency in measurement. A drug should not be discarded as being ineffective, even at the upper limits of therapeutic blood levels, when a slight increase in dosage would have led to suppression of attacks. On the other hand, drug levels can be helpful in detecting noncompliance or poor absorption in instances of inadequate seizure control. The management of seizures is facilitated by having patients chart their daily medication and the number, time, and circumstances of each episode. Furthermore, in some instances, asking the patients about seizure frequency may be unreliable. Some patients find it helpful to use a dispenser that is filled with medications with sufficient pills to last the week. This indicates to the patient whether a dose had been missed and whether the supply of medications is running low.

In general, higher serum concentrations of drugs are necessary for the control of focal seizures than for generalized ones. The usual blood level assay is of the total concentration of the drug (see Table 15-6); this is not a precise reflection of the amount of drug entering the brain, because—in the case of the most widely used antiepileptics—the large proportion of drug is bound to albumin and does not penetrate nervous tissue. Also, in patients who are malnourished or chronically ill or who have a constitutional reduction in proteins, there may be intoxication at low total serum levels. Certain antiepileptic drugs also

Table 15-7

CHOICES OF ANTIEPILEPTIC DRUGS IN CHILDHOOD SEIZURE DISORDERS

SEIZURE TYPE	INITIAL CHOICE	SECOND	THIRD
Generalized tonic-clonic	Valproate, carbamazepine	Lamotrigine, oxcarbazepine	Phenytoin
Myoclonic	Valproate, levetiracetam	Lamotrigine	Phenobarbital, clobazam
Absence	Valproate	Topiramate, levetiracetam, ethosuximide	Lamotrigine
Focal	Carbamazepine, phenytoin	Valproate, levetiracetam, oxcarbazepine	Lamotrigine, vigabatrin, topiramate
Infantile spasms	ACTH, vigabatrin,	Valproate	Lamotrigine
Lennox-Gastaut	Valproate	Topiramate, lamotrigine	Levetiracetam

have active metabolites that are not measured by methods ordinarily used to determine serum concentrations but nonetheless produce toxicity. This is particularly true for the epoxide of carbamazepine. The situation may be further complicated by interactions between one drug and the metabolites of another, as, for example, the inhibition of epoxide hydrolase by valproic acid, leading to toxicity through the buildup of carbamazepine epoxide. In circumstances of unexplained toxicity in the face of conventionally obtained serum levels that are normal, measurement may be undertaken of the levels of free drug and the concentration of active metabolites.

The use of saliva for measurement of free drug levels has merit but has not been adopted frequently in practice. The measurements correlate with free drug levels. It has the advantage of allowing the patient to collect a sample before breakfast and avoid venipuncture.

Finally, the pharmacokinetics of each drug plays a role in toxicity and the serum level that is achieved with each alteration in the dose. This is particularly true of phenytoin, which, as the result of saturation of liver enzymatic capacity, has nonlinear kinetics once serum concentration exceeds 10 mg/mL. For this reason, a typical increase in dose from 300 to 400 mg daily results in a disproportionate elevation of the serum level and toxic side effects. Elevations in drug concentrations are also accompanied by prolongation of the serum half-life, which increases the time to reach a steady-state concentration of phenytoin after dosage adjustments. Contrariwise, carbamazepine is known to induce its own metabolism, so that doses adequate to control seizures at the outset of therapy are no longer effective several weeks later.

Antiepileptic Drug Interactions

Antiepileptic drugs have manifold interactions with each other and with a wide variety of other drugs. Although many such interactions are known, only a few are of clinical significance and most pertain to older generations of medications, requiring adjustment of drug dosages (Kutt). Among the interactions, valproate often leads to accumulation of active phenytoin and phenobarbital by displacing them from serum proteins, as well as slightly elevating serum total levels. Some of the agents that alter the concentrations of antiepileptic medications are chloramphenicol, which causes the accumulation of phenytoin and phenobarbital, and erythromycin, which causes the accumulation of carbamazepine. Antacids reduce the blood phenytoin concentration, whereas histamine blockers used to reduce gastric acid output do the opposite. Salicylates reduce the total plasma levels of antiepileptic drugs but elevate the free fraction by displacing the drug from its protein carrier. More importantly, warfarin levels are decreased by the addition of phenobarbital or carbamazepine and may be increased by phenytoin although, with this last drug there may be unexpected alterations of the international normalized ratio (INR) in either direction. Enzyme-inducing drugs such as phenytoin, carbamazepine, and barbiturates can greatly increase the chance of breakthrough menstrual bleeding in women taking oral contraceptives and may lead to failure of contraceptive medications, and adjustments in the amount of estradiol must be made. These interactions are emphasized further below under the discussions of each agent.

Hepatic function greatly affects antiepileptic drug concentrations, since most of these drugs are metabolized in the liver. Serum levels must be checked more frequently than usual if there is liver failure, and with hypoalbuminemia it is advisable to obtain free drug levels for reasons just mentioned. Renal function has an indirect effect on the concentrations of the commonly used antiepileptics, but some agents, such as levetiracetam, gabapentin, and pregabalin, are excreted through the kidneys and require dosage adjustment in cases of renal failure. The main renal effects of the drugs in general are alterations in protein binding induced by uremia. In end-stage renal failure, serum levels are not an accurate guide to therapy and the goal should be to attain adequate free concentrations, typically, 1 to 2 μg/mL. In addition, uremia causes the accumulation of phenytoin metabolites, which are measured with the parent drug by enzyme-multiplied immunoassay techniques. In patients who are being dialyzed, total blood levels of phenytoin tend to be low because of decreased protein binding; in this situation it is also necessary to track free (unbound) levels as it is for other highly protein bound drugs. Because dialysis removes many drugs, particularly levetiracetam, phenobarbital, topiramate, ethosuximide, and gabapentin, dosage of these drugs may have to be increased or doses may have to be administered after dialysis.

Skin Eruptions From Antiepileptic Drugs

Rashes are the most frequent idiosyncratic reactions to the drugs used to treat epilepsy. The aromatic compounds (phenytoin, carbamazepine, phenobarbital, primidone, and lamotrigine) are the ones most often responsible. Furthermore, there is a high degree of cross-reactivity within this group, particularly between phenytoin, carbamazepine, and phenobarbital, and possibly, lamotrigine. The problem arises most often in the first month of use. The typical eruption is maculopapular, mainly on the trunk; it usually resolves within days of discontinuing the medication. More severe rashes may develop, sometimes taking the form of erythema multiforme and Stevens-Johnson syndrome, or even toxic epidermal necrolysis, especially with lamotrigine, discussed further below.

Certain polymorphisms in HLA genes (HLA-B*1502) have been associated with an increased risk of these types of severe skin reactions in those of Asian ancestry. A polymorphism in HLA-A*3101 may be associated with skin eruptions in Caucasians (McCormack and colleagues). Another rare systemic hypersensitivity syndrome associated with the use of antiepileptic medications is one of high fever, rash, lymphadenopathy, and pharyngitis. Eosinophilia and hepatitis (or nephritis) may follow.

If any of these reactions require that one of the aromatic drugs be replaced, valproate, gabapentin, topiramate, or levetiracetam are reasonable substitutes, depending, of course, on the nature of the seizures and other factors.

Discontinuation of Antiepileptic Drugs

Withdrawal of medications may be undertaken in patients who have been free of seizures for a prolonged period. There are few firm rules to guide the physician in this decision. One plan, applicable to most forms of epilepsy, is to obtain an EEG whenever withdrawal of medication is contemplated. We have taken the approach that if the tracing is abnormal by way of showing paroxysmal activity, it is generally better to continue treatment. However, a normal EEG may not be helpful in making the decision to discontinue medications. A prospective study showed that in patients who had been seizure-free during 2 years of treatment with a single drug, one-third relapsed after discontinuation of the drug, and this relapse rate was much the same in adults and children, and whether the drug was tapered over a period of weeks versus months (Callaghan and colleagues). The relapse rate was lower in patients with absence and generalized-onset seizures than in patients with focal seizures. Another study gave results similar to those of the large Medical Research Council Antiepileptic Drug Withdrawal Study— namely, that after 2 years on a single anticonvulsant during which no seizures had occurred, the rate of relapse was 40 percent 2.5 years later and 50 percent at 5 years after discontinuation; this compared to a seizure recurrence rate of 20 percent for patients remaining on medication (Specchio and colleagues). Some have suggested that a longer seizure-free period is associated with a lesser rate of relapse.

Often in practice, the suggestion to stop medications after a lengthy seizure-free period comes from the patient, for example if pregnancy is planned or there are untoward side effects but otherwise, the change is never risk-free and therefore is infrequently impelled by the physician. Decisions regarding the cessation of medication are also tempered by patient's desire to continue driving and their concern that another seizure may prevent or delay a return to driving.

Patients with juvenile myoclonic epilepsy, even those with long seizure-free periods, should probably continue medication life-long, but there have been no thorough studies to support this dictum. In young women with this disorder who plan to become pregnant, changing from valproate to levetiracetam may be sensible. The appropriate duration of treatment for postinfarction epilepsy has not been studied, and most neurologists continue to use one drug indefinitely. Interestingly, epilepsy caused by military brain wounds tends to wane in frequency or to disappear in 20 to 30 years, thereafter, no longer requiring treatment (Caveness). Childhood uncomplicated absence seizures do not require lifelong treatment either.

As discussed earlier, a curious and unexplained lesion in the splenium of the corpus callosum has been detected in patients who have had their antiepileptic drug(s) withdrawn in the previous few days. In a review of 16 patients, there was no clinical correlate for this change (Gürtler and colleagues). A broad range of drugs was implicated, and the lesion was most prominent on T2-weighted MRI sequences. Various metabolic derangements cause similar lesions; the mechanism in all these instances has not been established and the lesion is very often reversible (Doherty and colleagues, Garcia-Monco and colleagues).

Specific Drugs in the Treatment of Seizures

General Comments

The putative mechanisms of action of the most commonly used drugs are reasonably well known, but gaps remain. A schematic depiction of putative drug actions at excitatory and inhibitory synapses is adopted in Fig. 15-4 (Bialer and White) and summarized in Table 15-5. There it is apparent that for each of these two physiologic classes of neurons (excitatory and inhibitory), some medications have their main effect on voltage-gated ion channels and others, on membrane receptors or intracellular vesicular activity.

Phenytoin, carbamazepine, levetiracetam, and valproate are representative antiepileptic drugs that may be considered "broad spectrum" and are more or less equally effective in the treatment of both generalized and focal seizures (see Table 15-6 for typical initial dosages). The first two of these drugs act by blocking voltage-gated sodium channels, thus preventing abnormal neuronal firing and seizure spread. Lamotrigine has become an alternative for treating focal seizures with a different side effect profile from the other three (Schmidt).

Because carbamazepine (or the related oxcarbazepine) and levetiracetam have somewhat fewer side effects, one or the other is preferred as the initial drug by many neurologists, though phenytoin and valproate have very similar therapeutic and side-effect profiles. In many cases, levetiracetam, phenytoin, or carbamazepine alone will control seizures. If not, the use of valproate (which facilitates GABA activity) alone, or the combined use of two medications, produces better control. Levetiracetam has attained popularity largely because of its lack of interactions with other antiepileptic and other medications including chemotherapeutic agents and anticoagulant medications. Carbamazepine, levetiracetam, and valproate are probably preferable to phenytoin for children because they do not coarsen facial features and do not produce gingival hypertrophy or gynecomastia. Because of the high incidence of myoclonic epilepsy in adolescence, it has been the practice of many neurologists to use valproate as the first drug in this age group. Weight gain, menstrual irregularities (see later) during the period of initiation of valproate, and its teratogenic effects also must be accounted for in the choice of initial drug for otherwise uncomplicated seizures in young women.

Most of the commonly used antiepileptic drugs cause, to varying degrees, a decrease in bone density and an increased risk of fracture from osteoporosis in older patients, particularly in women. Several mechanisms are probably active, among them, induction of the cytochrome P450 system, which enzymatically degrades vitamin D. No specific recommendations have been offered to counteract this effect of bone loss, but many practitioners have advised patients to take calcium supplements, vitamin D, or one of the bisphosphonates if there is no contraindication, and to periodically check bone density.

Finally, several reports and meta-analyses over the past decades have suggested that antiepileptic drugs taken together as a class, increase the incidence of depression and suicide, both in individuals with epilepsy and psychiatric patients. The issue may never be entirely resolved

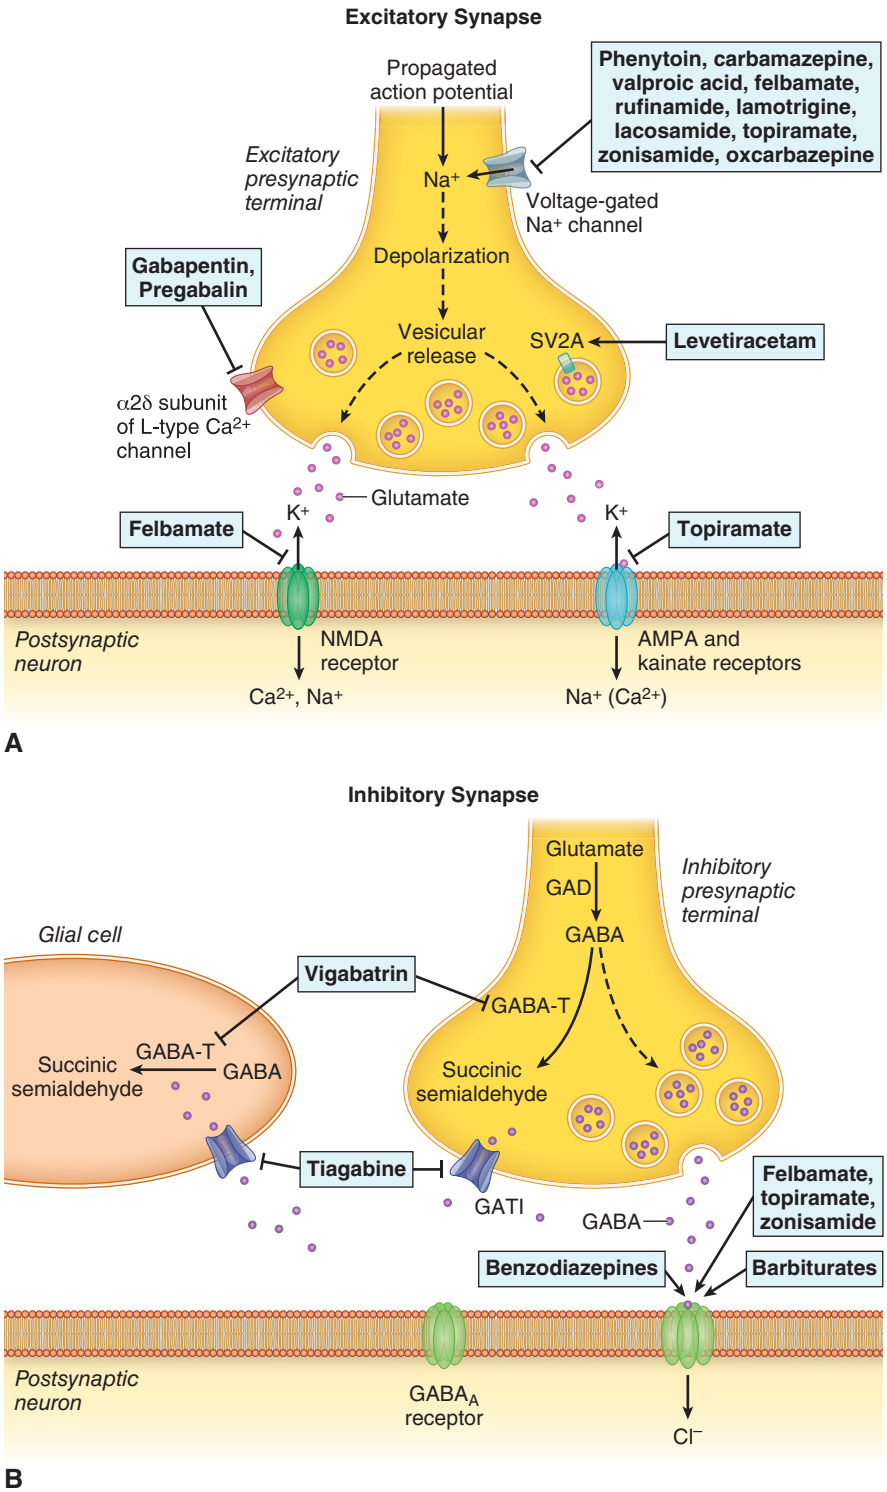

Figure 15-4. Schematic depiction of sites and mechanisms of action of antiepileptic drugs on excitatory and inhibitory synapses. GABA, gamma amino butyric acid; GAD: glutamic acid decarboxylase; GATI: GABA transporter (also known as SLC6A1). (Reproduced with permission from Bialer M, White HS. Key factors in the discovery and development of new antiepileptic drugs. *Nat Rev Drug Discov.* 2010;9(1):68–82.)

because of confounding factors but a patient level-analysis showed no such relationship in epilepsy once underlying depression was accounted for (Arana and colleagues). However, this assessment was contrary to an earlier FDA meta-analysis and it may not hold for certain drugs, for example, levetiracetam.

Phenytoin This sodium channel blocker has been used for decades for focal and generalized seizures. Its advantages are low cost, wide availability, ease of monitoring of blood levels and ability to rapidly achieve therapeutic levels with, oral, intravenous, and intramuscular preparations. Rash, fever, lymphadenopathy, eosinophilia

and other blood dyscrasias, and polyarteritis are manifestations of idiosyncratic *phenytoin hypersensitivity*; their occurrence calls for discontinuation of the medication. *Overdose* with phenytoin causes ataxia, diplopia, and stupor. The prolonged use of phenytoin leads to hirsutism, enlargement of gums from hyperplasia of connective tissue and epithelium with subsequent periodontal disease, and coarsening of facial features in children. A clinical trial suggested that folate supplementation may prevent gingival hyperplasia in children (Arya and colleagues). Chronic phenytoin use over several decades may occasionally be associated with peripheral neuropathy and probably with a form of cerebellar degeneration (Lindvall and Nilsson); it is not clear if these are strictly dose-related effects or idiosyncratic reactions. An antifolate effect on blood and interference with vitamin K metabolism have also been reported, for which reason pregnant women taking phenytoin (and in fact most other antiepileptic drugs) should be given folate supplementation and vitamin K before delivery and the newborn infant also should receive vitamin K to prevent bleeding. Phenytoin should not be used together with disulfiram, chloramphenicol, sulfamethizole, or cyclophosphamide, and the use of either phenobarbital or phenytoin is not advisable in patients receiving warfarin because of the undesirable interactions already described. Choreoathetosis is a rare idiosyncratic side effect. Fosphenytoin for intramuscular and intravenous administration allows somewhat faster attainment of serum levels and may have minor advantages in special circumstances, especially the availability of the IM route. Intravenous phenytoin and fosphenytoin, including their risks, are discussed further in the section on status epilepticus.

Carbamazepine This drug, also a blocker of sodium channels like phenytoin, causes many of the same side effects as phenytoin, but to a slightly lesser degree. There is induction of hepatic enzymes and "autoinduction," leading to declining drug levels after a few weeks of administration. Mild leukopenia is common, and there have been rare instances of pancytopenia, hepatic enzyme abnormalities, pancreatitis, hyponatremia (resulting from inappropriate antidiuretic hormone [ADH] secretion), and, rarely, diabetes insipidus as idiosyncratic reactions. It is advisable therefore, that a CBC and liver function tests (some practitioners omit the latter because of the infrequency of hepatic problems) be done before or soon after treatment is instituted and that counts are rechecked regularly. Idiosyncratic rashes, some as severe as Stevens-Johnson syndrome and toxic epidermal necrolysis may occur, particularly in Asian individuals carrying the HLA-B*1502 haplotype as mentioned above. It has not been considered useful to check all patients for this haplotype, but screening for the haplotype is recommended in genetically at-risk populations.

Oxcarbazepine, an analogue of carbamazepine, has fewer of these side effects than the parent drug, especially marrow toxicity, but its long-term therapeutic value is not as well established. It has the advantage of being titrated upward at a more rapid rate than carbamazepine. Dose-related side effects are similar to carbamazepine but it has less hepatic enzyme induction. Some patients report weight gain after continued use. Hyponatremia has been reported in 3 percent of patients taking oxcarbazepine. Should drowsiness or increased seizure frequency occur, this complication should be suspected. Rashes occur at the same or slightly lower rate than with carbamazepine and there is considerable cross-reactivity for this side effect. Elevated cholesterol and osteoporosis are lesser effects, shared also with carbamazepine.

Valproate This drug in all its related forms is considered to be GABA-ergic, acting through glutamic acid decarboxylase, but also displaying some sodium channel blocking features. All preparations of this drug are occasionally hepatotoxic, an adverse effect that is usually (but not invariably) limited to children 2 years of age and younger. The use of valproate with hepatic enzyme-inducing drugs increases the risk of liver toxicity. However, mild elevations of serum ammonia and mild impairments of liver function tests in an adult do not require discontinuation of the drug. An increasingly emphasized problem with valproate has been weight gain during the first months of therapy. In one study there was an average addition of 5.8 kg, and even more in those disposed to obesity. In addition, menstrual irregularities and polycystic ovarian syndrome may appear in young women taking the drug, perhaps as a consequence of the aforementioned weight gain. Pancreatitis is a rare but important complication of valproate. Tremor and slight bradykinesias have been seen and they vaguely simulate parkinsonism. The major issues, however, pertain to its use in pregnancy as discussed earlier.

An intravenous form of valproate is available and may be useful in status epilepticus. The maximum recommended rate of administration is 3 mg/kg per min.

Phenobarbital Introduced as an antiepileptic drug in 1912, it is as effective as phenytoin and carbamazepine, but because of its dose-related toxic effects—drowsiness and mental dullness, nystagmus, and staggering, as well as the availability of better alternatives—it is now infrequently used in adults. It inhibits sodium currents through the sodium channel and has been found to have some additional GABAergic effect. The drug strongly induces cytochrome P450 and therefore has interactions with many medications. There are infrequent disorders of connective tissue, such as frozen shoulder and Dupuytren contractures that have been attributed to long-term use. The adverse effects of *primidone* are much the same. Both drugs may provoke behavioral problems in developmentally delayed children, and they are still used to advantage as an adjunctive anticonvulsant and as primary therapy in infantile seizures. The rate of teratogenicity is increased (stated to be approximately 5.5 percent) and comparable to other main-line drugs.

Lamotrigine This drug closely resembles phenytoin in having a broad spectrum of antiseizure activity but has different features relating to toxicity. It functions by selectively blocking the slow sodium channel, thereby preventing the release of the excitatory transmitters glutamate and aspartate. It is effective as a first-line and adjunctive drug for generalized and focal seizures and may be an alternative to valproate in young women because it does not provoke weight gain and ovarian problems. The main limitation to its use has been a serious rash in approximately 1 percent of patients, requiring discontinuation of the drug, and lesser dermatologic eruptions in 12 percent. It should be pointed out that some registries have reported considerably lower

rates of these complications and the slow introduction of the medication may reduce the incidence of drug eruptions (see Skin Eruptions From Antiepileptic Drugs). Rare cases of reversible chorea have been reported, especially with the concurrent use of phenytoin. Combined use with valproate greatly increases the serum level of lamotrigine. It has been said to have a more favorable teratogenic profile than most other drugs. Dosing depends greatly on the concurrent use of other drugs, reducing its dose and rapidity of escalation if used with other enzyme-inducing AEDs such as phenytoin or carbamazepine and particularly with valproate.

Levetiracetam This novel drug with uncertain mechanism has been useful in the treatment of both partial and generalized seizures. The agent interacts with the SV2A synaptic vesicle protein, but how this relates to its antiepileptic properties is still being investigated. It is well tolerated if initiated slowly but may produce considerable sleepiness and dizziness if used at high doses. It also may produce irritability and depression or exaggerate underlying depression, even to the point of suicidality. A major advantage is that there are no important interactions with other antiepileptic drugs and it is renally excreted for which reason it is often chosen as a first-line agent in patients who have organ failure and require numerous medications, as well as those receiving hepatically metabolized chemotherapeutics. There are some data showing a favorable teratogenic profile.

Other antiepileptic drugs Two other drugs, *gabapentin* and *vigabatrin*, were synthesized specifically to enhance the intrinsic inhibitory system of GABA in the brain. Gabapentin is chemically similar to GABA, but its anticonvulsant mechanism is not known; it has an apparent effect on calcium channels. It is moderately effective in partial and secondary generalized seizures and has the advantage of not being metabolized by the liver. Vigabatrin inhibits GABA transaminase. Vigabatrin is no longer used in adults because of the side effect of photoreceptor retinal damage. *Tiagabine* is considered to be an inhibitor of GABA reuptake.

Topiramate has much the same mode of action and probably a broader effectiveness as tiagabine. It will rarely cause serious dermatologic side effects, especially if used with valproate, and appears to induce renal stones in 1.5 percent of patients, lower in women. Angle-closure glaucoma has also been reported as a complication. A minor problem has been the development of hyperchloremic metabolic acidosis. It has high teratogenicity in most studies.

Lacosamide, a potent drug for seizures that have a focal onset and generalize or remain focal, is currently used mainly as an adjunctive therapy. Like levetiracetam, its mechanism of action is not entirely known but it has been shown to modulate voltage-gated sodium channel activity. It may be titrated upward rapidly and has limited pharmacokinetic interactions, but its effective range of blood levels is narrow; also, like levetiracetam, it is renally excreted. The availability of an intravenous preparation is also notable. The main but infrequent side effects are headache and diplopia. The drug may prolong the P-R interval and worsen heart failure for which reason an ECG is often checked.

Ethosuximide and valproate are equally effective for the treatment of absence seizures, the former having fewer cognitive side effects (Glauser and colleagues). The use of ethosuximide is virtually limited to this indication. It is good practice, to avoid excessive sleepiness, to begin with a single dose of 250 mg of ethosuximide per day and to increase it every week until the optimum therapeutic effect is achieved. *Methsuximide* is useful in individual cases where ethosuximide and valproate have failed. In patients with benign absence attacks that are associated with photosensitivity, myoclonus, and clonic or tonic-clonic seizures (including juvenile myoclonic epilepsy), valproate is the drug of choice. Valproate is particularly useful in children who have both absence and grand mal attacks, as the use of this drug alone often permits the control of both types of seizures. The concurrent use of valproate and clonazepam has been known to produce absence status.

Zonisamide, similar to topiramate, seems to be useful for myoclonic epilepsy but its main use is currently as an adjuvant. It is not predominantly a sodium channel blocker and can be taken with carbamazepine. Some clinicians have found it to produce fewer cognitive side effects than topiramate.

New antiepileptic medications are being introduced regularly, among the newer ones is brivaracetam that is likely to display broad activity against seizure types and lack of interaction with other medications seen with levetiracetam. Perampanel, retigabine, rufinamide, pregabalin, felbamate, eslicarbazepine, and several in the benzodiazepine class including clobazam find special use, mostly in epilepsy clinics that treat recalcitrant seizures. The medications used in the neonatal and infant population are discussed below.

Treatment of Seizures in the Neonate and Young Child

This specialized area of neonatal seizures is discussed by Volpe, and in children, by Guerrini. In general, phenobarbital has been preferred for seizure control in infancy. Probably the form of epilepsy that is most difficult to treat is the childhood *Lennox-Gastaut* syndrome. Some of these patients have as many as 50 or more seizures per day, and there may be no effective combination of anticonvulsant medications. Valproic acid (900 to 2,400 mg/d) will reduce the frequency of spells in approximately half the cases. Some of the relatively newer drugs—lamotrigine, topiramate, vigabatrin—are each effective in approximately 25 percent of cases. Clonazepam also has had limited success. In the case of Dravet syndrome, a disorder of the sodium channel, antiepileptic drugs that block that channel are avoided (see Cannabinoids, below).

In the treatment of infantile spasms, ACTH or adrenal corticosteroids had been used, but vigabatrin is now found to be as effective, including in patients with underlying tuberous sclerosis (Elterman and colleagues).

Status Epilepticus

Recurrent generalized convulsions at a frequency that precludes regaining of consciousness in the interval between seizures (convulsive status) constitutes the most serious problem in epilepsy, with an overall mortality previously reported at 20 to 30 percent (Towne and colleagues), but has been lower in more recent years. Some patients who

die of epilepsy do so because of uncontrolled seizures of this type, complicated by the effects of the underlying illness or an injury sustained as a result of a convulsion. Rising temperature, acidosis, hypotension, and renal failure from myoglobinuria are a sequence of life-threatening events that may be encountered in cases of convulsive status epilepticus. Prolonged convulsive status (for longer than 30 min) also carries a risk of serious neurologic sequelae (epileptic encephalopathy). The MRI during and for days after a bout of status epilepticus may show signal abnormalities in the region of a focal seizure or in the hippocampi, most often reversible, but we have had several such patients who awakened and were left in a permanent amnesic state. The MRI changes are most evident on T2 and diffusion-weighted sequences. With regard to acute medical complications, from time to time a case of neurogenic pulmonary edema is encountered during or just after the convulsions, and some patients may become extremely hypertensive, making it difficult to distinguish the syndrome from hypertensive encephalopathy.

The etiologies of status epilepticus vary among age groups, but all the fundamental causes of seizures are able to produce the syndrome. The most recalcitrant cases we have encountered in adults have been associated with viral or paraneoplastic encephalitis, old traumatic injury, and epilepsy with severe mental retardation. Stroke and brain tumor have, in contrast, been infrequent causes. Several groups have emphasized autoimmune forms of encephalitis including the paraneoplastic variety as the most common explanations for new-onset *refractory status epilepticus* but add that over half of cases remain cryptogenic (Gaspard and coworkers).

Table 15-8

APPROACH TO THE TREATMENT OF STATUS EPILEPTICUS IN ADULTS

Initial assessment
Ensure adequate ventilation, oxygenation, blood pressure
Intubate if necessary, based on low oxygen saturation and labored breathing
Insert intravenous line
Administer glucose and thiamine in appropriate circumstances
Send toxic screen
Assess quickly for cranial and cervical injury if onset of seizures is unwitnessed
Immediate suppression of convulsions
Lorazepam or diazepam, 2 to 4 mg/min IV to a total dose of 10 to 15 mg with blood pressure monitoring when higher rates or doses are used
Initiation or reloading with anticonvulsants
Phenytoin 15–20 mg/kg IV at 25–50 mg/min in normal saline or fosphenytoin at 50 to 75 mg/min
General anesthetic doses of medication for persistent status epilepticus
Midazolam 0.2 mg/kg loading dose followed by infusion at 0.1 to 0.4 mg/kg/h or propofol 2 mg/kg/h
Further treatment if convulsions or electrographic seizures persist after several hours
May add valproate or phenobarbital 10 mg/min to total dose of 20 mg/kg as additional anticonvulsants intravenously, or carbamazepine or levetiracetam by nasogastric tube if there is gastric and bowel activity
Consider neuromuscular paralysis with EEG monitoring if convulsions persist
Pentobarbital 10 mg/kg/h
Inhalational anesthetics (isoflurane)

Treatment of Convulsive Status Epilepticus (Table 15-8)

The many regimens that have been proposed for the treatment of status epilepticus attest to the fact that no one of them is altogether satisfactory and none is clearly superior (Treiman and colleagues).

We have had the success with the following program, which reflects several published approaches (Bleck). When the patient is first seen, an initial assessment of cardiorespiratory function is made and an oral airway established. A large-bore intravenous line is inserted; blood is drawn for glucose, BUN, electrolytes, and a metabolic and drug screen. A normal saline infusion is begun and a bolus of glucose is given (with thiamine if malnutrition and alcoholism are potential factors). To rapidly suppress the seizures, we generally use diazepam intravenously at a rate of about 2 mg/min until the seizures cease or a total of 20 mg has been given; alternatively, lorazepam, 0.1 mg/kg given by intravenous push at a rate not to exceed 2 mg/min, is now favored, being marginally more effective than diazepam because of its clinically longer duration of action (see Table 15-8).

Immediately thereafter, a loading dose (20 mg/kg) of phenytoin is administered by vein at a rate of less than 50 mg/min. More rapid administration risks hypotension and heart block; consequently, it is recommended that the blood pressure and electrocardiogram be monitored during the infusion. Phenytoin must be given through a freely running line with normal saline (it precipitates in other fluids) and should not be injected intramuscularly. A study has demonstrated the superiority of using lorazepam instead of phenytoin as the first drug to control status, but this is not surprising considering the longer latency of onset of phenytoin (Treiman and colleagues). Recently intravenous valproate 40 mg/kg or levetiracetam 60 mg/kg have been used as alternatives to phenytoin.

In the field, emergency medical technicians can administer lorazepam or midazolam. Attesting to the benefit of rapidly treating seizures, it has been shown that intramuscular administration is slightly superior to the intravenous route simply because of the delay in inserting an intravenous line (Silbergleit and colleagues). It has also been shown that diazepines can be administered by paramedical workers in nursing homes with good effect in status epilepticus, terminating the seizures in about half of cases (Alldredge and colleagues).

Nonetheless, a long-acting antiseizure medication such as phenytoin must be given immediately after a diazepine has controlled the initial seizures. An alternative is the water-soluble drug fosphenytoin, which is administered in the same dose equivalents as phenytoin but can be injected at twice the maximum rate. Moreover, it can be given intramuscularly in cases where venous access is difficult. However, the delay in hepatic conversion of fosphenytoin to active phenytoin makes the latency of clinical effect approximately the same for both drugs.

In an epileptic patient known to be taking seizure medications chronically but in whom the serum level of drug is unknown, it is probably best to administer the full recommended dose of phenytoin. If it can be established that the serum phenytoin is above 10 mg/mL, a lower loading dose may be advisable. If seizures continue, an additional 5 mg/kg is indicated. If this fails to suppress the seizures and status has persisted for 20 to 30 min, an endotracheal tube should be inserted and O_2 administered.

Having emphasized the dangers of this syndrome, at each stage of treatment it is worthwhile considering if a refractory convulsive episode is of psychogenic, nonepileptic nature. The reader is referred to the previous section on this subject.

Several approaches have been suggested to control status epilepticus that persists after these efforts. At this stage we have resorted to the approach of giving high doses of midazolam (0.2 mg/kg loading dose followed by an infusion of 0.1 to 0.4 mg/kg/h as determined by clinical and EEG monitoring) (Kumar and Bleck). If seizures continue, the dose can be raised as blood pressure permits. We have used in excess of 20 mg/h because of a diminishing effect over days. This regimen of midazolam and phenytoin may be maintained for several days without major ill effect in previously healthy patients. Propofol given in a bolus of 2 mg/kg and then as an intravenous drip of 2 to 8 mg/kg/h is an effective alternative to midazolam, but after 24 h the drug behaves like a high dose of barbiturate and there may be hypotension. Prolonged use of propofol may precipitate hypertriglyceridemia-associated pancreatitis or a fatal shock and acidosis (propofol syndrome).

Valproate, phenytoin, and levetiracetam are available as intravenous preparations, making them suitable for administration in status epilepticus. Metanalyses have variously shown that one of these medications is superior to another (i.e., levetiracetam versus phenytoin), either in terms of treating benzodiazepine-refractory status epilepticus or its safety profile. Another dependable approach is an infusion of either pentobarbital, starting with 5 mg/kg, or phenobarbital, at a rate of 100 mg/min until the seizures stop or a total dose of 20 mg/kg is reached; a long period of stupor must be anticipated after. Hypotension often limits the continued use of the barbiturates, but this problem can be managed by fluid infusions, dopamine, and neosynephrine (Parviainen and colleagues).

If none of these measures controls the seizures, a more aggressive approach is taken to temporarily subdue all brain electrical activity using general anesthesia. The preferred medications for this purpose have been pentobarbital or propofol, which, despite their moderate efficacy as primary anticonvulsants, are easier to manage than the alternative inhalational anesthetic agents. An initial intravenous dose of 5 mg/kg pentobarbital or 2 mg/kg propofol is given slowly to induce an EEG *burst-suppression* pattern, which is then maintained by the administration of pentobarbital, 0.5 to 2 mg/kg/h, or propofol, up to 10 mg/kg/h. Every 12 to 24 h, the rate of infusion is slowed to determine whether the seizures have stopped. Most instances of status epilepticus that cannot be controlled with the combination of standard anticonvulsants and midazolam will respond to high doses of barbiturates or to propofol, but these infusions cause hypotension and cannot be carried out for long periods (Lowenstein and Aldredge). More recent work has shown that prolonged infusions of neurosteroid medications such as allopregnanolone, a modulator of synaptic and extrasynaptic $GABA_A$ receptors, may be effective as an adjunctive agent in treating highly refractory status epilepticus (Vaitkevicius and colleagues). Even a ketogenic diet, more commonly employed in childhood epilepsy as discussed further on, has been suggested as an ancillary treatment in these difficult cases of truly refractory status epilepticus (Thakur and colleagues).

Should the seizures continue, either clinically or electrographically, despite all these medications, one is justified in the assumption that the convulsive tendency is so strong that it cannot be checked by reasonable quantities of medications. However, a few patients in this predicament have survived and awakened, even at times with minimal neurologic damage depending on the underlying cause.

The volatile anesthetic agent isoflurane has also been used in these circumstances with good effect, as we have reported (Ropper and colleagues), but the continuous administration of inhalational anesthetic agents is impractical in most critical care units. Halothane has been relatively ineffective as an anticonvulsant, but ether, although impractical, has in the past been effective in some.

In the end, in patients with truly intractable status, one usually depends on phenytoin, phenobarbital (smaller doses in infants and children than are shown in Table 15-8), and on measures that safeguard the patient's vital functions. Ketamine infusions have been a last resort, in combination with a midazolam infusion. A few times over the years, we have also resorted to inducing ketosis in adults by manipulating the nutrition given through a nasogastric tube. As a cautionary note, a series suggested that adverse events such as infection as well as mortality are higher in patients receiving intravenous anesthetic drugs compared to those who did not receive them but the possibility of confounding by the severity of illness must be taken into account before accepting a causal relationship (Sutter and colleagues, 2014).

A word is added here concerning neuromuscular paralysis and continuous EEG monitoring in status epilepticus. With failure of aggressive anticonvulsant and anesthetic treatment, there may be a temptation to paralyze all muscular activity, an effect easily attained with drugs such as pancuronium, while neglecting the underlying seizures. The use of neuromuscular blocking drugs without a concomitant attempt to suppress seizure activity is inadvisable. If such measures are undertaken, continuous or frequent intermittent EEG monitoring is essential; this may also be also helpful in the early stages of status epilepticus in that it guides the dosages of anticonvulsants required to suppress the seizures.

In the related but less-serious condition of *acute repetitive seizures*, in which the patient awakens between convulsions, a diazepam gel, which is well absorbed if given rectally, is available and has been found useful in institutional and home care of epileptic patients. A similar effect has been attained by the nasal or buccal (transmucosal)

administration of midazolam, which is absorbed from these sites (5 mg/mL, 0.2 mg/kg nasally; 2 mL to 10 mg buccally). Midazolam may be preferred among the diazepines for transmucosal use because it produces somewhat less respiratory depression than the others in the class and has been more effective at controlling seizures (McIntyre and colleagues). Still, only half were controlled. These approaches have found their main use in children with frequent seizures who live in supervised environments, where a nurse or parent is available to administer the medication.

Absence status should be managed by intravenous lorazepam, valproic acid, or both, followed by ethosuximide. Nonconvulsive generalized status is treated along the lines of convulsive status, usually stopping short of using anesthetic agents (Meierkord and Holtkamp). In the case of epilepsia partialis continua, typically a difficult condition to fully control, a balance must be found between stopping the phenomenon and the risk of overuse of medications that can produce stupor. The patient must be involved by way of determining how troubling the movements are.

Surgical Treatment of Epilepsy

The surgical excision of epileptic foci that have not responded to intensive and prolonged medical therapy is being used with increasing effectiveness. At these centers, it has been estimated that approximately 25 percent of all patients with epilepsy are candidates for surgical therapy and more than half of these may benefit from extirpation of the epileptic cortical focus. With increasing experience and standardized approaches, especially in patients with temporal lobe epilepsy, it has been suggested that many patients are waiting too long before the surgical option is employed. A perspective that may promote surgery even further is the observation that approximately 60 percent of patients with focal seizures will respond to a conventional anticonvulsant, but that among the remainder, few will respond to the addition of a second or third drug.

However, considerable effort, time, and technology are required to determine the site of epileptic discharge and the method of safe removal of the cortical tissue. To locate the discharging focus requires a careful analysis of clinical, imaging, and EEG findings, often including those obtained by long-term video/EEG monitoring and, sometimes, intracranial EEG recording by means of intraparenchymal depth electrodes and subdural strip and grid electrodes. Functional imaging, magnetoencephalography, and EEG power spectrum analysis have been introduced to supplement these methods.

The most favorable candidates for surgery are those with focal seizures that induce altered consciousness and a unilateral temporal lobe focus. In this group, rates of cure and significant improvement approach 90 percent in some series but overall, are probably closer to 50 percent after 5 years. A randomized trial gave representative results after temporal lobectomy of 58 percent of 40 carefully studied patients remaining seizure-free after 1 year, in contrast to 8 percent on medication alone (Wiebe and colleagues). Furthermore, among those patients who remain free of seizures for 1 year after surgery, more than half are still free of seizures after 10 years and most of the remainder had one or fewer episodes per year (Yoon and colleagues). It should be emphasized that most of the patients who underwent surgery in these studies still required anticonvulsant medication. Even in the group of patients with temporal lobe foci who have no lesion on MRI but have subtle signal changes in the hippocampus, 60 percent of patients can be made free of disabling seizures with surgery (Bell and colleagues). Of course, as discussed earlier, advances in MRI, especially the use of higher field strength magnets, have permitted the detection of subtle lesions that may have been missed in earlier studies.

Excision of cortical tissue that contains a structural lesion outside of the temporal lobe accomplishes complete seizure-free states in approximately 50 percent. Taking all seizure types together, only approximately 10 percent of patients obtain no improvement at all and less than 5 percent are worse. The matter of resection of areas of focal cortical dysplasias in children is a highly specialized area. The histologic features of the dysplasia (Blümcke and Spreafico), including their association with other lesions such as tumors and vascular malformations are important determinants of the success of surgery (Fauser and colleagues). A single-center study of 116 children with drug-resistant epilepsy has showed greater freedom from seizures and improved quality of life in those who underwent epilepsy surgery compared to those who received only medical therapy (Dwivedi and colleagues).

Other surgical procedures of value in highly selected cases are sectioning of the corpus callosum, which is for the most part palliative, and hemispherectomy, which may be curative in special circumstances. The most encouraging results with callosotomy have been obtained in the control of intractable partial and secondarily generalized seizures, particularly when atonic drop attacks are the most disabling seizure type. Removal of the entire cortex of one hemisphere, in addition to the amygdala and hippocampus, has been of value in children, as well as in some adults with severe and extensive unilateral cerebral disease and intractable contralateral motor seizures and hemiplegia. Rasmussen encephalitis, Sturge-Weber disease, and large porencephalic cysts at times fall into this category. Surgical, focused radiation, or endovascular reduction of arteriovenous malformations may reduce the frequency of seizures, but the results in this regard are somewhat unpredictable (see Chap. 34).

Vagal Nerve Stimulation

This technique has found some favor in cases of intractable partial and secondarily generalizing seizures. A pacemaker-like device is implanted in the anterior chest wall and stimulating electrodes are connected to the vagus nerve at the left carotid bifurcation. The procedure is well tolerated except for hoarseness in some cases. Several trials have demonstrated an average of 25 percent reduction in seizure frequency among patients who were resistant to all manner of anticonvulsant drugs (Vagus Nerve Stimulation Study Group; and Chadwick). The mechanism by which vagal stimulation produces its effects is unclear,

and its role in the management of seizures continues to be studied. Stimulation of the cerebellum and of other sites in the brain has also been used in the control of seizures, with no clear evidence of success.

Ketogenic Diet

Since the 1920s, interest in this form of seizure control has varied, being revived periodically in centers caring for many children with intractable epilepsy. Despite the absence of controlled studies showing its efficacy or an agreed-on hypothesis for its mechanism, several trials in the first half of the twentieth century, and again more recently, demonstrated a reduction in seizures in half of the patients, including handicapped children with severe and sometimes intractable episodes. The diet is used mainly in children between the ages of 1 and 10 years. The regimen is initiated during hospitalization by starvation for a day or two to induce ketosis, followed by a diet in which 80 to 90 percent of the calories are derived from fat (Vining). The difficulties in making such a diet palatable leads to its abandonment by about one-third of children and their families.

A summary of experience from the numerous trials of the ketogenic diet has been reviewed (Lefevre and Aronson) and its use in a study of 58 children has been reported (Kinsman and colleagues). The diet was found to be effective in refractory cases of epilepsy in childhood, reducing seizure frequency in two-thirds of children and allowing a reduction in the amount of anticonvulsant medication in many. It has also been commented that some benefit persists even after the diet has been stopped. Nephrolithiasis is a complication in somewhat less than 10 percent of children, and this risk is particularly high if topiramate is being used. The ketogenic diet is the main treatment for children with GLUT1 deficiency syndrome.

Cannabinoids

For lack of a better place to comment, we note that cannabinoids are being introduced for the treatment of epilepsy, most prominently to date in cases of Dravet syndrome. A double-blind placebo-controlled trial in children and young adults with Dravet syndrome and drug-resistant seizures showed a reduction in frequency of convulsive seizures as well as an improvement in overall condition as reported by caregivers in those treated with cannabidiol compared to placebo, but also a higher rate of adverse events in the cannabidiol group (Devinsky and colleagues, 2017).

Safety and Regulation of Physical and Mental Activity

Driving and Epilepsy

A person with incompletely controlled epilepsy should not be allowed to drive an automobile. Only a few states in the United States and most provinces of Canada mandate that physicians report patients with seizures under their care to the state motor vehicle bureau. Nonetheless, physicians should counsel such a patient regarding the obvious danger to himself and others if a seizure should occur while driving (the same holds for the risks of swimming, bathing, climbing, or operating machinery unattended). What few data are available suggest that accidents caused directly by a seizure are rare and, in any case, 15 percent have been the result of a first episode of seizure that could not have been anticipated. In some states where a driver's license has been suspended on the occurrence of a seizure, there is usually some provision for its reinstatement—such as a physician's declaration that the patient is under medical care and has been seizure-free for some period of time (usually 6 months or 1 to 2 years). The Epilepsy Foundation website can be consulted for updated information regarding restrictions on driving, and this serves as an excellent general resource for patients and their families (http://www.efa.org).

General Health Measures

The most important factors in seizure breakthrough, next to the abandonment of medication or a natural reduction of serum levels of medication, are loss of sleep and abuse of alcohol or other drugs. The need for moderation in the use of alcohol must be stressed, as well as the need to maintain regular hours of sleep.

With proper safeguards, even potentially more dangerous sports, such as swimming, may be permitted. However, operating unguarded machinery, climbing ladders, or taking baths behind locked doors are not advisable; such a person should swim only in the company of a good swimmer. There is concern about mothers with epilepsy bathing their infants without additional safety guards.

Psychosocial difficulties are common and must be identified and addressed early. The stigma of epilepsy remains an issue in society. Advice and reassurance to attempt to pursue a normal life will aid in preventing or overcoming any feelings of inferiority and self-consciousness of many younger patients with epilepsy. However, the situation is rarely so simple, and patients and their families may benefit from more extensive counseling.

Coma and Related Disorders of Consciousness

In hospital and emergency neurology, the clinical analysis of unresponsive and comatose patients is an urgent practical necessity. The underlying disease and the direction in which it is evolving must be determined rapidly in order to protect the brain against irreversible damage. When called upon, the physician must therefore be prepared to implement prompt action that allows little time for deliberate, leisurely investigation.

Some idea of the dimensions of the problem of coma, and how little it has changed over time, can be obtained from published statistics. Almost ninety years ago, in two large municipal hospitals, it was estimated that 3 percent of all emergency admissions were for diseases that had caused coma. Alcoholism, cerebral trauma, and cerebrovascular diseases were the most common, accounting for 82 percent of the comatose patients admitted to the Boston City Hospital (Solomon and Aring). Epilepsy, drug intoxication, diabetes, and severe infections were the other major causes. It is perhaps surprising to learn that contemporary figures from large city hospitals differ only slightly, with intoxication, stroke, and cranial trauma still standing as the "big three" of coma-producing conditions. For example, in a series described in the 1980s (Plum and Posner) (Table 16-1), a majority was the result of exogenous (drug overdose) and endogenous (metabolic) intoxications and hypoxia, 25 percent of cases proved to have cerebrovascular disease, and intracranial masses—such as tumors, abscesses, and hemorrhages—made up about one-third of cases. Subarachnoid hemorrhage, meningitis, and encephalitis accounted for another 5 percent. Perhaps the proportions of the main causes have changed but in a more contemporary review of 14 studies of coma etiology, excluding trauma, the main causes were stroke (including intracerebral and subarachnoid hemorrhage), postanoxic coma, poisoning (including intoxication), and metabolic encephalopathy (Horsting et al). Common in many series, although obvious and often transient, is coma that follows seizures or resuscitation from cardiac arrest.

The terms *consciousness, confusion, stupor, unconsciousness*, and *coma* have been endowed with so many different meanings that it is almost impossible to avoid ambiguity in their usage. They are not strictly medical terms but are also literary, philosophic, and psychologic ones. The word *consciousness* is the most ambiguous of all. William James remarked that everyone knows what consciousness is until they attempt to define it. To the psychologist, consciousness denotes a state of continuous awareness of one's self and environment, essentially self-consciousness. Knowledge of self includes all "feelings, attitudes and emotions, impulses, volitions, and the active or striving aspects of conduct"; in short, a near continuous self-awareness of a person's mental functioning, particularly of cognitive processes. These can be judged only by the individual's verbal account of his introspections and indirectly, by his actions.

Physicians, aspiring to be practical, give greater credence to the patient's behavior and reactions to stimuli than to what the patient reports. In this way the term *consciousness* is used in its broadest operational meaning—namely, the state of awareness of self and environment, and normal responsiveness to external stimulation and inner need. This narrow definition has an advantage in that *unconsciousness* has the opposite meaning: A state of unawareness of self and environment or a suspension of those mental activities by which people are made aware of themselves and their environment, coupled with an observable diminished responsiveness to environmental stimuli. The last of these qualities, a*rousal*, or *alertness,* or the *level of consciousness*, refers to the appearance of being awake as displayed by the facial muscles, eye opening, fixity of gaze, and body posture, that is, wakefulness.

A distinction is made in medicine between the *level* of consciousness reflected in the degree of alertness, and the *content* of consciousness, reflecting the quality and coherence of thought and behavior. For neurological purposes, the loss of normal arousal is the more important aspect of disordered consciousness and the one identified by laypersons and physicians as being the central feature of coma. For psychiatry, the bizarre and illogical qualities of *psychosis* are a component of the study of psychiatric disease. However, there many situations in which a reduced level of alertness and altered content of consciousness coincide. These are characterized as states of *confusion*, or *delirium* and are among the most ubiquitous syndromes in medicine as discussed in Chap. 19.

Much more could be said about the history of our ideas concerning consciousness, and the theoretical problems with its definition. There has been a polemic among philosophers of mind as to whether it will ever be possible to understand mind and consciousness in terms of reductionist physical entities, such as neural networks that can be extracted from functional imaging data, and cellular

Table 16-1

FINAL DIAGNOSIS IN 500 PATIENTS ADMITTED TO HOSPITAL WITH "COMA OF UNKNOWN ETIOLOGY"

Metabolic and other diffuse disorders	326 (65%)
Drug poisoning	149
Anoxia or ischemia	87
Hepatic encephalopathy	17
Encephalomyelitis and encephalitis	14
Subarachnoid hemorrhage	13
Endocrine disorders (including diabetes)	12
Acid–base disorders	12
Temperature regulation	9
Uremic encephalopathy	8
Pulmonary disease	3
Nutritional disorders	1
Nonspecific metabolic coma	1
Supratentorial mass lesions	101 (20%)
Intracerebral hematoma	44
Subdural hematoma	26
Cerebral infarct	9
Brain tumor	7
Brain abscess	6
Epidural hematoma	4
Thalamic infarct	2
Pituitary apoplexy	2
Closed head injury	1
Subtentorial lesions	65 (13%)
Brainstem infarct	40
Pontine hemorrhage	11
Cerebellar hemorrhage	5
Cerebellar tumor	3
Cerebellar infarct	2
Brainstem demyelination	1
Cerebellar abscess	1
Posterior fossa subdural hemorrhage	1
Basilar migraine	1
Psychiatric disorders	8 (2%)

Note: Listed here are only those patients in whom the initial diagnosis was uncertain, and a final diagnosis was established. Thus, obvious poisonings and closed head injuries are underrepresented.
Source: Adapted from Plum and Posner.

and molecular systems. Although it serves little practical purpose to review these subjects here, one constructive approach is to define the neurobiologic correlates of those elements of clinical consciousness that are subject to observation by behavioral, electrical, and particularly imaging methods. These controversies are informed in neurology by analyses of those neurologic disorders that disturb perception and consciousness of perception (e.g., phantom limb and "blindsight").

STATES OF NORMAL AND IMPAIRED CONSCIOUSNESS

The states of drowsiness, stupor, and coma as described below, exist in a continuum and with gradations and fluctuations between these summary descriptions. The following characteristics provide a convenient terminology for describing the states of awareness and responsiveness of patients.

Normal Alertness

This is the condition of a normal person when awake. The individual is fully responsive to a thought or perception and indicates by behavior and speech the same awareness of self and environment as that of the examiner. There is attention to, and interaction with, the immediate surroundings. This normal state may fluctuate during the day from one of keen alertness or deep concentration with a marked constriction of the field of attention to one of mild general inattentiveness, but even in the latter circumstance, the normal individual can be brought immediately to a state of full alertness and mental function.

Confusion

The term *confusion* admittedly lacks precision, but in operational terms, it denotes an inability to think with customary speed, clarity, and coherence. Almost all states of confusion are marked by some degree of inattentiveness and disorientation and for some investigators, these last two qualities have come to define confusion or are considered obligate findings. In this condition, the patient does not consider all elements of the immediate environment. This state also implies a degree of imperceptiveness and distractibility, referred to in the past as "clouding of the sensorium." Sidestepping for the moment the difficulty in defining *thinking*, a term that refers variably to problem-solving or to the coherence of ideas, confusional states incorporate a disorder of thinking. Confusion results most often from a process that influences the brain globally, such as a toxic or metabolic disturbance or a dementia. In addition, any condition that causes drowsiness or stupor, including the natural state that comes from sleep deprivation, results in some degradation of mental performance and the emergence of inattentiveness, which qualifies as a state of confusion. In this way, confusion, as mentioned, exists along the axis of *content* of consciousness but is most closely linked to alertness and the *level* of consciousness.

Special forms of confusional state can also accompany focal cerebral disease, particularly in the right hemisphere, or result from focal disorders that disturb language, memory, or visuospatial orientation, but a distinction is made between these limited disruptions in mental function and the more common global confusional state. The focal disorders of mental function represent special states that are analyzed differently, matters discussed further in Chaps. 19 and 21.

The mildest degree of confusion may be so slight that it can be overlooked unless the examiner searches for deviations from the patient's normal behavior and ability to carry on a coherent conversation. The patient may even be roughly oriented as to time and place, with only occasional irrelevant remarks betraying a lack of clarity and slowness of thinking. Their responses are inconsistent, attention span is reduced, and they are unable to stay on one topic, together suggesting a fundamental flaw in attention. This is usually accompanied by disorientation and distractibility, leaving the patient at the mercy of every stimulus.

In parallel, sequences of movement reveal poor planning and impersistence.

Severely confused and inattentive persons are unable to do more than carry out the simplest commands, and these only inconsistently and in brief sequence. Speech may be limited to a few words or phrases; or the opposite pertains—namely, some confused individuals are voluble. They give the appearance of being unaware of much that goes on around them, are disoriented in time and place, do not grasp their immediate situation or the predicament of their own confusion, and may misidentify people or objects. These illusions may lead to fear or agitation. Occasionally, hallucinatory, illusionary, or delusional experiences impart a psychotic cast to the clinical picture, obscuring the deficit in attention.

Most events that involve the confused patient leave no trace in memory; in fact, the capacity to recall events of the past hours or days is one of the most delicate tests of mental clarity. Another is the use of *working memory*, which requires the temporary storage of the solution of one task for use in the next. A deficit in working memory can be demonstrated by tests of serial subtraction or the spelling of words or repeating a phone number forward and then backward. All of these defects are tied to impaired registration of information rather than to a fault in memory and again betray inattention as a central feature of most confusional states.

The observed behavior of a confused person transcends inattention. It may incorporate clouded interpretation of internal and external experience, and an inability to integrate and attach symbolic meaning to experience (apperception). The degree of confusion often varies from hour to hour. It tends to be least pronounced in the morning and increases as the day wears on, peaking in the early evening hours ("sundowning") when the patient is fatigued, and environmental cues are not as clear.

In current medical writings, the terms *delirium* and *confusion* are used interchangeably. However, in the syndrome of delirium tremens, observed mostly in withdrawal from alcohol, the vivid hallucinations; extreme agitation; trembling, startling easily, and signs of overactivity of the autonomic nervous system have suggested to us that the term *delirium* should be retained for this type of distinctive confusional syndrome as elaborated in Chap. 19. An agitated, hypersympathetic, hallucinatory state occurs in other circumstances besides alcohol withdrawal. As a result, trials in the ICU have had to create the terms "quiet delirium" and "agitated delirium", which simply are throwbacks to the original terms. However, the widespread adoption of the term delirium as representative of all nondescript confusional states makes it difficult to persevere in the polemic of separating a calm confusional state from the agitated form.

Drowsiness and Stupor

Drowsiness denotes an inability to sustain a wakeful state without the application of external stimuli. Mental, speech, and physical activity are reduced. The state is indistinguishable from light sleep, sometimes including slow arousal elicited by speaking to the patient or applying a tactile stimulus. Furthermore, in distinction to stupor discussed later, drowsy individuals sustain alertness for at least some brief period, without the further necessity of external stimuli. As a rule, some degree of inattentiveness and mild confusion are coupled with drowsiness, both improving with arousal. The patient shifts positions somewhat naturally and without prompting. The lids droop; there may be snoring, the jaw and limb muscles are slack, and the limbs are relaxed.

Stupor describes a state deeper than drowsiness, in which the patient can be roused only by vigorous and repeated stimuli and usually repeated stimulation to sustain arousal. Responses to spoken commands are either absent, curtailed, or slow and inadequate. Restless or stereotyped motor activity is common, and there is a reduction or elimination of the natural shifting of body positions. When left unstimulated, these patients quickly drift back into a deep sleep-like state. The eyes are usually found to be displaced slightly outward and upward, a feature that is shared with sleep. The breathing pattern may or may not be altered, depending on how the underlying disease has affected the nervous system. In psychiatry, the term *stupor* had been used in a second sense—to denote an uncommon condition in which the perception of sensory stimuli is presumably normal but activity is suspended and motor activity is profoundly diminished (catatonia, or catatonic stupor). A practical method of making distinctions between drowsiness and stupor was given by Fisher, who suggested that a verbal command is required to overcome drowsiness whereas a noxious stimulus is required to overcome stupor.

Coma

The patient who is incapable of being aroused by external stimuli or inner need, is comatose. There are variations in the degree of coma, and the findings and signs depend in part on the underlying cause of the disorder. In its deepest stages, no meaningful or purposeful reaction of any kind is obtainable and corneal, pupillary, and pharyngeal responses are diminished. In lighter stages, sometimes referred to by the ambiguous terms *semicoma* or *obtundation*, most of the above reflexes can be elicited, and the plantar reflexes may be either flexor or extensor (Babinski sign). The depth of coma and stupor may be gauged by the response to externally applied stimuli and is most useful in assessing the direction in which the disease is evolving, particularly when compared in serial examinations.

Relationship of Sleep to Coma

Persons in sleep give little evidence of being aware of themselves or their environment; in this respect, they are unconscious. Sleep shares a number of other several features with the pathologic states of drowsiness, stupor, and coma. These include yawning, closure of the eyelids, cessation of blinking and reduction in swallowing, upward deviation or divergence or roving movements of the eyes, loss of muscular tone, decrease or loss of tendon reflexes, and even the presence of Babinski signs and irregular respirations, sometimes Cheyne-Stokes in type. Upon being awakened from deep sleep, a normal person may be confused for a few moments, as every physician knows from personal experience. Nevertheless, sleeping persons may still respond to unaccustomed stimuli and are capable of some mental activity in the form of dreams that leave

traces of memory, thus differing from stupor or coma. The most important difference, of course, is that persons in sleep, when stimulated, can be roused to normal and persistent consciousness. There are important physiologic differences as well. Cerebral oxygen uptake does not decrease during sleep, as it usually does in coma. Recordable electrical activity—electroencephalographic (EEG) and cerebral evoked responses—and spontaneous motor activity differ in the two states, as indicated later in this chapter and in Chap. 18. The anatomic and physiologic bases for these differences are only partly known.

VEGETATIVE AND MINIMALLY CONSCIOUS STATES, LOCKED-IN SYNDROME, AND AKINETIC MUTISM

Several conditions are juxtaposed to the continuum of drowsiness, stupor, and coma. They stand apart as a result of special characteristics or by their underlying cause but, with the exception of the locked-in state, they are each form of diminished consciousness.

Vegetative State (Unresponsive Wakefulness)

With increasing refinements in the treatment of severe systemic diseases and cerebral injury, larger numbers of patients, who formerly would have died, have survived for indefinite periods without regaining meaningful mental function, regrettably termed the "*vegetative state*," and recently renamed unresponsive wakefulness. For the first week or two after severe cerebral injury, these patients are in a state of deep coma. Then they begin to open their eyes, at first in response to painful stimuli, and later spontaneously and for increasingly prolonged periods. The patient may blink in response to threat or to light and intermittently, the eyes move from side to side, seemingly following objects or fixating momentarily on the physician or a family member and giving the erroneous impression of recognition. Respiration may quicken in response to stimulation, and certain automatisms—such as swallowing, bruxism, grimacing, grunting, and moaning—may be observed (Zeman). However, the patient remains unresponsive and for the most part, unconscious, does not speak, and shows no signs of awareness of the environment or inner need; motor activity is limited to primitive postural and reflex movements of the limbs. There is loss of sphincter control. There may be arousal or wakefulness in alternating cycles as reflected in partial eye opening, but the patient regains neither awareness nor purposeful behavior as gauged by an examiner at the bedside. It is, in effect, an awake unconscious state. One sign of the vegetative state is a lack of consistent visual following of objects; because brief observation of ocular movements is subject to misinterpretation, repeated examinations are required.

Perspectives on the completeness of unresponsivity that is established by bedside examination in the vegetative state have been altered by the findings of what would be considered by most investigators as conscious activity that can be detected by functional imaging in response to certain commands and verbal cues such as the individual's name as detailed below.

If the vegetative syndrome of unconscious awakening persists for 3 months after nontraumatic brain injury or 12 months after traumatic injury, the syndrome has been termed the *persistent vegetative state* (PVS; Jennett and Plum). These terms had gained acceptance and apply to the clinical appearance whatever the underlying cause. Additional terms, besides unresponsive wakefulness, that have been used to describe this syndrome of preserved autonomic and respiratory function without cognition include *apallic syndrome* (also called awake unawareness) and *neocortical death*. A position paper has codified the features of the PVS and suggests dropping a number of related ambiguous terms, although some, such as *akinetic mutism*, discussed further on, have a more specific neurologic meaning and are still useful (Multi-Society Task Force on PVS).

The most common pathologic bases of the vegetative state are diffuse cerebral injury as a result of closed head trauma, widespread neuronal loss in the cortex after cardiac arrest or other form of hypoxemia, and thalamic necrosis from a number of causes. The vegetative state or the minimally conscious state described further on, may also be the terminal phase of progressive cortical degenerative processes such as Alzheimer and Creutzfeldt-Jakob disease, where the pathologic changes are mainly cortical but may include the thalamus.

It is worth noting that the prominent pathologic changes in the vegetative state can be in the thalamic and subthalamic nuclei, as in the widely known Quinlan case (Kinney et al) rather than solely in the cortex as often stated; this holds for postanoxic as well as traumatic cases. A review of the pathology of the vegetative state found these thalamic changes but attributed them to secondary degeneration from white matter and cortical lesions (J.H. Adams and colleagues). In several of our cases, the thalamic damage stood almost alone as the cause of persistent "awake coma." In traumatic cases, the pathologic findings are often of diffuse subcortical white matter degeneration (described as *diffuse axonal injury*), thalamic degeneration, and ischemic damage in the cortex. Further insight is found in a study of brain morphometry by MRI, which determined that in patients with early vegetative or minimally conscious states, there was global brain atrophy but the thalamic and basal ganglionic structures were disproportionately affected (Lutkenhoff and colleagues).

Taken together, these anatomic findings indicate that in the PVS, the cortex is either diffusely injured or effectively disconnected and isolated from the thalamus, or the thalamic nuclei required for the maintenance of alertness are destroyed (see further on under Anatomy and Physiology of Alertness and Coma). In either the traumatic or anoxic types of PVS, atrophy of the cerebral white matter leads to secondary ventricular enlargement and thinning of the corpus callosum.

These observations notwithstanding, there is little doubt that the nature of the vegetative state is complex and may be separable into categories defined by the locus of brain damage. For example, an observation in a 23-year-old woman who had been vegetative for 5 months after a

head injury, there was cortical activity in the middle and superior temporal gyri in response to the presentation of spoken sentences that was similar to the brain activity elicited by the same stimuli in normal individuals (Owen and colleagues). Several similar demonstrations of vegetative patients have shown that there can be brain activation to the patient's own name and not to other names (Di et al). Further compelling demonstrations of cognitive processing in vegetative and minimally conscious patients have been reported by functional MRI. Five of 54 patients, all with traumatic brain injury, but none after anoxic ischemic damage, could willfully modulate focal brain activity by imagining playing tennis (frontal lobe activation) or mentally navigating a familiar place such as their home (temporal lobe activation) (Monti and colleagues). In one patient, this activity was used as a means of communication. Using highly processed EEG, patients with acute coma who were unresponsive but not in a vegetative state, 16 of 104 had patterns of activation in response to commands or stimuli and a larger proportion of those recovered than those without this activation (Claassen et al) These data suggest that some forms of mental processing can go on during a vegetative state (more persuasively during the minimally conscious state), but it is not clear if this situation is representative of the state and does it provide information about self-awareness, a requisite for consciousness.

At a minimum, these demonstrations emphasize the care that must be taken in establishing diagnoses of PVS and minimally conscious states and in assuming the patient is truly unresponsive. Whether these findings with functional imaging simply reflect preserved islands of function in severe brain injury that cannot be examined clinically or whether they require an entire rethinking of the neurologic examination that determines the state of consciousness cannot yet be stated (Ropper, 2010).

An additional observation of some consequence is the finding of axonal growth over time in a patient with traumatic brain injury who had been in a minimally conscious state (further on) for 19 years and then began to speak and comprehend, while remaining virtually quadriplegic. Voss and colleagues, using MRI diffusion tensor imaging, have shown axonal sprouting in the posterior parietal and midline cerebellar regions. They compared the results of tensor imaging to a patient who had been in a minimally conscious state for 6 years without improvement and to 20 normal individuals. Their findings are subject to several interpretations, but axonal growth in the parietal lobes offers a potential explanation for the few instances in which recovery from severe injury does occur. When combining these with findings of other groups, a case can be made for the posterior parietal regions as necessary for integrated consciousness and also raise the possibility that certain islands of limited awareness may be dissociated from global brain function (Laureys and colleagues, 1999).

It is difficult to predict which comatose patients will later fall permanently into the vegetative or minimally conscious categories. Of 45 patients with signs of the vegetative state at 1 week after onset, 13 had awakened and 5 of these had satisfactory outcomes. After being vegetative for close to 2 weeks, only 1 recovered to a level of moderate disability; after 2 weeks, the prognosis was uniformly poor (Plum and Posner, 1980). Larger studies have given similar results (Higashi and colleagues, 1977). As a rough guide to prognosis specifically in head injury, Braakman and colleagues found that among a large group of comatose patients, 59 percent regained consciousness within 6 h, but of those in a vegetative state at 3 months, none became independent. At no time before 3 or 6 months was it possible to distinguish patients who would remain in a vegetative state from those who would die. Further comments regarding recovery are made in the next section on the minimally conscious state.

A study by the Multi-Society Task Force on PVS concluded that the outcome from a vegetative state is better in traumatic as compared to nontraumatic cases. J.H. Adams and coworkers have proposed that this reflects differences in the state of thalamic neurons in the two situations. They suggested that after acute hypoxia, neurons subjected to ischemic necrosis are liable to be permanently lost; by contrast, in trauma, the loss of thalamic neurons is more frequently secondary to transsynaptic degeneration following diffuse axonal injury, allowing a greater potential for recovery. Many of these ideas are speculative.

Laboratory features The vegetative state is associated with a grossly abnormal EEG and is characterized by one of a number of abnormal patterns. There may be predominantly low-amplitude delta-frequency background activity, burst suppression, widespread alpha and theta activity, an alpha coma pattern, and sleep spindles, all of which have been described in this syndrome, as summarized by Hansotia (see Chap. 2). One important feature is a lack of the normal change in the background EEG activity during and immediately after stimulating the patient.

In all these clinical states, the profound and widespread dysfunction of the cerebrum is also reflected by extreme reductions in cerebral blood flow (CBF) and metabolism, measured with positron emission tomography (PET) and other techniques. On the basis of PET studies in a patient with carbon monoxide poisoning, Laureys and colleagues observed that the main difference between the vegetative state and the later state in which the patient has recovered was the degree of hypometabolism in the parietal lobe association area. Anatomic changes in this same cortical region have been implicated in the transition from minimally conscious to a more awake state. The finding in PET studies that noxious somatosensory stimulation fails to activate the association cortices is consistent with the concept that large regions of cortex are isolated from thalamic input or that the critical parietal interpretive areas are isolated from the rest of the cortex.

Of practical value is the observation that the CT and MRI may show progressive and profound cerebral atrophy in cases of vegetative state. In the absence of this atrophy after several months or more, it may be unwise to offer a pessimistic prognosis.

Minimally Conscious State

The vegetative state blends into a less severe but still profound disorder of consciousness that has been termed

"minimally conscious state," wherein the patient is capable of some rudimentary behavior such as following a simple command, gesturing, or producing single words or brief phrases, always in an inconsistent way from one examination to another (Giacino et al). There is preservation of the ability to carry out basic motor behaviors that demonstrate a degree of awareness. The minimally conscious state is found as a transitional or permanent condition and is sometimes difficult to separate from akinetic mutism discussed further on. Any notion of such a patient's self-awareness is conjectural, but there may be an impressive array of behaviors and activation of associative regions of the cerebral cortex that suggest that processing of external information is taking place beyond a rudimentary level (see discussion by Bernat). The causes and pathologic changes underlying the minimally conscious state are identical to those of the vegetative state, including the frequent finding of thalamic and multiple cerebral lesions. Viewed from on perspective, the distinction between them is one of degree.

It is useful to maintain a critical view of reports of remarkable recovery after months or years of prolonged coma or the vegetative state. When the details of such cases become known, it is sometimes evident that recovery might reasonably have been expected. There are, however, instances of partial recovery in patients—particularly children and young adults—who display vegetative features for several weeks or, even several months after injury (Andrews and Childs and Mercer). Such observations cast doubt on unqualified claims of success with certain therapies, such as specialized sensory stimulation. Nevertheless, the rare occurrence of late recovery in adults must be acknowledged (see Andrews; Higashi et al; and Rosenberg et al, 1977) and a relation of awakening to the recovery of connections to the parietal lobes has already been mentioned.

Cases of improvement from the "minimally conscious state" are more plausible than those from the vegetative state. Contrasting the notion that late recovery is exceptional, a case series (Estraneo and colleagues) of 50 consecutive patients in PVS for a year, 10 showed improvement at an average of 2 years but all were severely impaired. In anohter series (Luaté and coworkers), none of 12 vegetative patients improved at 5 years but 13 of 39 minimally conscious cases emerged to consciousness with severe disability. Of course, the application of these terms to a patient often leads to the withdrawal of care, and a self-fulfilling poor prognosis. This is a much-discussed problem that has not been satisfactorily addressed but it emphasizes that simply labeling patients with PVS or MCS has implications for accurately assessing the natural history of some diseases.

A provocative therapeutic observation has been improved function by stimulating the medial (intralaminar) thalamic nuclei through implanted electrodes in a patient who had been initially vegetative and had made a natural transition to a minimally conscious state after traumatic brain injury (Schiff and colleagues). Longer periods of eye opening and increased responses to execute commands, such as bringing a cup to his mouth, were observed, including, for the first time since his injury, intelligible verbalization. The authors point out that this individual had preserved language cortex and connections between thalamus and cortex. Whether this remarkable result is generalizable is not known.

It must be remarked that the degree of disability that families find acceptable varies greatly and leads to difficult decisions regarding the continuation of medical care. The knowledgeable, sympathetic, and flexible physician is in the best position to offer perspective and guide these matters over the long periods of time required, as discussed at the end of this chapter.

Locked-in Syndrome

The states of coma described above, and the vegetative state must be distinguished from a syndrome in which there is little or no disturbance of consciousness, but only an inability of the patient to respond adequately with motor activity and speech. This condition is referred to as the *locked-in syndrome* or the *deefferented state*. The term *pseudocoma* as a synonym for this state is best avoided because it is used by some physicians to connote the unconsciousness of the hysteric or malingerer, the dissociative state, or catatonia. The locked-in syndrome is most often caused by a large lesion of the ventral pons (basis pontis), usually as a result of occlusion of the basilar artery. Such infarctions spare both the somatosensory pathways, and the ascending neuronal systems responsible for arousal and wakefulness, as well as certain midbrain elements that allow the eyelids to be raised in wakefulness. The damage essentially completely interrupts the descending corticobulbar and corticospinal tracts, depriving the patient of speech and the capacity to respond in any way except by voluntary vertical gaze and by blinking. Severe motor neuropathy (e.g., Guillain-Barré syndrome), pontine myelinolysis, or periodic paralysis may produce a similar effect.

Akinetic Mutism

One could logically refer to the locked-in state as *akinetic mutism* insofar as the patient is akinetic (motionless) and mute, but this is not the sense in which the term was originally used by Cairns and colleagues, who described a patient who gave the appearance of being awake but was unresponsive (actually, their patient was able to answer in whispered monosyllables). Following each of several drainings of a third ventricular cyst, the patient again became responsive but had no memory of events that had taken place when she was in the akinetic mute state. This state of apparent vigilance in an imperceptive and unresponsive patient has been referred to by French authors as *coma vigile*, but this is also confusing because the same term has been applied to the vegetative state.

The term *akinetic mutism* has been applied to yet another group of patients who are silent and inert as a result of bilateral lesions of the anterior parts of the frontal lobes or in the thalamus, leaving intact the motor and sensory pathways. The patient is profoundly apathetic, lacking to an extreme degree the psychic drive or impulse to action. There is a marked delay in verbal and motor responses (abulia), however, the abulic patient, unlike Cairns' patient, registers most of what is happening about him and if intensely stimulated, may speak normally, relating events observed in the recent and distant past.

Catatonia

The is a state in which the individual appears unresponsive, in a way that simulates stupor, light coma, or akinetic mutism. It is most often associated with psychosis. There are no signs of structural brain disease, such as pupillary or reflex abnormalities. As in the normal awake state, oculocephalic responses are muted—that is, the eyes move concurrently with the head as it is turned. There is usually resistance to eye opening, and some patients display a waxy flexibility of passive limb movement that gives the examiner a feeling of bending a wax rod (*flexibilitas cerea*); there may also the retention for a long period of seemingly uncomfortable limb postures (*catalepsy*). Peculiar motor mannerisms or repetitive motions, seen in a number of these patients, may give the impression of seizures; choreiform jerking has also been reported, but the latter sign should also suggest the possibility of seizure activity. The EEG shows normal posterior alpha activity that is attenuated by stimulation. Catatonia is discussed further in Chaps. 19 and 49.

Because there is considerable imprecision in the use of terms by which the states of reduced consciousness are designated, the physician is better advised to supplement designations such as *coma* and *akinetic mutism* by simple descriptions indicating whether the patient appears awake or asleep, drowsy or alert, aware or unaware of his surroundings, and responsive or unresponsive to a variety of stimuli. This requires that the patient be observed more for a longer period and more frequently than the several minutes usually devoted to this portion of the neurologic examination.

BRAIN DEATH

In the 1950s, European neurologists called attention to a state of coma in which the brain was irreversibly damaged and had ceased to function, but pulmonary and cardiac function could still be maintained by artificial means. Mollaret and Goulon referred to this condition as *coma dépassé* (a state beyond coma). A Harvard Medical School committee in 1968 called it *brain death* and established a set of clinical criteria by which it could be recognized (see Beecher et al; the report is often said to be from the "Beecher Committee"). R.D. Adams, who was a member of the committee, defined the state as one of complete unresponsiveness to all modes of stimulation, arrest of respiration, and absence of all EEG activity for 24 h. The concept that a person is dead if the brain is dead and that death of the brain may precede the cessation of cardiac function has over the years posed a number of important ethical, legal, and social problems, as well as medical ones. All aspects of brain death have since been the subject of close study by several professional and governmental committees, which for the most part have followed the 1968 guidelines for determining that the brain is dead and equating this state with the traditional version of death as the inevitable dissolution of the body after cardiac and respiratory function have permanently ceased. The American Academy of Neurology published guidelines on this subject in 1995 and affirmed them with some refinements in 2010. The monograph by Wijdicks is a comprehensive modern source on the subject of brain death and also addresses the subject from an international perspective.

The philosophical underpinnings of the equating of brain death to death, giving it the same status as cessation of cardiorespiratory death, are more complex. In particular, the ethical and moral dimensions of brain death are subject to differing interpretations in various societies, religions, and cultures. Some of these are reviewed in a perspective article by prominent writers (Magnus, Wilford, and Caplan), who suggest that the wide medical and societal acceptance of brain death makes it an important construct, not to be abandoned because of philosophical objections. One justification for equating brain death with somatic death is the general inevitability of cardiorespiratory failure in patients who fulfill the standard criteria. This tenet has exceptions, among the most striking of which is a well-studied case of 20-year survival in a boy who had meningitis (Reptinger and colleagues), and other cases of long that have been described with varying degrees of documentation. These have been collected (Shewmon) making the point that arguments equating brain death with death on the basis of the brain's role in creating "somatic unity" are weakened by the existence of such long surviving cases as well as by delivery of live babies from brain-dead mothers. Further clouding the issue of validity of brain death is the proposal by British and Scandinavian neurologists that death of the brain stem alone is adequate to fulfill the precepts of brain death. In the end, these philosophical concerns truly matter but the operational state called brain death at the moment serves both patients and society well and is compatible with most of the world's religions.

The central considerations in the clinical diagnosis of brain death are (1) absence of all cerebral functions; (2) absence of all brain stem functions, including spontaneous respiration; and (3) irreversibility of the state. Following from the last of these criteria, it is necessary to demonstrate an irrefutable cause of the underlying catastrophic brain damage (e.g., trauma, cardiac arrest, cerebral hemorrhage) and to exclude reversible causes such as drug overdose and extreme hypothermia.

In the diagnosis of brain death, the absence of cerebral function is demonstrated by the presence of deep coma and total lack of spontaneous movement and of motor and vocal responses to all visual, auditory, and cutaneous stimulation. Spinal reflexes (deep tendons reflexes) may persist, and the toes often flex slowly in response to plantar stimulation; but a well-developed Babinski sign is unusual (although its presence does not exclude brain death). Extensor or flexor posturing is seen from time to time as a transitional phenomenon just before or after brain death becomes evident, and the status of these movements in the diagnosis is ambiguous, but most criteria consider these movements to be incompatible with brain death, as they reflect functioning of brain stem centers. The physician should therefore proceed cautiously in declaring a patient dead in the presence of posturing and should consider conducting the examination again at a later time.

The complete absence of brain stem function is judged by the loss of spontaneous eye movements, the resting

position of both globes at the meridian of the palpebral fissures, and lack of response to oculocephalic and caloric (vestibulo-ocular) testing; the presence of dilated or midposition fixed pupils (not smaller than 3 mm); paralysis of bulbar musculature (no facial movement or gag, cough, corneal, or sucking reflexes); absence of motor and autonomic responses to noxious stimuli; and absence of respiratory movements. The clinical findings should show complete absence of brain function, not an approximation that might be reflected, for example, by small or poorly reactive pupils, slight eye deviation with oculovestibular stimulation, or posturing of the limbs, as mentioned earlier.

As a demonstration of destruction of the medulla, it has become customary to perform an a*pnea test* to demonstrate unresponsiveness of the medullary centers to a high carbon dioxide tension. This test is conducted by first employing preoxygenation of the lungs for several minutes with high-inspired oxygen tension, the purpose of which is to displace nitrogen from the alveoli and create a reservoir of oxygen that will diffuse into the pulmonary circulation. The patient can then be disconnected from the respirator for several minutes, during which time 100 percent oxygen is being delivered by cannula or ventilator that has its pumping mechanism turned off; this allows the arterial PCO_2 to rise to above 50 or 60 mm Hg (typically, CO_2 rises approximately 2.5 mm Hg/min at normal body temperature—slower if the patient is hypothermic). The induced hypercarbia serves both as a stimulus to breathing and confirms that spontaneous ventilation mediated by medullary centers has failed. (Of course, peripheral causes of ventilatory failure such as paralytic drugs and Guillain-Barre syndrome should not be present.) If no breathing is observed and blood gases show that an adequate level of PCO_2 has been attained, this component of brain death is corroborated. Several sets of formal criteria have incorporated a CO_2 concentration of 60 mm Hg (7.98 kPa [kilopascals]) as adequate to stimulate the medulla, even under circumstances in which it has been badly damaged. In our experience, patients who have severely brain stem damage but nonetheless breathe and therefore are not brain dead, have shown this activity at a PCO_2 well below 50 mm Hg, but there are exceptions in which higher levels are required as a stimulus.

The risks of apnea testing are minimal, as discussed in the American Academy of Neurology's 2010 document, but hypotension, hypoxemia, cardiac arrhythmias, and lung barotrauma may occasionally occur. In patients who cannot tolerate the test for more than a brief period because it produces hypotension, raising the arterial CO_2 by insufflation of this gas has been suggested, but this approach has not been studied extensively. Delivering oxygen during the test with a low tidal volume and a ventilator rate of 1 to 2 breaths per minute or by continuous positive airway pressure may ameliorate hypoxia and resultant hypotension, but this technique has also not been adequately studied.

Many, but not all, brain-dead patients have diabetes insipidus. The absence of this syndrome in some cases reflects the imprecision of the clinical examination in detecting a total loss of brain function. Other ancillary bedside tests may be conducted to corroborate brain death. Among the ones used in special circumstances is the absence of tachycardia in response to the injection of atropine; this reflects the loss of cardiac innervation by damaged medullary vagal neurons.

The authors have observed dramatic spontaneous movements when severe hypoxia is attained following terminal disconnection from the ventilator. These include opisthotonos with chest expansion that simulates a breath, elevation of the arms and crossing them in front of the chest or neck (given the name *Lazarus sign* by Ropper in 1984), head-turning, shoulder shrugging, and variants of posturing-like movements. For this reason, it may be advisable for the family not to be in attendance immediately after mechanical ventilation has been discontinued.

The EEG provides confirmation of cerebral death, and some institutions prefer to include corroboration by the demonstration of electrocerebral silence ("flat" or, more accurately, isoelectric EEG, shown first by Schwab). However, most U.S. institutions do not require an EEG for the confirmation of death. Electrocerebral silence is considered to be present if there is no electrical potential of more than 2 mV during a 30-min recording except for artifacts created by the ventilator, electrocardiograph, and surrounding electrical devices; as importantly, the absence of these artifacts suggests a technical problem with the recording.

There are cases on record in which a patient with an isoelectric EEG has had preserved brain stem reflexes so that cerebral unresponsiveness and a flat EEG do not alone, in most criteria and guidelines, signify brain death; isoelectric EEG may also be reversible in states of profound hypothermia or intoxication with sedative-hypnotic drugs and immediately following cardiac arrest. Therefore, it has been recommended that the diagnosis of brain death not be entertained until several hours have passed from the time of initial observation. If the examination is performed at least approximately 6 h after the precipitating event, and there is *prima facie* evidence of overwhelming brain injury from trauma, or massive cerebral hemorrhage (the most common conditions causing brain death), there is probably no need for serial testing. If cardiac arrest was the antecedent event, or the cause of neurologic damage is unclear, or drug or alcohol intoxication could reasonably have played a role in suppressing the brain stem reflexes, it is advisable to wait for about 24 h before repeating the testing and pronouncing the patient dead. Toxicologic screening of the serum or urine is requisite in these circumstances.

The impact of any requirement to perform a second brain death examination at some interval such as 6 h has been studied (Lustbader and coworkers). This extensive survey in New York State, where a second examination had been recommended by a panel, was instructive; of 1,311 adult and pediatric cases, none who were found to be brain dead regained brain stem function on a second test that was performed about 18 h later. However, 12 percent had cardiac arrest and in others, consent for organ donation was withheld during the time between examinations. Several authoritative authors have argued on this basis against the need for a second brain death test.

Because evoked potentials show variable abnormalities in brain-dead patients, they are probably not of primary value in the diagnosis but if performed, all cerebral activity should be absent. Some centers use nuclide brain scanning or cerebral angiography to demonstrate an absence of blood flow to the brain, equating this with brain death. This approach is acceptable and may be necessary if facial trauma, burns, or other injury prevent evaluation of pupillary and ocular reflexes but there are technical pitfalls in the use of these methods. The specificity of radionuclide scanning is close to 100 percent but there is a self-referential aspect to this statement as the clinical diagnosis has been used as a gold standard. An additional problem arises in the observation that the sensitivity may be only about 75 percent (Joffe et al). False-negative tests are possible if a small amount of filling of the intracranial vertebral arteries with angiography or nuclide uptake in the inferior cerebellum is demonstrated. The same can be said for a degree of imprecision in transcranial Doppler sonography, which in brain death shows a to-and-fro, *pendelfluss* blood-flow pattern in the basal vessels.

The main difficulties that arise in relation to brain death are perhaps not the technical ones discussed above, but those involving the sensitive conversations with the family of the patient and, to some extent, with other medical professionals. These tasks often fall to the neurologist. It is best not to embark on clinical or EEG testing for brain death unless there is a clear intention on the part of the physician to remove the ventilator or follow through with organ donation at the end of the process. The nature of testing for brain death and its potential outcome should be explained to the family in plain language. The family's desires regarding organ transplantation should be sought after adequate time has passed for them to absorb the shock of the circumstances. Neurologists must, of course, resist pressures from diverse sources that might lead them to the premature designation of a declaration of brain death. To avoid the appearance of conflict of motivations, most centers have a separate team, often from an organ bank, to address the issues of organ transplantation after brain death has been established. The complex matter of a family's desire to maintain ventilation and other medical support in a brain-dead relative is best addressed with consideration and counseling by the physician and clergy, ethics ("optimal care") committees, and hospital staff, so as to avoid confrontation. Time often allows such situations to be defused.

At the same time, it should be clarified that brain death is an operational state that allows transplantation to proceed or typically mandates withdrawal of ventilation and blood pressure support. Patients with overwhelming brain injuries need not fulfill these absolute criteria in order for medical support to be withdrawn. If the case for recovery is futile and the family and physician agree, of if the patient's wishes are unequivocally known from preceding documents or discussions, support can be withdrawn in most jurisdictions and the obligate quest for brain death becomes a trap.

A task force for the determination of *brain death in children* (updated by Nakagawa et al) has recommended the adoption of essentially the same criteria as for adults. However, the difficulty in evaluating the status of nervous function in relation to perinatal insults, has led this group to suggest that the determination not be made before the seventh postnatal day and that the period of observation should be extended to 48 h. As with adults, the possibility of reversible brain dysfunction from toxins, drugs, hypothermia, and hypotension must always be considered.

RECURRING STUPOR AND COMA

Aside from repeated drug overdose, recurring episodes of stupor are usually a result of the recurrence of an underlying endogenous biochemical derangement such as the hyperammonemia of hepatic failure. A similar periodic hyperammonemic coma in children and adults can come about from urea cycle enzyme defects, such as ornithine transcarbamylase deficiency. These are discussed in Chap. 36.

Under the title of *idiopathic recurring stupor*, a rare condition has been described in adult men who displayed a prolonged state of deep sleepiness lasting from hours to days intermittently over a period of many years. Despite the impression of a sleep disorder related to narcolepsy, the EEG showed widespread fast (beta) activity, and both the stupor and EEG changes were reversed by flumazenil, a benzodiazepine receptor antagonist. During the bouts, a many-fold increase of circulating endozepine-4, an ostensibly naturally occurring diazepine agonist, was present in the serum and spinal fluid. Subsequently, the authors of the original reports (Lugaresi et al) found, by the use of more advanced techniques, that intoxication with lorazepam may have accounted for at least some of the cases. Although such cases in which diazepine antagonists reverse episodes of recurrent coma continue to be reported (Huberfeld et al), the status of this entity remains ambiguous because of the difficulty in excluding exogenous ingestion of drugs. The vigilance-producing drug, modafinil, has also been effective in one report (Scott and Ahmed).

A peculiar form of transient unresponsiveness in elderly individuals has been described (Haimovic and Beresford). It accounted for 2 percent of hospitalized patients referred to them for coma. The EEG and other evaluations gave no explanation, but their 5 patients had various systemic illnesses. It may recur but appears to be benign. We have experience with three such patients over the years, all men in their seventh or eighth decades, who had no systemic illness and who showed no Babinski signs, pupillary abnormalities and, for the most part, eye movement limitations (one had disproportionately better horizontal than vertical gaze with oculocephalic testing). Their eyes were closed and they could be aroused briefly and inconsistently to a drowsy state. EEG showed mild diffuse slowing but without organized sleep-like activity. Patients with advanced Parkinson disease will occasionally and intermittently display a similar episodic unresponsiveness but with eyes open.

It is unclear to us whether migraine can cause a similar syndrome of unresponsiveness, as suggested in a study

of familial hemiplegic migraine (Fitzsimmons and Wolfenden). Basilar migraine may exceptionally cause transient stupor and coma. Catatonic stupor and Kleine–Levin syndrome of periodic hypersomnolence (Chap. 18) and the behavioral change of catatonia also need to be considered.

THE ELECTROENCEPHALOGRAM AND DISTURBANCES OF CONSCIOUSNESS

The EEG provides confirmations of the fact that states of impaired consciousness are expressions of neurophysiologic changes in the cerebrum. Some form of alteration of brain electrical activity occurs in almost all disturbances of consciousness except for milder degrees of confusion, delirium tremens, and in catatonia, where the preservation of normal background EEG activity can aid in diagnosis. These alterations usually consist of disorganization of the EEG background pattern, including disappearance of the normal alpha rhythm and replacement by random slow waves of low to moderate voltage in the initial stages of confusion and drowsiness; a more regular pattern of slow, 2- to 3-per second waves of high voltage in stupor; slow low-voltage waves or intermittent suppression of organized electrical activity in deep coma of cerebral hypoxia and ischemia; and, ultimately, complete absence of electrical activity in brain death.

The EEG broadly reflects the depth of certain metabolic comas, particularly those caused by hepatic or renal failure. In these conditions, the slow waves become higher in amplitude as coma deepens, ultimately assuming a high-voltage rhythmic delta pattern and a triphasic configuration. Not all cerebral disorders that cause confusion, stupor, and coma have the same effects on the EEG. In cases of intoxication with sedatives, fast (beta) activity initially replaces normal rhythms. Coma in which myoclonus or twitching is a major clinical feature may show frequent sharp waves or a sharpness of the background slowing of the EEG. A relatively normal EEG is characteristic of delirium tremens as already commented. The differences in EEG changes among metabolic derangements probably represent biologic distinctions at the neuronal level that have not yet been elucidated (see also Chap. 2).

In some deeply comatose patients, the EEG may transiently show diffuse and variable alpha frequency (8- to 12-Hz) activity, which may be mistaken for the normal physiologic alpha rhythm. In addition to these aberrant features, the activity displays no reactivity to sensory stimuli. Alpha coma is associated with pontine or diffuse cortical lesions and has a poor prognosis (Iragui and McCutchen). An even less common EEG abnormality is "spindle coma," in which sleep spindles dominate the record (see "Disorders of Sleep Related to Neurologic Disease" in Chap. 18). The EEG may also demonstrate continuous seizure activity (nonconvulsive status), making it valuable in the diagnosis of unresponsive states of obscure cause.

ANATOMY AND NEUROPHYSIOLOGY OF ALERTNESS AND COMA

Our current understanding of the anatomy and physiology of alertness comes largely from the experiments of Bremer and of Moruzzi and Magoun in the 1930s and 1940s. Observing cats in which the brain stem had sectioned between the pons and midbrain and at the level of the lower medulla, Bremer found that the rostral section caused a sleep-like state and "synchronized" EEG rhythms that were characteristic of sleep; animals with the lower section remained awake with appropriate "desynchronized" EEG rhythms. He interpreted this to mean, in large part correctly, that a constant stream of sensory stimuli, provided by trigeminal and spinal sources, funneled through the upper brain stem was required to maintain the awake state. Subsequently, a system of "nonspecific" projections from the thalamus to all cortical regions, independent of any specific sensory nucleus, has been demonstrated. A critical refinement of this concept resulted from the observation by Moruzzi and Magoun that electrical stimulation of the medial midbrain tegmentum and adjacent areas just above this level caused a lightly anesthetized animal to become suddenly alert and its EEG to change correspondingly, that is, to become "desynchronized," in a manner identical to normal arousal by sensory stimuli. The sites at which stimulation led to arousal consisted of a series of points extending from the nonspecific medial thalamic nuclei down through the caudal midbrain. These loci were situated along a loosely organized core of neurons that anatomists refer to as the reticular system or reticular formation.

The anatomic studies of the Scheibels have described widespread innervation of the reticular formation by multiple bifurcating and collateral axons of the ascending sensory systems, implying that this area is maintained in a tonically active state by ascending sensory stimulation. Because this region, especially the medial thalamus, projects widely to the cerebral hemispheres, the concept arose of a *reticular activating system* (RAS or ARAS, ascending reticular activating system) that maintains the alert state and the inactivation or destruction of which led to an unarousable state. In this way, despite a number of experimental inconsistencies (see Steriade), the paramedian upper brain stem tegmentum and lower diencephalon have come to be conceived as the locus of the arousal system of the brain. The anatomic boundaries of the RAS are somewhat indistinct. The neurons of this system are interspersed throughout the paramedian regions of the upper (rostral) pontine and midbrain tegmentum; at the thalamic level, the RAS includes the functionally related posterior paramedian, parafascicular, and medial portions of the centromedian and adjacent intralaminar nuclei.

What is salient for clinical work is that the nuclei of the reticular formation receive collaterals from the spinothalamic and trigeminal–thalamic pathways and project not just to the sensory cortex of the parietal lobe, as do the thalamic relay nuclei for somatic sensation, but to the whole of the cerebral cortex. Thus, it would seem that sensory

stimulation has a double effect—it conveys information to the brain from somatic structures and the environment and also activates those parts of the nervous system on which the maintenance of consciousness depends. The cerebral cortex not only receives impulses from the RAS but reciprocally modulates this incoming information via corticofugal projections to the reticular formation. Although the physiology of the RAS is far more complicated than this simple formulation would suggest, it nevertheless, as a working idea, retains a great deal of clinical credibility, and makes comprehensible some of the neuropathologic observations noted further on, as well as the effects of deep brain stimulation to improve function in minimally conscious patients (see further on).

The presence of normal alpha rhythm with the eyes closed is a marker for wakefulness, but its representation at the cortical surface is not required for wakefulness as it is obliterated in cases of bilateral occipital infarction. It is, of course, possible that deep nuclei are still projecting the rhythm to other parts of the cerebrum and it was assumed that this maintains wakefulness but even this precept is not clear. Although for many years it has been stated that arousal causes a desynchronization of brainwave activity (in distinction to the synchronized activity of sleep), it has become apparent that during wakefulness, there also is a widespread low-voltage fast rhythm (gamma rhythm of frequency of 30 to 60 Hz). This activity, coordinated by the thalamus, has been theorized to synchronize cortical activity and to account perhaps for the unification of modular aspects of experience (color, shape, motion) that are processed in different cortical regions. In this way, the rhythm is said to "bind" various aspects of a sensory experience or memory. This fast and widespread electrographic activity is not appreciated with the usual EEG surface recordings but it can be extracted by sophisticated mathematical transformations. Using such electrophysiologic methods that the gamma rhythm can be detected over the primary somatosensory cortex after an electrical stimulus on the contralateral hand is perceived, but not if the patient fails to perceive it (Meador et al). The clinical relevance of the rhythm is uncertain, but it has elicited interest because it may give insight into several intriguing questions about conscious experience.

In the last decade, a novel perspective on the anatomical basis of consciousness has been derived from the study of functional and anatomical connectivity of brain regions as reflected by functional MRI studies and diffusion tensor imaging, respectively. At least three such interconnected networks have been detected, a salience network that has been theorized to underlie conscious perception of stimuli, a default mode network for internal thought, and an executive control network for externally guided awareness. Of these, the salience network was most closely correlated with behavioral signs of awareness but that changes in the default network corresponded to regaining consciousness after coma (Qin and colleagues, 2015). These studies are interesting but only correlative and their meaning and place in clinical concepts will certainly evolve in the next decades.

METABOLIC AND TOXIC ENCEPHALOPATHIES

Many diseases and exogenous agents interfere with the metabolic activities of the nerve cells in the cerebral cortex and the central nuclei of the brain. The better-known examples are hypoxemia, global ischemia, hypoglycemia, hyper- and hypo-osmolar states, acidosis, alkalosis, hypokalemia, hyperammonemia, hypercalcemia, hypercarbia, drug intoxication, and severe vitamin deficiencies (see Chap. 39). In general, the loss of consciousness in these conditions parallels a reduction in cerebral metabolism. For example, in the case of global ischemia, in which oxygen and glucose are removed from the brain, an acute drop in CBF to 25 mL/min/100 g brain tissue from its normal 55 mL/min/100 g causes slowing of the EEG and syncope or impaired consciousness; a drop in CBF below 12 to 15 mL/min/100 g causes electrocerebral silence, coma, and cessation of most neuronal metabolic and synaptic functions. Even lower levels of ischemia are tolerated if they arise more slowly, but neurons cannot survive when flow is reduced below 8 to 10 mL/min/100 g. Oxygen consumption of 2 mg/min/100 g (approximately half of normal) is incompatible with an alert state. In other types of metabolic encephalopathy, CBF may stay near normal while metabolism is greatly reduced. An exception is the coma that arises from seizures, in which metabolism and blood flow are greatly increased. Extremes of body temperature (above 41°C [105.8°F] or below 30°C [86°F]) also induce coma through a nonspecific effect on the metabolic activity of neurons. Some of these metabolic changes are probably epiphenomena, reflecting in each encephalopathy a specific type of dysfunction in neurons and their supporting cells. Again, in reference to reducing the level of consciousness, for most metabolic alterations, the rate of change of the underlying derangement is as important as its absolute level.

The endogenous metabolic toxins that are responsible for coma in many common medical conditions cannot always be identified. In diabetes, for example, acetone bodies (acetoacetic acid, β-hydroxybutyric acid, and acetone) are present in high concentration but which causes coma is not entirely clear; similarly in uremia, there is probably an accumulation of dialyzable small molecular toxins, notably phenolic derivatives of the aromatic amino acids but these are not clearly the proximate cause of coma. In hepatic coma, elevation of blood NH_3 (ammonia) to five to six times normal levels corresponds roughly to the level of coma but the direct effect of ammonia on neurons is not fully characterized. Lactic acidosis may affect the brain by lowering arterial blood pH to less than 7.0 and this alone may suffice to alter neuronal metabolism globally. The impairment of consciousness that accompanies pulmonary insufficiency is related mainly to hypercapnia. Restated, the toxic effects of these molecules have not been confirmed or well understood, as further on. In acute hyponatremia (Na < 120 mEq/L) of whatever cause, neuronal dysfunction is probably a result of the intracellular movement of water, leading to neuronal swelling and loss of potassium chloride from the cells. The mode of action of

bacterial toxins and cytokines released during the systemic inflammatory response of sepsis is likewise incompletely understood.

Drugs such as general anesthetics, which are addressed more fully in a later section, alcohol, opiates, barbiturates, antiepileptic drugs, antidepressants, and benzodiazepines induce coma by their direct effects on neuronal membranes in the cerebrum and RAS or on neurotransmitters and their receptors. Others, such as methyl alcohol and ethylene glycol, both acts directly and by producing a metabolic acidosis. Although the coma of toxic and metabolic diseases usually evolves through stages of drowsiness, confusion, and stupor (and the reverse sequence occurs during emergence from coma), each disease imparts its own characteristic clinical features.

The sudden and excessive neuronal discharge that characterizes an epileptic seizure is another common mechanism of coma. Focal seizure activity has little effect on consciousness until it spreads from one side of the brain (and the body if there is a convulsion) to the other. Coma then ensues, presumably because the extension of the seizure discharge to deep central neuronal structures paralyzes their function. In other types of seizures, in which consciousness is interrupted from the very beginning, a diencephalic origin has been postulated (centrencephalic seizures of Penfield, as discussed in Chap. 15), but this idea has been contentious for decades.

Concussion exemplifies yet another pathophysiologic mechanism of coma. In closed head injury, it has been shown that at the moment of the concussive injury, there is a transient but large increase in intracranial pressure, on the order of 200 to 700 lb/in^2, lasting a few thousandths of a second. The vibration set up in the skull and transmitted to the brain was for many years thought to be the basis of the abrupt paralysis of nervous function that characterizes concussive head injury (commotio cerebri). While not excluding this mechanism, it is as likely that the sudden swirling motion of the brain induced by acceleration or deceleration from a blow to the head produces a rotation (torque) of the cerebral hemispheres around the axis of the upper brain stem. Disruption of the function of neurons in this region due to mechanical deformation is probably the proximate cause of loss of consciousness. These same physical forces, when extreme, cause multiple shearing lesions or hemorrhages in the diencephalon and upper brain stem. Chap. 34 fully discusses the subject of concussion.

Yet another form of coma is the artificial produced by inhalation anesthetics. The effects of general anesthesia had for many years been attributed to changes in the physical chemistry of neuronal membranes. More recently, it has been recognized that interactions with ligand-gated ion channels, particularly gamma-aminobutyric acid (GABA)-A receptors and alterations in neurotransmitter function, are a more likely mechanism of anesthesia-induced unconsciousness. Summaries of what is known about the metabolic neurochemistry of anesthetics are available (Campagna and colleagues and Brown and coworkers); they emphasize changes in neurotransmitter function rather than alterations in membrane fluidity but still do not give a unified theory of the effects of these agents, partly because different classes of drug act at different sites. Inhalation anesthetics are unusual among coma-producing drugs with respect to the sequence of inhibitory and excitatory effects that they produce at different concentrations. With anesthesia, sufficient inhibition of brain stem activity can be attained to eliminate the pupillary responses and the corneal reflexes. Both return to normal by the time the patient is able to speak. Sustained clonus, exaggerated tendon reflexes, and Babinski signs are common during the process of arousal. Rosenberg and associates systematically studied these findings. Preexisting focal cerebral deficits from strokes often worsen transiently with the administration of anesthetics, as is true to a lesser extent with other sedatives, metabolic encephalopathies, and hyperthermia.

PATHOLOGIC ANATOMY OF COMA AND HERNIATION SYNDROMES

Coma due to damage to the brain is produced by one of two broad types of processes: The first is clearly structural, or morphologic, consisting either of a discrete structural lesion in the upper brain stem and lower diencephalon (which may be primary or secondary to compression) or of widespread destructive changes throughout the hemispheres. The second type is metabolic or submicroscopic of the type discussed above under the topic or metabolic encephalopathy, resulting in suppression of neuronal activity in the cerebrum and RAS. The clinical examination in coma is designed to separate these mechanisms and to gauge the depth or seriousness of underlying dysfunction.

With regard to visible structural lesions, the study of a large number of coma cases has disclosed 3 types of lesions, each of which directly or indirectly damage the function of the RAS or its projections to the cerebral hemispheres. In the *first type*, a large mass in one cerebral hemisphere is demonstrable—chiefly a tumor; abscess; massive infarct; or intracerebral, subdural, or epidural hemorrhage. These mass lesions cause coma by secondary compression of the midbrain and central thalamic region of the RAS. Either lateral displacement or direct compression of these structures by the advancing medical temporal lobe which is forced into the tentorial opening may be the proximate cause of compression (see below and also Chap. 30). Likewise, a cerebellar lesion may compress the adjacent upper brain stem reticular region by displacing it forward and upward. A detailed clinical record will show the coma to have coincided with these displacements and herniations as discussed further on.

In the *second* structural configuration, which occurs less frequently, a destructive lesion is located immediately within the thalamus or midbrain, in which case the neurons of the RAS are damaged directly. This pattern characterizes upper brain stem stroke from basilar artery occlusion, thalamic and upper brain stem hemorrhages, and some forms of traumatic damage.

In the *third type of structural damage,* there is widespread bilateral damage to the cortex and cerebral white matter, the result of traumatic damage (contusions, diffuse

axonal injury), bilateral ischemic strokes or hemorrhages, encephalitis, meningitis, hypoxia, or global ischemia. The coma in these cases results from interruption of thalamocortical impulses or from generalized destruction of cortical neurons. It is only if the cerebral lesions are bilateral and extensive that consciousness is impaired. Many of the diseases in this category also cause severe thalamic damage of the type mentioned earlier.

Thus, the pathologic changes found in cases of coma are compatible with physiologic deductions—namely that the state of coma correlates with lesions of the diencephalic cortical-activating systems. Small and discrete lesions restricted to the upper dorsal brain stem and lower midline thalami are the smallest ones sufficient to produce coma. A study by Parvizi and Damasio, on the basis of 9 cases of restricted dorsal bilateral pontine lesions, suggested that damage at a site caudal to the midbrain RAS may also cause coma. This view expands our concepts of the areas of the reticular system that are necessary for (Bodien et al), but further study is justified. One conceptual explanation for this configuration implicating the pons in coma would be the disruption of noradrenergic input from the locus coeruleus to the reticular system.

However, in the largest group of cases of coma, no structural lesion is revealed by any technique of conventional pathology. Instead, a metabolic or toxic abnormality or generalized electrical discharge (seizure) causes neuronal failure at a subcellular or molecular level.

As pointed out above, large, destructive, or space-consuming lesions of the cerebrum, such as hemorrhage, tumor, abscess, or infarction with brain swelling, usually impair consciousness indirectly by lateral and downward displacement of the subthalamic–upper brain stem structures and herniation of the medial part of the temporal lobe (uncus, hippocampus) into the opening in the tentorium. One consequence of purely lateral displacement of the midbrain, perhaps in contrast to the conventional notion of compression by herniation, is that the upper midbrain is pushed against the opposite edge of the tentorium (the *Kernohan notch* or, more properly, the *Kernohan-Woltman phenomenon*). This configuration causes weakness and a Babinski sign ipsilateral to the hemispheral lesion and later, extensor posturing on that side. The posterior cerebral artery and rarely the cisternal segment of the ipsilateral oculomotor nerve may also be compressed at the edge of the tentorium, leading to infarction of the occipital lobe in the former, and ophthalmoparesis with pupillary enlargement in the latter.

It follows from the foregoing discussion that unilateral destructive lesions of the hemispheres, such as infarcts or hemorrhages, do not usually cause coma unless they create some degree of mass effect, which secondarily compresses the upper brain stem. There are exceptions in which patients with massive strokes affecting the territory of the internal carotid artery are drowsy and inattentive from the onset, even before brain swelling occurs. More often, they are simply apathetic with a tendency to keep their eyes closed, a state that may be misinterpreted as stupor.

The term *herniation* refers to the translocation of a portion of the cerebral or cerebellar hemisphere from its normal position to an adjacent compartment that is bounded by dural folds, a phenomenon that is evident both at the autopsy table and by imaging of the brain. Thus, herniations are termed *transfalcine* (across the falx) or *transtentorial* (through the tentorial aperture) or are named by the structure that is displaced—*cerebellar, uncal*, etc. Figure 16-1 and Table 16-2 describe these displacements of brain tissue between dural compartments. Plum and Posner, following from observations by McNealy and Plum, divided the transtentorial brain stem displacements into two groups: one a central herniation syndrome with downward displacement and midline compression of the upper brain stem, and the other a unilateral insertion of the medial temporal lobe, including the uncal gyrus, into the tentorial opening and subsequent compression of the midbrain from the sides.

According to these authors, the *central syndrome* takes the form of a rostral–caudal deterioration of brain stem function: There is first apathy and drowsiness and, often, periodic Cheyne-Stokes pattern of respiration; following this, the pupils become small and react very little to light; "doll's-head" ("doll's-eyes," oculocephalic) eye movements are still elicitable, as are deviations of the eyes in response to cold-water caloric testing. Bilateral Babinski signs can be detected early; later, grasp reflexes and decorticate postures appear. These signs give way to a downward gradient of brain stem signs: coma; medium-sized fixed pupils that are referable to midbrain damage; bilateral decerebrate postures; loss of vestibulo-ocular (caloric, oculovestibular) responses all of which are the result of pontine damage; irregular breathing patterns that implicate medullary destruction; and death.

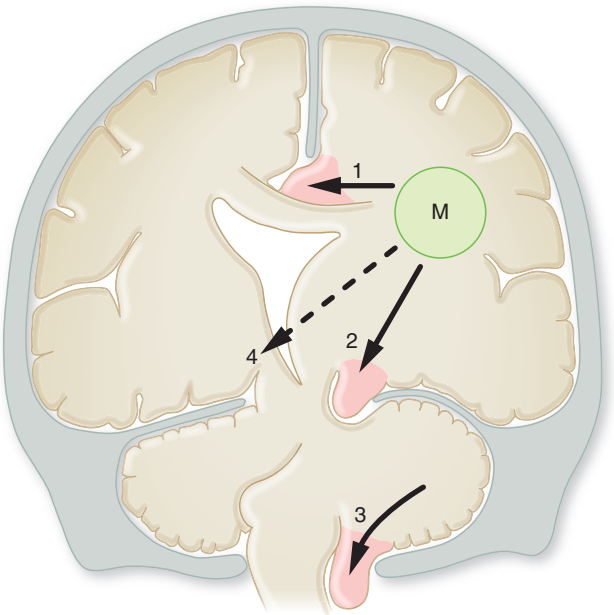

Figure 16-1. Schematic depiction of brain herniations between dural compartments. Transfalcial (*1*), transtentorial uncal-parahippocampal (*2*), cerebellar tonsillar (*3*), and horizontal (*4*), causing Kernohan–Woltman notch phenomenon. Herniations are shown in pink. M = mass.

Table 16-2

CLINICOPATHOLOGIC FEATURES OF TEMPORAL LOBE–TRANSTENTORIAL HERNIATION

PATHOLOGIC CHANGE	MECHANISM	CLINICAL DISORDERS
Injury to outer fibers of ipsilateral oculomotor nerve	Strangulation of nerve between herniating tissue and medial petroclinoid ligament; stretching of nerve over clivus from lateral displacement of midbrain; entrapment of nerve between posterior cerebral and superior cerebellar arteries from downward displacement of midbrain	Pupillary dilatation (Hutchinson pupil), ophthalmoplegia later
Creasing of contralateral cerebral peduncle (Kernohan notch)	Pressure of laterally displaced midbrain against sharp edge of tentorium	Hemiplegia ipsilateral to herniation (*false localizing sign*) and bilateral corticospinal tract signs
Lateral flattening of midbrain, and zones of necrosis and secondary hemorrhages in tegmentum and base of subthalamus, midbrain, and upper pons (Duret hemorrhages)	Crushing of midbrain between herniating temporal lobe and opposite leaf of tentorium and vascular occlusion (hemorrhages around arterioles and veins)	Cheyne-Stokes respirations; stupor; coma; bipyramidal signs; decerebration; dilated, fixed pupils and alterations of gaze (facilitated oculocephalic reflex movement giving way to loss of all response to head movement and labyrinthine stimulation)
Unilateral or bilateral infarction (hemorrhagic) of occipital lobes	Compression of posterior cerebral artery against the tentorium by herniating temporal lobe	Usually none detectable during coma; hemianopia (unilateral or bilateral) with recovery
Raised intracranial pressure and hydrocephalus	Lateral flattening of aqueduct and third ventricle and blockage of perimesencephalic subarachnoid space	Increasing depth of coma, rising blood pressure, bradycardia (Cushing response)

The *uncal syndrome*, the result of herniation of the medial temporal lobe into the tentorial opening, differs in that drowsiness in the early stages is accompanied or preceded by unilateral pupillary dilatation, most often on the side of the mass, as a result of compression of the third nerve by the advancing uncal gyrus.
